§ 27. Chromium Iodides and Oxyiodides

A. Moberg[1] observed that a soln. of chromous chloride does not give a precipitate with potassium iodide, but the soln. acquires a reddish-brown colour. H. Moissan prepared **chromous iodide**, or **chromium diiodide**, CrI_2, by heating chromic iodide in hydrogen. The greyish-white product forms a blue soln. with water; and this, on exposure, becomes green owing to the absorption of oxygen. The presence of this salt in water can induce the dissolution of the insoluble forms of the anhydrous chromic halides. W. Biltz and E. Birk gave 5·196 for the sp. gr. of **chromous hexamminodiiodide**, $CrI_2.6NH_3$.

J. Inglis observed that when a soln. of potassium dichromate is treated with an excess of conc. hydriodic acid, a dense black precipitate of iodine separates out. J. M. Ordway said that a soln. of a mol of hydrogen iodide dissolves 3 mols of chromic oxide. P. Guyot found that by heating the mixture of potassium dichromate and hydriodic acid, there remains after the expulsion of the iodine, a mixture of potassium iodide, and what was said to be **chromic iodide**, or **chromium triiodide**, CrI_3. H. Moissan obtained red crystals of anhydrous chromic iodide by the action of iodine vapour carried by a current of nitrogen over red-hot chromium; R. Hanslian observed no reaction at the b.p. of iodine. According to G. O. Higley, the violet *enneahydrate*, $CrI_3.9H_2O$, or $[Cr(H_2O)_3(H_4O_2)_3]$, is formed by passing hydrogen iodide into 30 c.c. of water in which 12·3 grms. of barium carbonate are suspended and then adding 14·5 grms. of violet chromic sulphate, and sat. the filtrate at 10° with hydrogen iodide. The dark violet or black crystals yield an olive-green powder. The salt decomposes on keeping with the evolution of hydrogen iodide; it is very hygroscopic; and it is soluble in alcohol, and in acetone, but insoluble in chloroform. W. Biltz and E. Birk gave 4·915 for the sp. gr. at 25°/4°.

S. M. Jörgensen[2] treated a soln. of chromic hexamminonitrate with a soln. of potassium iodide, and obtained **chromic hexamminotriiodide**, $[Cr(NH_3)_6]I_3$. The yellow, rhombic plates are isomorphous with the bromide. W. Biltz and E. Birk gave 2·425 for the sp. gr. at 25°/4°; and 220·6 for the mol. vol. E. Rosenbohm gave $10 \cdot 53 \times 10^{-6}$ mass units for the magnetic susceptibility. A. Benrath found that in the presence of hydriodic acid, $[Cr(NH_3)_5I]I_2$, and $[Cr(NH_3)_5(H_2O)]I_3$ are formed. P. Pfeiffer, and P. Pfeiffer and M. Tilgner prepared **chromic trisethylenediaminotriiodide**, $[Cr\ en_3]I_3.H_2O$; P. Pfeiffer and H. Pietsch, **chromic bisethylenediaminopropylenediaminotriiodide**, $[Cr\ en_2pn]I_3.2H_2O$; and P. Pfeiffer and M. Haimann, **chromic trispropylenediaminotriiodide**, $[Cr\ pn_3]I_3.H_2O$. O. T. Christensen obtained a yellow crystalline powder of **chromic aquopentamminotriiodide**, $[Cr(NH_3)_5(H_2O)]I_3$, by the action of hydriodic acid on a soln. of the corresponding hydroxide. H. J. S. King also prepared this salt.

H. J. S. King prepared **chromic hydroxypentamminodiiodide**, $[Cr(NH_3)_5(OH)]I_2.\frac{1}{2}H_2O$, as in the case of the chloride. An addition product with potassium iodide was also obtained. P. Pfeiffer and R. Stern obtained **chromic cis-hydroxyaquobisethylenediaminodiiodide**, $[Cr\ en_2(H_2O)(OH)]I_2$; and P. Pfeiffer and R. Prade, the **trans-salt.** O. T. Christensen prepared red, octahedral crystals of **chromic nitritopentamminodiiodide**, $[Cr(NH_3)_5(NO_2)]I_2$; and A. Werner and J. von Halban, **chromic**

nitratopentamminodiiodide, $[Cr(NH_3)_5(NO_3)]I_2$. S. M. Jörgensen obtained lilac plates of **chromic chloropentamminodiiodide,** $[Cr(NH_3)_5Cl]I_2$, associated with one and two mols. of mercuric iodide. P. T. Cleve prepared garnet-red, rhombic prisms of **chromic chloroaquotetramminodiiodide,** $[Cr(NH_3)_4(H_2O)Cl]I_2$. S. M. Jörgensen obtained bluish-violet, octahedral crystals of **chromic iodopentamminodiiodide,** $[Cr(NH_3)_5I]I_2$, as well as the corresponding chloride, and nitrate. H. Freundlich and R. Bartels studied the hydrolysis of the salt: $[Cr(NH_3)_5I]^{\cdot\cdot}+H_2O=I'+[Cr(NH_3)_5(H_2O)]^{\cdot\cdot\cdot}$. P. T. Cleve prepared **chromic iodoaquotetramminodiiodide,** $[Cr(NH_3)_4(H_2O)I]I_2$, in rose-red octahedra; A. Werner and J. V. Dubsky, **chromic dihydroxydiaquodiamminoiodide,** $[Cr(NH_3)_2(H_2O)_2(OH)_2]I$; E. Weinmann, **chromic dihydroxydiaquoethylenediaminoiodide,** $[Cr(H_2O)_2\,en(OH_2)]I$; P. Pfeiffer and W. Osann, **chromic dihydroxydiaquodipyridinoiodide,** $[CrPy_2(H_2O)_2(OH)_2]I$; P. Pfeiffer and T. G. Lando, P. Pfeiffer and P. Koch, and P. Pfeiffer and A. Trieschmann, **chromic cis-dichlorobisethylenediaminoiodide,** $[Cr\,en_2Cl_2]I$, and also the trans-salt; E. Rosenbohm, **chromic dichlorotetramminoiodide,** $[Cr(NH_3)_4Cl_2]I$, with the magnetic susceptibility $19{\cdot}74\times10^{-6}$ mass units; A. Werner, **chromic dichloroaquotriamminoiodide,** $[Cr(NH_3)_3(H_2O)Cl_2]I$; S. Guralsky, and A. Werner, **chromic dibromoaquotriamminoiodide,** $[Cr(NH_3)_3(H_2O)Br_2]I$; P. Pfeiffer, **chromic cis-dibromobisethylenediaminoiodide** $[Cr\,en_2Br_2]I.H_2O$, as well as the **trans-salt ;** P. Pfeiffer and M. Tapuach, **chromic dibromodiaquodipyridinoiodide,** $[CrPy_2(H_2O)_2Br_2]I.4H_2O$; P. Pfeiffer and T. G. Lando, complex salts of mercuric iodide with **chromic diiodobisethylenediaminoiodide,** $[Cr\,en_2I_2]I$; P. Pfeiffer and P. Koch, a complex salt of mercuric iodide with **chromic cis-thiocyanatobisethylenediaminoiodide,** $[Cr\,en_2(SCy)_2]I.HgI$; P. Pfeiffer and A. Trieschmann, and H. Schwarz, **chromic oxalatobisethylenediaminoiodide,** $[Cr\,en_2(C_2O_4)]I$; S. M. Jörgensen, **chromic hydroxydecamminopentaiodide,** $[Cr(OH)(NH_3)_{10}]I_5.H_2O$; F. Pintus prepared **chromic trisethylenediaminotriiodide,** $[Cr\,en_3]I_3$. S. M. Jörgensen, **chromic hydroxydecamminohydroxydichlorodiiodide,** $[Cr_2(OH)(NH_3)_{10}]Cl_2I_2(OH)$, and **chromic hydroxydecamminochlorotetraiodide,** $[Cr_2(OH)_6(NH_3)_{10}]ClI_4.H_2O$; P. Pfeiffer and R. Stern, **chromic dihydroxyquaterethylenediaminotetraiodide,** $[Cr_2(OH)_2\,en_4]I_4.2\tfrac{1}{2}H_2O$; S. M. Jörgensen, **chromic trihydroxyaquohexamminotriiodide,** $[Cr_2(OH)_3(H_2O)(NH_3)_6]I_3.H_2O$; R. F. Weinland and E. Büttner, **chromic hexacetatodihydroxytriamminoiodide** $[Cr_3(CH_3COO)_6(NH_3)_3(HO)_2]I$; R. F. Weinland and E. Gussmann, **chromic hexacetatodihydroxytripyridinoiodide,** $[Cr_3(CH_3COO)_6Py_3(OH)_2]I$; and P. Pfeiffer and W. Vorster, **chromic hexahydroxysexiesethylenediaminohexaiodide,** $[Cr_4(OH)_6en_6]I_6.H_2O$, and an addition product with mercuric iodide.

S. M. Jörgensen prepared the complex **chromic chloropentamminodiiodomercuriiodide,** $[Cr(NH_3)_5Cl]I_2.HgI$, as well as $[Cr(NH_3)_5Cl]I_2.2HgI_2$; P. Pfeiffer, **chromic diiodobisethylenediaminoiodomercuriiodide,** $[Cr\,en_2I_2]I.HgI_2$; P. Pfeiffer and P. Koch, **chromic dithiocyanatobisethylenediaminoiodomercuriiodide,** $[Cr\,en_2(SCy)_2]I.HgI_2$; and P. Pfeiffer and W. Vorster, **chromic hexahydroxysexiesethylenediaminohexaiodomercuriiodide,** $[Cr_4(OH)_6en_6]I_6.2HgI_2.8H_2O$.

As indicated above, J. Inglis,[3] and P. Guyot obtained no evidence of the formation of an oxyiodide by the action of hydriodic acid on potassium chromate. H. Giraud said that an oxyiodide is formed as a deep red, oily liquid, boiling at 149°, by the action of sulphuric acid on a mixture of potassium dichromate and iodide. H. Rose found that iodine, not **chromyl iodide,** is formed; nor could S. G. Rawson verify this, nor could he obtain an oxyiodide by the action of calcium iodide on chromyl chloride in a sealed tube; by the action of the vapour of chromyl chloride on ethyl iodide, or by the action of hydrochloric acid, acetic acid, or hydrofluosilicic acid on a mixture of potassium iodide, chromium trioxide, and solid zinc chloride. I. Walz obtained some iodate by the action of chromic acid on iodine. H. S. Fry treated chromium trioxide with acetyl iodide and obtained only iodine. There was no evidence of the formation of chromyl iodide.

According to P. Guyot, when potassium chromate is treated with colourless hydriodic acid, garnet-red crystals of **potassium iodochromate,** $KCrO_3I$, are produced. If the salt contains an excess of iodine it may have a brown tint, but on exposure to the air it gradually assumes its normal colour. It is decomposed in the presence of water into hydriodic acid and potassium dichromate. When heated it gives off iodine copiously ; on boiling it with hydriodic acid more iodine is given off, potassium iodide and chromic iodide remaining behind.

§ 28. Chromium Sulphides

O. Schumann [1] made some observations on the relative affinities of chromium and the metals for sulphur and oxygen. According to A. Moberg, when chromous chloride is treated with ammonium sulphide, a black precipitate—presumably **chromous sulphide** or **chromium monosulphide,** CrS—is formed ; E. M. Péligot obtained it by the use of potassium sulphide and observed that the precipitate is insoluble in an excess of the precipitant. M. Traube observed that the sulphide occurs among the products of the reduction of chromic sulphate heated in hydrogen. H. Moissan observed that when chromous chloride is heated to 440° in hydrogen sulphide, this sulphide is formed ; this is also the case when chromic sulphide is heated in hydrogen. A. Moulot obtained this sulphide by heating chromium in an atm. of hydrogen sulphide in an electric furnace. The black mass prepared at a high temp. forms opaque, prismatic crystals of sp. gr. 4·08. The black, non-crystalline powder has a sp. gr. 3·97. W. F. de Jong and H. W. V. Willems found that the crystals of the monosulphide, prepared by heating sulphur and chromium at 600°, have an X-radiogram in agreement with a hexagonal lattice with $a=3\cdot44$ A., and $c=5\cdot67$ A.; and sp. gr. 4·85. M. Picon gave 1550° for the m.p. The crystals scratch quartz. M. Picon found that chromous sulphide is more resistant to the action of carbon at a high temp., in vacuo, than is the corresponding oxide. The sulphide melts without dissociation at 1550°. E. Wedekind and C. Horst gave $28\cdot4\times10^{-5}$ mass units for the magnetic susceptibility at 19·5°. Chromous sulphide is easily attacked by oxidizing agents, but not by reducing agents. Chromous sulphide is but slightly reduced when heated to 1200° in hydrogen; with oxygen, at a red-heat, chromic oxide and sulphate, and sulphur dioxide are formed; when heated in air, it glows, forming chromic oxide, but no sulphur is obtained; with water-vapour, chromic oxide and hydrogen sulphide are formed; with fluorine, combination occurs with incandescence, and similarly also with hydrogen fluoride; at 340°, chlorine forms chromic chloride; and carbon, in an electric furnace, forms a product free from sulphur. Molten potassium hydroxide or carbonate produces sulphate and chromate. According to M. Houdard, by heating a mixture of aluminium (7 grms.) and chromium (5·6 grms.) in a current of hydrogen sulphide, a black, crystalline mass is obtained, which evolves hydrogen sulphide with water, giving a deposit of alumina and leaving a reddish-black, crystalline residue, which, when washed with dil. hydrochloric acid, corresponds with **chromous sulphoaluminate,** $Al_2S_3.CrS$, or $Cr(AlS_2)_2$. Its optical properties resemble those of the spinels, and the crystals have the cubic structure. If excess of chromium is used, the sesquisulphide seems to be formed and the crystalline mass obtained is only with difficulty attacked by dil. hydrochloric acid, whilst nitric acid slowly destroys the double compound, leaving a black, crystalline residue of CrS. For chromous sulphochromite, *vide infra.*

H. Moissan observed that **chromic sulphide,** or **chromium hemitrisulphide,** or **chromium sesquisulphide,** Cr_2S_3, can be formed by the direct union of the elements, for chromium filings at 700° unite with sulphur vapour to form this compound; and it is also formed when hydrogen sulphide is passed over chromium at 1200°. J. J. Berzelius prepared this compound by heating an intimate mixture of sulphur and chromic oxide in vacuo; and L. R. von Fellenberg melted a mixture of chromic oxide, sulphur, and potassium carbonate. O. Harten obtained it by passing hydrogen sulphide over white-hot chromic oxide, or chromium trioxide. O. Schumann working at a lower temp. obtained only a 25 per cent. conversion. H. Moissan added that the reaction with chromic oxide, not previously calcined, sets in at about 440°. W. Müller obtained a large proportion of chromic oxide by passing hydrogen sulphide over heated potassium chromate, and extracting the potassium sulphide with water. J. L. Lassaigne heated a mixture of chromic chloride and sulphur at a red-heat, but, added J. J. Berzelius, the reaction is incomplete. J. von Liebig obtained chromic sulphide by passing hydrogen sulphide over strongly heated chromic chloride. J. J. Berzelius prepared the sulphide by melting chromic oxide and potassium pentasulphide at a high temp., and extracting the alkali sulphide with water. R. Schneider recommended preparing chromic sulphide by treating sodium sulphochromite with dil. hydrochloric acid, and heating the well-washed product in a current of carbon dioxide. F. Wöhler, and C. Brunner heated potassium chromate with potassium polysulphide, when, according to A. Schafarik, a complex alkali chromic sulphide is probably formed. K. Brückner found that when a mixture of chromic oxide and sulphur is heated in air, the oxide is not decomposed; chromium trioxide inflames and forms chromic oxide with a small proportion of sulphide; potassium chrome-alum with a prolonged heating forms chromic oxide and potassium sulphate, but if the mixture is heated for only a short period, a potassium and chromium sulphide is formed—*vide supra,* for the action of sulphur on chromates. H. Rose obtained chromic sulphide by passing the vapour of carbon disulphide over heated chromic oxide; W. Müller passed the vapour over heated potassium chromate and extracted the alkali sulphide by water; a large proportion of chromic oxide is formed if ammonium chromate is employed. E. Kopp obtained a pyrophoric mixture by reducing chromic sulphate in hydrogen; M. Traube showed that the black product is a mixture of chromic sulphide and oxide. M. Traube obtained some sulphide by heating acid chromic sulphate in dry hydrogen sulphide; A. Moulot heated the sulphate mixed with potassium polysulphide; and K. Brückner, with sulphur. H. Moissan heated chromic oxalate in hydrogen sulphide; and R. Schneider heated the higher chromium sulphides—*e.g.* $Cr_4S_7=2Cr_2S_3+S$.

Analyses of chromic sulphide in agreement with the formula Cr_3S_3 were reported by L. R. von Fellenberg, O. Harten, A. Gautier and L. Hallopeau, and A. Mourlot. A. Schafarik, W. Müller, and M. Traube obtained rather too high a proportion of sulphur. J. L. Lassaigne's analysis must have been made on a very impure sample. According to the temp. at which it has been prepared, chromic sulphide appears as a black or dark grey powder; or in bright black, or greyish-black crystals in some cases resembling graphite. A. Schafarik gave 2·79 to 3·77 for the sp. gr. of the crystals. If heated in the absence of air, H. Moissan observed that chromous sulphide is formed. M. Picon found that chromic sulphide loses sulphur at 1350°, melts at 1550°, and then has a composition $CrS_{1\cdot06}$. A. Karl said that the sulphide is triboluminescent. When the powder is used as anode in the electrolysis of 2 per cent. sulphuric acid, K. Fischbeck and E. Einecke found that as hydrogen sulphide is formed, tervalent chromium passes into soln. O. Stelling studied the X-ray spectrum. E. Wedekind and C. Horst gave $23\cdot28\times10^{-6}$ mass units for the magnetic susceptibility. M. Traube, A. Schafarik, and J. L. Lassaigne observed that chromic sulphide burns like a pyrophorus when heated in air or oxygen forming chromic oxide—W. Müller said that some green basic sulphate is formed. H. V. Regnault observed that with water vapour, hydrogen sulphide and a little chromic oxide are formed. H. Rose said that chromic sulphide is scarcely attacked by chlorine even at a high temp.; but J. J. Berzelius, H. Moissan, L. R. von Fellenberg, and O. Harten observed that the sulphide is partially decomposed by chlorine at ordinary temp., but decomposition into chromic chloride is complete at higher temp. W. Müller observed only a slight action with hydrochloric acid. J. Milbauer and E. Tucek studied the action of sulphur dioxide on the heated sulphide. According to J. J. Berzelius, some forms of chromic sulphide are decomposed by nitric acid, while other forms are attacked with difficulty. A. Schafarik observed that fuming nitric acid does not attack the sulphide in the cold, but the boiling acid readily decomposes the sulphide, and J. L. Lassaigne said that the boiling acid has very little action. H. Moissan found that nitric acid, or aqua regia attacks the sulphide with difficulty, while J. L. Lassaigne said that aqua regia converts it into chromic chloride and sulphuric acid. F. Göbel found that chromic sulphide is decomposed when heated in carbon monoxide, and carbon disulphide is formed. J. L. Lassaigne found that with fused potassium nitrate it forms potassium chromate and sulphate; but J. J. Berzelius said that it is not dissolved by soln. of potassium hydroxide or sulphide. S. M. Jörgensen treated a soln. of chromic chloropentamminodichloride with ammonium polysulphide; on adding alcohol, and allowing the turbid liquid to stand in a dark place, he obtained brick-red, rhombic plates of **chromic chloropentamminopentasulphide,** $[Cr(NH_3)_5Cl]S_5$. It is sparingly soluble in cold water, and freely soluble in hot water. It is decomposed by hydrochloric acid. S. M. Jörgensen treated chromic trihydroxyaquohexamminotrichloride with ammonium polysulphide, and obtained cinnabar-red, octahedral crystals of **chromic trihydroxyaquohexamminohemienneasulphide,** $[Cr_2(OH)_3(H_2O)(NH_3)_6]_2S_{11}.2H_2O$.

The formation of complex sulphides was studied by M. Gröger, H. Moissan, and R. Schneider. These salts can be regarded as **sulphochromites,** $M'CrS_2$, or salts of **hydrosulphochromous acid,** $HCrS_2$, or $H_2Cr_2S_4$. This acid was reported by R. Schneider to be formed as an unstable product when sodium sulphochromite is treated with dil. hydrochloric acid in the absence of air. It forms Cr_2S_4 when exposed to air; and, when heated in the absence of air, it furnishes chromic oxide and hydrogen sulphide. If potassium sulphotetrachromite, $K_2Cr_4S_7$, be similarly treated with dil. hydrochloric acid, grey crystals of **hydrosulphotetrachromous acid,** $H_2Cr_4S_7$, are formed. The crystals retain the form of the original crystals. The acid decomposes into hydrogen and chromic sulphides when heated in a current of carbon dioxide; it is unstable in air, forming water and the sulphide Cr_4S_7.

M. Gröger prepared **sodium sulphochromite,** $NaCrS_2$, by heating to redness a mixture of chromium hydroxide, sodium carbonate and sulphur (1 : 9 : 11) in a porcelain crucible until the excess of sulphur is expelled. The cold mass is extracted with water, and the residue washed with dil. soda-lye, then with alcohol, and finally with absolute alcohol. R. Schneider heated a mixture of potassium and sodium carbonates, potassium chromate, and sulphur; and F. J. Faktor, a mixture of sodium chromate and thiosulphate. E. Kunheim obtained it by heating a mixture of sodium and chromic sulphates and carbon in the electric arc. The dark red powder was found by R. Schneider to consist of dark brick-red, hexagonal plates of sp. gr. 2·55 at 15°. If heated in the absence of air it suffers no change. It is stable in air at ordinary temp., but when heated in air, it gives off sulphur dioxide forming chromic oxide and sodium sulphate. It is insoluble in water, but is decomposed by aerated water. R. Schneider obtained hydrosulphochromous acid by the action of dil. hydrochloric acid in the absence of air, and when exposed to air, Cr_2S_4 is formed. M. Gröger found that sodium sulphochromite is not attacked by conc. hydrochloric acid; cold conc. sulphuric acid is without action, but the hot acid decomposes the salt; nitric acid, and aqua regia decompose the salt forming chromic and sodium sulphates. The salt is not attacked by soln. of sodium hydroxide or sulphide.

J. J. Berzelius treated a soln. of potassium chromate with hydrogen sulphide, and obtained a dark brown liquid and chromic oxide. The liquid was thought to contain a sulphide of chromium and potassium; it deposits chromic sulphide when exposed to air, or when treated with acids; but the precipitate is decomposed by the liquid, forming, in air, potassium chromate, and sulphur. J. Milbauer obtained greyish-green crystals of **potassium sulphochromite,** $KCrS_2$, or $K_2Cr_2S_4$, by treating chromic oxide with molten potassium thiocyanate. It is stable in air, but when roasted it forms sulphur dioxide and chromic oxide; it is insoluble in water and hot hydrochloric acid, but freely soluble in aqua regia. According to R. Schneider, **potassium sulphotetrachromite,** $K_2Cr_4S_7$, is obtained by fusing potassium chromate (1 part) with potassium carbonate (24 parts) and sulphur (24 parts) for 20 minutes at a bright red-heat, allowing the mass to cool slowly, and washing it thoroughly but rapidly with cold water. It forms reddish to bluish-grey hexagonal plates with metallic lustre, and has a sp. gr.=2·77 at 15°. When four times as much chromate is used in proportion to the carbonate and sulphur, or a weight of chromium hydroxide equal to this, a grey powder is left instead of crystals; prolonged washing of this powder with hot water leaves pure chromic sulphide, Cr_2S_3, as J. J. Berzelius stated long ago. Potassium sulphotetrachromite is stable in air; it loses potassium sulphide slowly when it is washed with water; at a red-heat in a current of hydrogen, it loses one-seventh of its sulphur, leaving steel-blue crystals of **potassium sulphodichromite,** KCr_2S_3, or $K_2Cr_4S_6$, which retain the form of the sulphotetrachromite. When this compound is heated in air, it loses sulphur dioxide and leaves behind chromic oxide and potassium sulphide. Aq. soln. of potassium hydroxide or ammonia have little action; nitric acid, and aqua regia decompose it with the liberation of sulphur; hydrochloric acid, in the absence of air, forms the acid $H_2Cr_4S_7$.

M. Gröger precipitated **copper sulphochromite,** $Cu(CrS_2)_2$, from a soln. of the sodium salt by the addition of copper sulphate; R. Schneider used modifications of the process. Copper sulphochromite is not attacked by water, or hydrochloric acid; but is easily decomposed by warming with nitric acid or aqua regia. M. Gröger prepared **silver sulphochromite,** $AgCrS_2$, or $Ag_2Cr_2S_4$, as a black powder, by adding silver nitrate to a soln. of the sodium salt. R. Schneider used a modification of the process. M. Gröger could not prepare calcium, strontium, or barium sulphochromite, by an analogous process. He obtained zinc sulphochromite, $Zn(CrS_2)_2$, by heating a mixture of zinc chromate and sulphur in hydrogen; and also by treating a soln. of chromic sulphate and zinc sulphate with ammonia, and heating the dried product in hydrogen, and then admixed with sulphur. The violet-brown mass is insoluble in water and hydrochloric acid, but is decomposed by nitric acid. The corresponding **cadmium sulphochromite,** $Cd(CrS_2)_2$, was similarly prepared. M. Gröger prepared **stannous sulphochromite,** $Sn(CrS_2)_2$, by the action of stannous chloride on a soln. of the sodium salt. It is not attacked by water or hydrochloric acid, but is oxidized by nitric acid. M. Gröger, and R. Schneider obtained **lead sulphochromite,** $Pb(CrS_2)_2$, by adding lead nitrate to a soln. of sodium sulphochromite. M. Gröger heated hydrated chromic oxide with sulphur in a current of hydrogen and obtained a greyish-black powder of **chromous sulphochromite,** $Cr(CrS_2)_2$, or Cr_3S_4. It is insoluble in water, boiling hydrochloric acid, and dil. sulphuric acid, but it is soluble in nitric acid with the separation of sulphur, and the formation of chromic sulphate and nitrate. It glows when heated in air, forming sulphur dioxide and chromic oxide. E. Wedekind and C. Horst said that its sp. gr. is 3·54 at 14°; E. Wedekind and T. Veit said that it is feebly magnetic; and E. Wedekind and C. Horst gave for the magnetic susceptibility $33{\cdot}26\times10^{-6}$ mass units. M. Gröger obtained chocolate-brown **manganese sulphochromite,** $Mn(CrS_2)_2$, by heating a mixture of sulphur and manganese and chromic oxides in an atm. of hydrogen. Similarly with black **ferrous sulphochromite,** $Fe(CrS_2)_2$, which was also obtained by treating a soln. of sodium sulphochromite with a soln. of a ferrous salt. The meteoritic mineral called **daubréelite,** found by J. L. Smith in meteoritic irons, is a ferrous sulphochromite, $FeS.Cr_2S_3$, or $Fe(CrS_2)_2$. Observations were also made by F. Zambonini, and A. Brezina and E. Cohen. S. Meunier synthesized it by the action of hydrogen sulphide on a red-hot mixture of ferrous and chromic chlorides, or on a mixture of iron and chromium. By treating a soln. of sodium sulphochromite with a cobalt salt, M. Gröger prepared **cobalt sulphochromite,** $Co(CrS_2)_2$, and similarly, by using a nickel salt soln., **nickel sulphochromite,** $Ni(CrS_2)_2$.

Other chromium sulphides have been reported. M. Gröger's **chromium tritatetrasulphide,** Cr_3S_4, as indicated above, is considered to be **chromium sulphochromite.** E. Wedekind and C. Horst gave $33{\cdot}26\times10^{-6}$ for the magnetic susceptibility of Cr_3S_4 at 15·5°. As indicated above, R. Schneider obtained **chromium tetritaheptasulphide,** Cr_4S_7, as a decomposition product of $H_2Cr_4S_7$; and chromium disulphide, CrS_2, or Cr_2S_4, as a decomposition product of $H_2Cr_2S_4$. T. L. Phipson reported **chromium hemiheptasulphide,** Cr_2S_7, to be formed by passing hydrogen sulphide into a soln. of potassium dichromate sat. with ammonia, and adding hydrochloric acid to the filtrate. G. Bender was unable to confirm this result, and said that the alleged sulphide is a mixture of sulphochromite and hydrated chromic oxide.

O. Nordenskjöld reported a complex salt, **mercuric chromium trithiocyanatohexasulphodiammine,** $Cr(SCy)_3.2NH_3.6HgS$, to be formed by the action of mercuric sulphide on mercuric tetrathiocyanatodiamminochromiate.

§ 29. Chromium Sulphates

E. M. Péligot[1] found that when the brown product obtained by reducing chromic chloride with potassium is treated with dil. sulphuric acid, some hydrogen is evolved, and a soln. of **chromous sulphate,** $CrSO_4$, is formed. H. Moissan treated chromium amalgam with dil. sulphuric acid; and A. Burger dissolved chromium from the aluminothermite process in sulphuric acid of sp. gr. 1·16 with the exclusion of air, at 90° to 100°, and obtained a blue soln. of chromous sulphate contaminated with some chromic sulphate. According to A. Asmanoff, an aq. soln. of chromic sulphate is reduced electrolytically at a lead cathode in an atm. of hydrogen. When reduction is complete, the chromous sulphate is precipitated by alcohol, washed with alcohol and ether, and dried in a current of hydrogen. The product is stable in dry air. H. Moissan obtained a white, crystalline powder of the *monohydrate* by treating moist chromous acetate with conc. sulphuric acid in the absence of air. This hydrate is more stable in air than is the heptahydrate; it is converted by a little water into the heptahydrate; and at a red-heat it forms chromic oxide, and sulphur dioxide and trioxide. B. Cabrera and S. P. de Rubies studied the magnetic qualities of the salt; and F. Allison and E. J. Murphy, the magneto-optic properties.

J. M. van Bemmelen observed that a sample kept for a year in a sealed tube exploded. H. Moissan obtained the *heptahydrate* by dissolving chromous acetate in dil. sulphuric acid in an atm. of carbon dioxide, and cooling the blue soln. The blue crystals are isomorphous with heptahydrated ferrous sulphate. They are soluble in water; and slightly soluble in alcohol. Conc. sulphuric acid converts the salt into the monohydrate. The aq. soln. is not wholly converted into chromic sulphate by boiling. The crystals and the blue soln. readily absorb oxygen from air, and with nitric oxide are coloured brown. According to A. Asmanoff, in presence of platinum as catalyst, the soln. oxidizes with evolution of hydrogen, the reaction being unimolecular. Sulphuric acid accelerates the reaction, but to a less extent than does hydrochloric acid. In absence of platinum, there is no measurable evolution of hydrogen with sulphuric acid present even in conc. up to $10N$, although the reaction takes place to some extent in presence of hydrochloric acid. In the latter case, the oxidation is accelerated by ammonium chloride. Very rapid oxidation takes place in ammonia soln., especially in presence of ammonium salts, which prevent the precipitation of chromous hydroxide. The reaction is then no longer unimolecular, but is autocatalyzed by the chromic ion. M. Berthelot found that the blue soln. mixed with ammonia and ammonium chloride readily absorbs acetylene and is thereby decolorized; after a short time the soln. becomes rose-red, and deposits a precipitate giving off ethylene. The acidic soln. absorbs no more acetylene than is the case with water.

According to C. Laurent, blue crystals of **ammonium chromous sulphate,** $(NH_4)_2SO_4.CrSO_4.6H_2O$, are formed by evaporating a soln. of the component salts in an atm. of carbon dioxide. The blue crystals resemble the double sulphates of the magnesium series. The salt is freely soluble in water; 100 c.c. of a sat. aq. soln. contain 55 grms. of the salt at 20°. The salt is insoluble in alcohol. It readily oxidizes in air. W. Traube and W. Passarge obtained **hydrazine chromous sulphate,** $(N_2H_4)_2H_2SO_4.CrSO_4$, by the action of hydrazine sulphate on a soln. of sulphuric acid and of chromous acetate in air-free water, covered with a layer of light petroleum as a protection from air. The precipitate is washed successively with water, alcohol and ether. C. Laurent prepared **sodium chromous sulphate,** $Na_2SO_4.CrSO_4.4H_2O$, by the action of sodium acetate on a sulphuric acid soln. of sodium sulphate. E. M. Péligot obtained rhombic prisms of **potassium chromous sulphate,** $K_2SO_4.CrSO_4.6H_2O$, by adding alcohol to a mixture of chromous chloride and a cold, sat. soln. of potassium sulphate. The crystals are isomorphous with those of potassium ferrous sulphate. C. Laurent also prepared **rubidium chromous sulphate,** $Rb_2SO_4.CrSO_4.6H_2O$; **cæsium chromous sulphate,** $Cs_2SO_4.CrSO_4.6H_2O$; **magnesium chromous sulphate,** $MgSO_4.CrSO_4.14H_2O$; **zinc chromous sulphate,** $ZnSO_4.CrSO_4.14H_2O$; as well as complexes of manganese and ferrous sulphates (*q.v.*).

The anhydrous **chromic sulphate,** $Cr_2(SO_4)_3$, reported by A. Schrötter[2] to be formed by heating a basic sulphate with conc. sulphuric acid until the acid begins to fume was supposed, by M. Traube, L. and P. Wöhler and W. Plüddemann, and M. Siewert, to be the acid salt. T. Klobb, however, obtained the red sulphate of the composition, $Cr_2(SO_4)_3$, by heating ammonium chromic sulphate with boiling, conc. sulphuric acid. A. Schrötter, and M. Siewert obtained it by heating the hydrated salt over 280° in a current of carbon dioxide. M. Siewert's, and T. Klobb's analyses agreed with the formula $Cr_2(SO_4)_3$; and A. Recoura gave the formula $Cr_2(SO_4)_6Cr_2$ in agreement with that for $Cr_2(SO_4)_6Fe_2$. The powder is rose-coloured in daylight, and green by gas-light. P. A. Favre and C. A. Valson gave 2·743 for the sp. gr. at 17·2°; A. Sénéchal, 2·221 at 30°; E. Moles and M. Crespi, 3·712 at 25°/4°; while L. F. Nilson and O. Pettersson gave 3·012 for the sp. gr.; 130·27 for the mol. vol.; 0·1718 for the sp. ht.; and 67·41 for the mol. ht. K. Friedrich found that the thermal decomposition curve is somewhat complex; the gases, sulphur dioxide and trioxide and oxygen, have one atm. press. at 750°. R. Robl observed but a faint luminescence in ultra-violet light. E. Kunheim studied the decomposition of mixtures of chromic sulphate and carbon in the electric arc.

According to A. Schrötter, crystals of the **violet hydrate,** which is provisionally taken to be the *octodecahydrate*, $Cr_2(SO_4)_3.18H_2O$, are obtained by allowing to stand for a few weeks a soln. of hydrated chromic oxide in the calculated quantity of conc. sulphuric acid. The soln. in water is dark blue by reflected light, and ruby-red by transmitted light; alcohol precipitates from the soln. a pale violet, crystalline powder and the soln. becomes colourless—only when there is an excess or a deficiency of acid does the soln. remain green. To obtain good crystals, he recommended dissolving the crystalline powder in a moderate quantity of water, adding dil. alcohol to the stage at which precipitation begins, and leaving the soln. to evaporate spontaneously in a vessel covered by a bladder. H. Löwel dissolved 50 grms. of dried hydrated chromic oxide in 125 grms. of conc. nitric acid; added 125 c.c. of water, and boiled for 15 min. When the liquid was cold, he added a cold soln. of 75 grms. of conc. sulphuric acid in 150 grms. of water, followed by 1200 grms. of alcohol. The precipitated crystalline powder was washed with alcohol, and dried between bibulous paper. H. Baubigny used a similar process. M. Traube allowed alcohol to drop into a soln. of chromium trioxide, conc. sulphuric acid, and water (1 : 1·5 : 3); at the end of the reduction, the chromic sulphate is precipitated by alcohol. If the temp. rises during the reduction, the green sulphate is formed. This can be converted to the violet form by boiling the liquid with nitric acid. T. W. Richards and F. Bonnet, and M. A. Graham used this process. M. Traube also obtained the violet sulphate by passing a mixture of chromic acid, conc. sulphuric acid, and water (1 : 1·5 : 2·25) into a wide basin in which a porcelain crucible containing ether is placed. Crystals of the sulphate are formed in a few hours. To complete the reduction, a few drops of alcohol may be added. G. O. Higley prepared this salt by adding 100 grms. of chrome-alum to a cold soln. of 100 c.c. of conc. sulphuric acid, and 330 c.c. of water; and pouring 260 c.c. of conc. sulphuric acid, with constant stirring, into the filtered soln. at 15° to 20°. Hydrochloric acid can be used as solvent for the alum. R. F. Weinland and R. Krebs obtained good crystals from a soln. of a mol of alum in 60 to 80 mols of H_2SO_4 in 95 per cent. soln. by cooling and evaporation in a vacuum desiccator; they also obtained the salt by adding alcohol to a soln. of chromium chlorosulphate; F. Krauss and co-workers used a similar process. A. Werner and A. Gubser obtained the salt by adding sulphuric acid to a violet soln. of chromic chloride; and P. M. Strong, by treating the mother-liquor from the preparation of the polychromosulphuric acid with the necessary quantity of green sulphate and sulphuric acid, concentrating the mixture on a water-bath; and allowing it to stand in the cold for 3 or 4 days to crystallize. E. Wydler also described the preparation of the salt.

There are differences of opinion about the water of crystallization. Analyses by G. O. Higley, A. Werner and A. Gubser, A. Étard, and M. Siewert correspond with the *hexadecahydrate*, $Cr_2(SO_4)_3.16H_2O$, for the air-dried salt; and by A. Sénéchal, with the *tetradecahydrate*, $14H_2O$. A. Schrötter said that the pentadecahydrate, $Cr_2(SO_4)_3.15H_2O$, is formed when the salt is dried at 35°. R. F. Weinland and R. Krebs obtained with all modes of preparation tried, needles and plates of the *heptadecahydrate*, $Cr_2(SO_4)_3.17H_2O$. A. Sénéchal obtained with the preparations with precipitated alcohol, $Cr_2(SO_4)_3.16{\cdot}0$ to $17{\cdot}5H_2O$, and after exposure to dry air, $Cr_2(SO_4)_3.14H_2O$; he also gave for the vap. press., p mm. of differently hydrated salts, $Cr_2(SO_4)_3.nH_2O$:

n		17·25	16·55	15·77	15·05	14·78
	25·6°	20·1	—	11·0	11·1	—
	29·3°	24·4	17·4	14·0	13·8	12·8
p at	34·0°	31·5	24·2	19·1	18·4	17·3
	38·5°	39·1	31·9	24·9	23·5	—
	40·4°	43·4	—	27·7	26·2	—

From these results, A. Sénéchal concluded that hydrates with $17H_2O$, $16H_2O$, $15H_2O$, and $14H_2O$ are chemical individuals, and that the tetradecahydrate slowly loses water at room temp. and has, at 29·3°, a vap. press. of 3 mm. M. Siewert said that when the salt was dried for an hour in the sun, it contained $12H_2O$; G. D. van Cleeff, that when the octodecahydrate is dried over sulphuric acid, it loses 3·5 to $4{\cdot}0H_2O$, at 75° it changes colour, with the loss of more water, and at 100°, it retains $4H_2O$; A. Schrötter, that the salt dried at 100° has 5 to $6H_2O$; A. Recoura, that at 90°, it forms the green hydrate with $8H_2O$; A. Kling and co-workers said $5H_2O$; and A. Étard, A. Schrötter, and A. Colson added that at 100°, the salt melts in its water of crystallization and retains $6H_2O$ and solidifies into a green gummy mass. G. N. Wyrouboff found that when dried at 110°, the salt retains $5H_2O$, and it loses no more water even when heated to 150°. M. Siewert stated that at 280°, in a current of carbon dioxide, most of the water is driven off, and all is expelled below a red-heat. G. T. Gerlach made some observations on this subject; and for those of A. Sénéchal—*vide infra*. According to W. R. Whitney, and A. Sénéchal, all products with less than $12H_2O$ are not to be considered as hydrates of the violet sulphate. G. N. Wyrouboff represented the violet sulphate by the formula $Cr_2(OH_2)_4(OH_2)_2(SO_2)_3(OH_2)_6$; and W. R. Whitney represented it by the formula $[Cr_2(H_2O)_{12}](SO_4)_36H_2O$, or $[Cr(H_2O)_6]_2(SO_4)_3.6H_2O$, which is taken best to represent the properties of the salt in aq. soln. and in the solid state. E. Moles and M. Crespi found that $[Cr(H_2O)_6]_2(SO_4)_3.5H_2O$ lost 3 mols. of water at 18°; and $[Cr(H_2O)_6]_2(SO_4)_3.2H_2O$ lost 10·7 mols. of water at 140°. According to F. Krauss and co-workers, the octodecahydrate furnishes the *enneahydrate*, $Cr_2(SO_4)_3.9H_2O$, which is stable between 30° and 100°, but the *trihydrate*, $Cr_2(SO_4).3H_2O$, has only a small range of existence. The three mols. of water are combined as in the zeolites and are therefore given up slowly. Complete dehydration occurs at about 325°.

According to A. Schrötter, and R. F. Weinland and R. Krebs, the violet hydrate forms octahedral crystals belonging to the cubic system. A. Schrötter gave 1·696 for the sp. gr. at 22°; and P. A. Favre and C. A. Valson, 1·867 at 15°. E. Moles and M. Crespi found the sp. gr. of $[Cr(H_2O)_6]_2(SO_4)_3.5H_2O$ to be 1·840 at 25°/4°, and the mol. vol. 375 to 379; and of $[Cr(H_2O)_6]_2(SO_4)_3.2H_2O$, 1·976 for the sp. gr. at 25°/4°, and 326 for the mol. vol. A. Schrötter observed that the violet salt is freely soluble in water; the percentage solubility is 54·65 per cent., but by analogy with violet hydrated chromic chloride, the solubility must depend on the equilibrium: violet sulphate$\rightleftharpoons$green sulphate. F. Krauss and co-workers observed that the dehydration curve showed breaks corresponding with 18-, 9-, 3-, and 0-hydrates. E. N. Gapon discussed some relationships of the m.p. P. A. Favre and C. A. Valson gave −3·255 Cals. for the heat of soln. per mol of $Cr_2(SO_4)_3.15H_2O$; and A. Recoura, −6·2 Cals. for a mol of $Cr_2(SO_4)_3.16H_2O$. The difference in the results may be due to differences in the proportions of the green and violet hydrates formed in different methods of preparation, etc. A. Sénéchal's results are in agreement with those of A. Recoura, for he found for the heat of soln. at 14° of the tetradecahydrate, −10·10 Cals.; for the pentadecahydrate, 8·3 Cals.; for the hexadecahydrate, −7·49 Cals.; and for the heptadecahydrate, 6·35 Cals. T. Dreisch studied the ultra-red absorption spectrum of soln. of chromic sulphate. E. Feytis said that there is no difference between the magnetic susceptibilities of the different hydrates, for the coeff. of magnetization are in all cases round about 1400×10^{-6}. G. Jäger and S. Meyer gave 31×10^{-6} mass units for the magnetic susceptibility of the soln. at 18°; and O. Liebknecht and A. P. Wills, 15×10^{-6} mass units at the same temp. V. N. Ipatieff and B. A. Mouromtseff found that soln. of chromic chloride are reduced by hydrogen under a press. of 200 atm. A. Mailfert studied the action of ozone. K. H. Butler and D. McIntosh found that the sulphate is insoluble in liquid chlorine and has no effect on the b.p. of the liquid. The violet crystals, said M. Traube, can be boiled with alcohol at 80° without passing into the green salt; on the other hand, A. Schrötter said that if a layer of alcohol be poured over the violet soln. contained in a narrow glass vessel, so as not to mix the liquids, the aq. soln. acquires a green colour starting from above and working downwards. This is attributed to the alcohol attracting or withdrawing water from the violet salt so as to form the green salt. According to A. Étard, cold monohydrated nitric acid, sulphuric acid, and phosphorus trichloride abstract water from the violet solid or soln. forming the green salt. The actual cause of the colour change is not certain. K. Schorlemmer investigated the oxidation of chromic salts to chromates by hydrogen dioxide. A. Violi found that molten sulphur converts the sulphate into chromic sulphide and sulphur dioxide. According to A. Recoura, complexes in which acetic anhydride replaces some of the water of hydrated salts are called *acetylated salts*; such an association, $Cr_2(SO_4)_3.4H_2O.4(C_2H_3O)_2O$, is formed by the slow action of finely powdered hydrated chromic sulphate on acetic anhydride.

According to A. Recoura, the **green hydrate,** which he regarded as the *henahydrate*, $Cr_2(SO_4)_3.11H_2O$, is obtained by reducing chromic acid in the presence of sulphuric acid, say, by pouring 40 c.c. of conc. sulphuric acid, and 35 c.c. of 95 per cent. alcohol into a mush of 50 grms. of chromium trioxide and 13 grms. of water. The product is dried in vacuo. A. Recoura obtained what he regarded as the *octohydrate*, $Cr_2(SO_4)_3.8H_2O$, by heating the violet sulphate to 100°. A. Étard, and A. Colson said that the product is a *hexahydrate*, and G. N. Wyrouboff, a *pentahydrate*. According to A. Sénéchal, the air-dried violet hydrate, $Cr_2(SO_4)_3.14H_2O$, begins to turn green in vacuo at 30°, and in air at 55° with the simultaneous loss of water. If the product be dissolved in water, and the violet sulphate crystallized out by cooling the soln. with ice-water, there remains, on evaporating the soln. to dryness, hexahydrated $Cr_2(SO_4)_3.6H_2O$, or $[Cr_2(SO_4)_3(H_2O)_6]$. This loses water at

80°, forming the trihydrate, $Cr_2(SO_4)_3.3H_2O$, or $[Cr_2(SO_4)_3(H_2O)_3]$, and at the same time its solubility is reduced. The trihydrate loses water at 150°, forming a greyish-green and then a greyish-red product which is insoluble in water, and loses all its water at 400°. The mol. vols. of the sulphates with 3 to 14 mols. of water are additive; but not so with those containing less water. E. Moles and M. Crespi gave 2·429 for the sp. gr. of $Cr_2(SO_4.H_2O)_3$ at 25°/4°, and 145 for the mol. vol. They also found that it lost 3·01 mols. of water at 350°. F. Krauss and co-workers showed that the dehydration curve of the green hydrate is the *dodecahydrate*, $Cr_2(SO_4)_3.12H_2O$, and when heated, 2 mols. of water behave like zeolitic water; then the hexahydrate, $Cr_2(SO_4)_3.6H_2O$, is formed; and finally, at about 400°, the anhydrous green chromate is formed. All the water in the green, amorphous *pentadecahydrate*, $Cr_2(SO_4)_3.15H_2O$, is zeolitic, and is all lost at 400° and 100 mm. Barium chloride precipitates all the SO_4 from a cold soln. of the violet sulphate, but not completely from a warm soln.; the green soln. of the dodecahydrate gives up most of the SO_4 to barium chloride, and all is given up at 100°. The cold soln. of the green, amorphous pentadecahydrate gives no precipitate with barium chloride, but if the soln. be aged, or boiled for some time, sulphate is precipitated.

According to A. Recoura, the hygroscopic green sulphate is stable, but the green aq. soln. gradually becomes violet. A freshly prepared soln. is precipitated neither by a barium salt nor by sodium hydrophosphate so that it behaves neither like a sulphate nor like a chromium salt. Alkali hydroxides precipitate from the soln. a basic salt with only two sulphate-radicles, namely, $Cr_2O(SO_4)_2$; and the heat of formation is $Cr_2O_{3aq.}+2H_2SO_4=Cr_2O_3.2SO_{3aq.}$; and $Cr_2O(SO_4)_{2aq.}+H_2SO_4=-0{\cdot}2$ Cal. The heat of transformation from the dissolved violet to the green salt is $-23{\cdot}15$ Cals., showing that the stable form is the violet salt. The isomerism between the green and violet sulphates is analogous to that between the green and violet chlorides or bromides. According to H. G. Denham, the green sulphate has twice the mol. wt. of the violet salt, and its formula is taken to be $[Cr_4(SO_4)_4](SO_4)_2$. It is strongly hydrolyzed in aq. soln. forming, in conc. soln., $[Cr_4(SO_4)_4](SO_4)(OH)_2$, and in dil. soln., $[Cr_4(SO_4)_4](OH)_4$. The transformation from the violet to the green sulphate is represented: $2Cr_2(SO_4)_3=[Cr_4(SO_4)_4](SO_4)_2$.

The basic or *modified sulphate* is a different case. Its soln. is obtained from the violet salt when heated, but it has not been obtained in the crystalline state—it furnishes a viscid syrup. The modified soln. is obtained by heating the violet soln. for a long time at 100°, and then cooling it rapidly. In the modified sulphate one-third of the sulphate can be precipitated by barium chloride. It is thought to be a complex base, $[Cr_4O(SO_4)_4](OH)_2$. A. Colson said that by heating a soln. of the violet salt, $Cr_2(SO_4)_3$, it is transformed into a pentasulphate, $HSO_4(CrSO_4)_2{-}O{-}(CrSO_4)_2.OH$, in which four of the SO_4-radicles are masked; if the boiling be continued a further hydrolysis occurs, and $SO_4Cr.O.O.Cr(SO_4)_2.O.CrSO_4$ is formed.

A. Colson said that there are three types of the green sulphate. These differ in their behaviour towards soln. of barium chloride, in their heats of formation, and in their sp. gr. The first type has *all three SO_4-radicles completely masked*, meaning that a soln. of a salt gives no precipitate with barium chloride. It is formed by the action of sulphur dioxide on a 5 per cent. soln. of chromic acid cooled by a freezing mixture; and also by evaporating a soln. of the green salt in sulphuric acid, extracting the unchanged violet salt by alcohol at 75°, and evaporating the liquid in vacuo. The green, hygroscopic, transparent plates, $Cr_2(SO_4)_3.6H_2O$, are soluble in alcohol at 75° but insoluble at 92°; the heat of formation is 33 cals.; and when the soln. has stood for about 3 days, it passes into a soln. of the second type in which two of the *three SO_4-radicles are masked*, meaning that barium chloride precipitates from the aq. soln. only one-third of the contained sulphate. B. Cabrera and S. P. de Rubies found that the electrical conductivity and unmasking of the SO_4-radicles of a soln. of the salt increase in a parallel way on keeping; no appreciable change in magnetic susceptibility occurs. The evaporation of the aged soln. in vacuo gives a salt, $Cr(SO_4)_3.8H_2O$, resembling that with three masked SO_4-

radicles. It loses water over phosphorus pentoxide in vacuo, and then consists of $Cr_2(SO_4)_3.7\frac{1}{2}H_2O$. Its heat of formation is 36·6 Cals. An isomeric form with two masked SO_4-radicles is said to be obtained by heating the violet sulphate to 90° and keeping the residue in water for 3 or 4 days below 5°. The two forms are said to differ in their heats of reaction with barium chloride, and in the electrical conductivity of their soln. In the third type *one only of the three SO_4-radicles is masked*, for, when the aq. soln. is treated with barium chloride, two-thirds of the contained sulphate is precipitated. This salt, $Cr_2(SO_4)_3.7\frac{1}{2}H_2O$, is prepared by the long-continued action of water on either of the two former types; or by precipitating hydrated chromic oxide from either soln., dissolving the product in sulphuric acid, and evaporating the soln. in vacuo. The heat of formation is 43·5 Cals.

It will be observed that the second and third types are formed by the progressive hydrolysis of the first type, and that there is simultaneously a change in the sp. gr., f.p., conductivity, and other properties of the soln. It is therefore assumed that the first type is to be regarded as $Cr_2(SO_4)_3.nH_2O$, or $[Cr_2(SO_4)_3].nH_2O$; the second, as $Cr_2(SO_4)_3(H_2O).nH_2O$, or $[Cr_2(H_2O)(SO_4)_2]SO_4.nH_2O$; and the third, as $Cr_2(SO_4)_3(H_2O)_2.nH_2O$, or $[Cr_2(H_2O)_2SO_4](SO_4)_2.nH_2O$; while the violet sulphate which has *no masked SO_4-radicles* is considered to be $Cr_2(SO_4)_3(H_2O)_3.nH_2O$, or $[Cr_2(H_2O)_3](SO_4)_3.nH_2O$. Each mol. of constitutional water is said to unmask one SO_4-radicle. According to the co-ordination theory, these four sulphates can be represented:

$$\begin{array}{cc} [Cr_2(H_2O)_{12}](SO_4)_3 & \underbrace{\begin{array}{ccc} [Cr_2(H_2O)_{10}(SO_4)](SO_4)_2 & [Cr_2(H_2O)_8(SO_4)_2]SO_4 & [Cr_2(H_2O)_6(SO_4)_3] \\ \tfrac{1}{3}SO_4\text{-masked.} & \tfrac{2}{3}SO_4\text{-masked.} & \text{All } SO_4\text{-masked.} \end{array}}_{\text{Green sulphate.}} \\ \text{Violet sulphate.} & \end{array}$$

It is of course possible that intermediate products are formed. A. Colson supposed that a cold soln. of chromic sulphate is an equilibrium mixture of the violet sulphate and three green sulphates: $Cr_2(SO_4)_3.6H_2O$, $Cr_2(SO_4)_2(OH)(HSO_4)$, and $Cr_2(SO_4)(OH)_2(HSO_4)_2$. Whatever be the nature of the complex salts existing in soln., a state of equilibrium is ultimately attained and this is dependent on the concentration and temp. of the liquid. T. W. Richards and F. Bonnet showed that the reactions which occur are reversible, for if $0·25N$-soln. of the green and violet salts are kept for a month at 30°, the amount of acid present, as indicated by the effect of the soln. on the inversion of cane-sugar, is the same in both cases, and approximates $0·043N$. At 50°, the acid so produced approximates to about $0·10N$, and at 100°, to $0·13N$. This shows that the hydrolytic equilibrium varies with the temp. The kinetics of the reactions have not been closely investigated, but some observations by A. Colson showed that the reactions are very slow at ordinary temp.; they are faster with warmer soln., and at 100°, the transformation into the modified salt occupies a few minutes. A. Kling and co-workers measured the variation with time of the amount of sulphuric acid in the soln. precipitable by benzidine hydrochloride, the lowering of the f.p. and the electrical conductivity of $0·5N$-green $Cr_2(SO_4)_4$. It was found that during the first twenty-four hours after the preparation of the soln. no sulphate precipitate is obtainable, but after that time the amount increases at first rapidly, and then gradually with passage of time. The mol. lowering of the f.p. and the electrical conductivity at first increase rapidly, even before the presence of the SO_4''-ion can be detected, and then attain a value which remains almost constant during the rest of the experiment. The green soln. of chromium sulphate tend towards a state of equilibrium, which is a function of the temp. and conc., and is the state towards which the violet soln. of the same conc. gradually pass. The properties of the chromium sulphate liquors with respect to their masked sulphate groups were studied by W. Schindler and K. Klanfer, E. Stiasny and co-workers, R. Reinicke, H. B. Merrill and co-workers, and G. Grasser.

By cooling conc. soln. of the violet salt crystals of that salt can be readily obtained, but with soln. of the green salt, or of the so-called modified salt, only gummy or glassy masses are obtained. A. W. F. Sprung found the sp. gr. of a 24 per cent. soln. of the violet salt to be 1·1619, when that of the modified salt is 1·1486; and P. A. Favre and C. A. Valson gave 1·0600 for a N-soln. of the violet salt at 15°; and 1·0556 with the modified salt at 14·9°. G. T. Gerlach found the sp. gr. of green soln. to be greater than those of violet soln.; and he gave for the sp. gr. at 15°/15° of violet soln. with the following percentage proportions of $Cr_2(SO_4)_3$:

$Cr_2(SO_4)_3$.		2·74	5·48	10·96	16·44	21·92	27·40	38·36	43·84
Sp. gr.	Green	1·0275	1·0560	1·1150	1·1785	1·2480	1·3250	—	—
	Violet	—	1·0510	1·1070	1·1680	1·2340	1·3055	1·4650	1·5530

According to A. Colson, an expansion occurs when a soln. of the violet salt passes into a soln. of the modified salt, and conversely the sp. gr. of a soln. of the green salt is intermediate between those of a soln. of the violet and of the modified salt. M. A. Graham found for the sp. gr. of soln. containing the following proportions of $Cr_2(SO_4)_3$ per litre:

$Cr_2(SO_4)_3$.	0°	10°	20°	30°	40°	50°
40·14 . .	1·0394	1·0391	1·0369	1·0342	1·0292	1·0242
63·39 . .	1·0617	1·0602	1·0585	1·0585	1·0512	1·0462
83·77 . .	—	—	1·0763	1·0763	1·0680	1·0628
126·30 . .	—	—	1·1160	1·1160	1·1062	1·1002

The soln. develop a green colour at 40° and 50° so that the solute is doubtless a mixture of the green and violet salts. A. W. F. Sprung found that the viscosity of the violet soln. is much greater than is the case with eq. soln. of the modified salt; M. A. Graham obtained the following values for the viscosities of soln. containing the indicated number of grams of $Cr_2(SO_4)_3$ per litre:

$Cr_2(SO_4)_3$.	10°	20°	25°	30°	40°	50°
19·64 . .	0·01577	0·01198	0·01062	0·00955	0·00776	0·00640
40·14 . .	—	0·01200	0·01065	0·00953	0·00774	0·00643
63·39 . .	0·01815	0·01355	0·01202	0·01076	0·00874	0·00787
83·77 . .	0·02028	0·01539	0·01396	0·01206	0·06975	0·00795
126·30 . .	0·02705	0·02072	0·01827	0·01621	0·01301	0·01041

The same remarks apply to these results as to those given with respect to the sp. gr. at 40° and 50°. G. D. van Cleeff observed that in the dialysis of soln. of the salt the dialyzed part contains more acid than the part which remains; this was confirmed by M. D. Dougal, and T. W. Richards and F. Bonnet found that when a violet soln. of chromium sulphate is subjected to dialysis, the ratio Cr/SO_4 of the salt that has diffused and the salt that has remained in the dialyzer is the same in both. When, however, a green soln. of chromium is similarly treated, the ratio Cr/SO_4 diminishes in the diffused portion and increases in the dialyzer—an observation in favour of the view that the change from violet to green involves a hydrolysis with formation of free acid and a soluble basic salt.

The lowerings of the f.p. of violet soln. of the sulphate have been measured by A. Colson, H. G. Denham, and H. C. Jones and E. Mackay. The last-named found that for soln. with 0·025, 0·050, 0·10, and 0·250 mol per litre, the f.p. was —0·121°, —0·230°, —0·417°, and —1·029°. The results indicate that for the most dil. soln., five ions per mol. are formed. For 0·083N-soln. of the modified sulphate, H. G. Denham gave —0·420° for the f.p. of the modified soln., and A. Colson, for very rapidly cooled modified 0·1N- and 0·2N-soln., respectively —0·45° and —0·85°. H. G. Denham also measured the f.p. of sulphuric acid soln. The results show that the f.p. of the modified soln. is less than that of the violet soln., and if the hydrolysis of the salt is hindered by the presence of sulphuric acid, the apparent mol. wt. of the modified sulphate is greater than that of the violet salt. T. W. Richards and F. Bonnet, and M. A. Graham examined the f.p. of mixed soln. of chromium sulphate and cane-sugar. H. G. Denham observed that the f.p. of soln. of $\frac{1}{12}N$-soln. of violet and modified sulphate sat. with hydrated chromic oxide are respectively

—0·335° and —0·268°. The results are taken to show the existence of a complex Cr_4-cation is formed, but migration experiments do not agree with the view that the complexity is due to the presence of such a complex. A. Colson found that soln. freshly prepared in the cold from the solid green sulphate show a small depression of the f.p. which rapidly rises until a value corresponding with that required for the violet soln. is attained. K. Flick studied the thermal decomposition of solid chromic sulphate.

According to A. Recoura, the heat of transformation of a mol of the dissolved green sulphate into the modified sulphate is 4·2 Cals., and into the violet sulphate, 23·15 Cals., so that the heat of transformation of a mol of the modified to the violet sulphate in soln., is 18·95 Cals. per mol. When a mol of dissolved sodium hydroxide is added to a mol of chromic sulphate in 12 litres of a modified soln., 15·61 Cals. are developed, while the addition of more sodium hydroxide develops only a little more heat; a mol of sodium hydroxide neutralizes only one-sixth of the sulphuric acid, and $\frac{1}{2}H_2SO_4$ in 12 litres of soln. with a mol of NaOH in 2 litres develops 15·63 Cals., it follows that about one-sixth the sulphuric acid was present in the soln. as free acid. A. Colson came to the same conclusion because he found that a mol of $Cr_2(SO_4)_3$ in modified soln. with $\frac{1}{2}Ba(OH)_2$ develops 18·7 Cals., while $\frac{1}{2}H_2SO_4 + \frac{1}{2}Ba(OH)_2$ develops 18·5 Cals. A mol of chromic sulphate in a green soln. with no precipitable SO_4, with 6 mols of potassium hydroxide develops 61·05 Cals., so that the heat of neutralization of the precipitated hydroxide with $3H_2SO_4$ is 33·12 Cals.; a similar soln. with one-third precipitable SO_4 develops with 6KOH, 57·6 Cals., and the heat of neutralization of the precipitated hydroxide with sulphuric acid is 36·6 Cals. Likewise with a mol of chromic sulphate with two-thirds precipitable SO_4 and 6KOH develops 43·5 Cals. With the violet soln. where all the SO_4 is precipitable, each SO_4 develops 6·65 Cals., for $H_2SO_4 + BaCl_2 = BaSO_4 + 2HCl + 9{\cdot}5$ Cals. Otherwise expressed, with a mol of $Cr_2(SO_4)_3$ in modified soln., the addition of $\frac{1}{2}$ a mol of $BaCl_2$ develops 7·20 Cals. per mol of $BaCl_2$, and with another $\frac{1}{2}$ mol of $BaCl_2$, 7·06 Cals. per mol of $BaCl_2$; and with yet another $\frac{1}{2}$ mol of $BaCl_2$, 0·15 Cal. Accordingly, only one-third of the total sulphate reacts with barium chloride. Using a mol of $Cr_2(SO_4)_3$ in an aged green soln., the addition of one mol of $BaCl_2$ develops 7·1 Cals.; 2 mols, 14·1 Cals.; and 3 mols, 14·7 Cals. This shows that two-thirds of the total SO_4 is precipitated. According to A. Kling and coworkers, a fresh soln. of a mol of chromic sulphate, in ice-cold water, exhibits no thermal change.

L. R. Ingersoll found for Verdet's constant for the electro-magnetic rotatory power for light of wave-length 0·8, 1·0, and 1·25μ, respectively 0·0067, 0·0045, and 0·0028 for soln. of chromic sulphate of sp. gr. 1·140. The absorption spectra of violet and green soln. of chromic sulphate were examined by D. Brewster, H. F. Talbot, W. N. Hartley, J. M. Hiebendaal, O. Knoblauch, W. Böhlendorff, A. Étard, G. Massol and A. Faucon, Y. Shibata and H. M. Vernon. H. C. Jones, and W. W. Strong found that with soln. of the violet sulphate at 5°, the three characteristic chromium bands appear—*viz.*, the ultra-violet band extending to $\lambda=2800$; the bluish-violet band from $\lambda=4100$ to 4450; and the yellowish-green band from $\lambda=5500$ to $\lambda=6200$. The bands at $\lambda=6800$ are very faint. The absorption in the visible spectrum is very strong. At 82°, the ultra-violet band extends to $\lambda=2900$, the bluish-violet band from $\lambda=4100$ to 4550, and the yellowish-green band from $\lambda=5500$ to 6300. The effect of a rise of temp. is therefore very small, usually involving a shifting of the long wave-length edges of all three bands towards the red. M. A. Graham found that the ultra-violet absorption spectra of green and violet soln. indicate that the change in colour which occurs is not due to simple hydrolysis, but is the result of a process involving both hydrolysis and a change in structure. T. Svensson found that the electrical conductivity of soln. of chromic sulphate slowly decreases in light.

The mol. electrical conductivity of the violet soln. has been determined by P. Walden, W. R. Whitney, A. Gubser, M. A. Graham, A. Colson, and H. C. Jones and E. Mackay. L. G. Winston and H. C. Jones observed for violet soln., the mol. conductivity, μ mhos, for soln. of a mol of the salt in v litres, and α, the percentage ionization,

	v . .	4	8	32	128	512	1024	4096
μ	0° .	61·8	82·7	128·2	180·0	229·1	256	335·5
	12·5° .	83·5	110·1	168·8	240·0	311·6	351·2	474
	25° .	106·0	138·6	210·0	301·5	400·5	489	636

	35° .	14·4	18·7	28·5	41·9	58·5	69·5	100·0

E. J. Schaefer and H. C. Jones made observations at higher temp., but the results are affected by the change from the violet to the green sulphate between 40° and 50°. H. H. Hosford and H. C. Jones gave for a modified green soln.:

v .	4	8	32	128	512	2048
μ	128·2	183·5	302·0	433·9	673·3	961·1
	160·0	227·8	354·4	522·7	811·1	1207·8
	189·6	262·9	417·4	606·0	977·3	1534·7

M. A. Graham gave for violet and the modified green soln.:

	v . .	16	32	64	128	256	512	1024
μ	violet 0°	85·37	100·0	117·7	139·2	166·6	194·2	232·2
	25°	151·5	177·1	211·8	255·0	310·2	379·5	476·9
μ	green 0°	168·1	187·7	211·2	233·2	255·2	270·8	282·1
	25°	245·7	285·2	336·5	390·4	450·7	515·0	568·5

W. R. Whitney observed that the modified green soln. has a higher conductivity than the violet, thus, $\frac{1}{30}N$-$Cr_2(SO_4)_3$ has a sp. conductivity 0·001489 in the violet state at 25° and 0·001927 in the modified green state. He also found that the conductivity with the addition of increasing proportions of sodium or barium hydroxide decreases to a minimum and thereafter increases. With a $\frac{1}{30}N$-soln., at 25°, the minimum is reached when the added sodium hydroxide is eq. to $\frac{1}{6}$th of the total sulphate present, or when the added barium hydroxide is eq. to one-third the total sulphuric acid. Hence, it is assumed that one-sixth of the sulphate in the green soln. is present as free sulphuric acid, and one-third as SO_4''-ions. This is in agreement with A. Recoura's assumption that the formation of the green soln. is attended by the formation of the salt $[Cr_4O(SO_4)_4]SO_4$. A. W. Thomas and M. E. Baldwin studied the $H^{\cdot}$-ion conc. of soln. of chromic sulphate. During the passage of an electric current through a soln. of the violet sulphate, chromium passes to the cathode; but in a soln. of the modified salt, the hydrogen ions migrate to the cathode much more quickly. T. W. Richards and F. Bonnet, and H. G. Denham found that no chromium goes to the anode in a modified green soln. so that no complex acid-ions are formed. The basic complex in the modified soln. seems to carry only one positive charge and has a transport number of 41 when that of SO_4'' is 70. F. C. Thompson and W. R. Atkin suggested that the active agent in tanning with chromic sulphate soln. is a negatively charged chromium complex, but F. L. S. Jones found that electrophoresis experiments on normal and basic soln. of chromic chloride and sulphate and of chrome-alum showed that anodic migration of chromium occurs only in basic sulphate soln., and therefore no such negative complex can exist in soln. of the chloride or of chrome alum. The subject was studied by H. B. Merrill and J. G. Niedercorn. P. Philipp found the magnetic susceptibility ranged from $31·93\times10^{-6}$ mass units for soln. of sp. gr. 1·3453 to $33·04\times10^{-6}$ mass units for soln. of sp. gr. 1·03086. T. Ishiwara, and K. Honda and T. Ishiwara gave for the anhydrous salt $13·3\times10^{-6}$ at 15·7°, and $9·7\times10^{-6}$ mass units at 300°; and for the enneahydrate, $4·5\times10^{-6}$ mass units at 16·9°, and $7·4\times10^{-6}$ at 434·8°.

According to F. P. Venable and F. W. Miller both the violet and the green, modified soln. are acid towards indicators owing to the hydrolysis. A. Recoura observed that distilling the aq. soln. furnishes an acidic distillate, while the dried salt does not lose acid at 100°. M. Krüger also found that alcohol poured over the green soln. takes up acid. F. P. Venable and F. W. Miller observed that eq. violet and green soln. required nearly the same amount of $\frac{1}{10}N$-NH_4OH to produce the first appearance of a permanent precipitate. Their conclusion was that the two soln. must therefore contain nearly the same proportion of acid, but as W. R. Whitney pointed out, the conclusion is wrong because alkali and ammonium hydroxides or carbonate turn the violet soln. green, and this change in colour precedes the formation of the permanent precipitate. C. R. C. Tichborne observed that if a soln. of chromic sulphate be heated to 177° under press. for 2 to 3 hrs., a precipitate of a basic sulphate is formed. G. Powarnin found that in dil. soln., chromium sulphate is more strongly hydrolyzed than aluminium sulphate; and that the hydrolysis is decreased in the presence of SO_4''-ions or Cl'-ions, and also by alcohol and formaldehyde. Many others have observed the hydrolysis of soln. of chromic sulphate. H. G. Denham measured the e.m.f., E, (H zero) of the cell $H_2 \mid Cr_2(SO_4)_{3\,\mathrm{violet}}, NH_4NO_3 \mid$ calomel electrode, and calculated the $H^{\cdot}$-ion conc., $[H^{\cdot}]$, and the percentage hydrolysis, x, as well as the ionization constant, K, where $K_1=[Cr(SO_4)(OH)][H^{\cdot}]/[Cr(SO_4)^{\cdot}]$, obtained from the hydrolytic reactions: $Cr_2(SO_4)_3+2H_2O \rightleftharpoons 2Cr(SO_4)OH+H_2SO_4$, or $Cr(SO_4)^{\cdot}+H_2O \rightleftharpoons Cr(SO_4)(OH)+H^{\cdot}$, for soln. of a mol of $Cr_2(SO_4)_3$ in v litres, at 25°,

v	6	8	16	32	64	128
E	−0·1417	−0·1444	−0·1533	−0·1604	−0·1713	−0·1653
$[H^{\cdot}]\times 10^2$	0·396	0·357	0·252	0·191	0·125	0·158
x	1·19	1·42	2·02	3·05	4·00	10·10
$K_1\times 10^4$	0·24	0·26	0·26	0·30	0·26	0·88

The great increase in the ionization constant with high dilution is taken to mean that another stage in the progressive hydrolysis occurs, namely, $Cr_2(SO_4)^{\cdot\cdot\cdot\cdot}+4H_2O \rightleftharpoons Cr_2(SO_4)(OH)_4+4H^{\cdot}$, for which he found that $K_2=[H^{\cdot}]^4[Cr_2(SO_4)(OH)_4]$-$[Cr_2(SO_4)^{\cdot\cdot\cdot\cdot}]$, or $K_2=0{\cdot}129\times 10^{-14}$. H. M. Vernon estimated the degree of ionization from the colour. M. A. Graham calculated from the conductivity of the violet soln. that the percentage hydrolysis is:

v	32	64	128	256	512	1024
x	1·78	3·19	4·76	8·08	16·24	33·98

At 0°, the violet soln. is only slightly hydrolyzed. The hydrolysis calculated from the effect on the velocity of inversion of cane sugar shows that the change from violet to green is much more rapid than the reverse process. A. Recoura found from the thermal data that in the modified green $\frac{1}{12}N$-soln., about one-sixth of the total sulphuric acid is free; and W. R. Whitney observed the effect of soln. of chromic sulphate on the hydrolysis of methyl acetate, and concluded that the green soln. possesses a hydrolyzing power equal to that of a mixture of one-sixth the eq. of free acid, with the corresponding amounts of the violet salt. The effects on the rate of inversion of cane sugar were too complex to enable a calculation to be made of the degree of hydrolysis of the soln. H. G. Denham calculated data for green modified soln. as in the case above cited for violet soln. and found

v	6	8	16	32	64	128
E	−0·0528	−0·0589	−0·0740	−0·0871	−0·0968	−0·1095
$[H^{\cdot}]$	0·1236	0·1005	0·05572	0·03342	0·02286	0·01393
x	37·1	40·2	44·6	53·4	72·9	88·8
K_1	0·18	0·21	0·23	—	—	—

The value of x is calculated on the assumption that the reaction is $[Cr_4(SO_4)_4](SO_4)_2+4H_2O \rightleftharpoons 2H_2SO_4+[Cr_4(SO_4)_4](OH)_4$; and K_1 is calculated for the formation of $[Cr_4(SO_4)_4](SO_4)(OH)_2$. As in the case of the violet soln., M. A. Graham calculated for the hydrolysis of the green modified soln., by the conductivity method,

v	16	32	64	128	256	512	1024
x	17·02	22·04	27·68	33·42	40·74	51·10	60·49

In both cases M. A. Graham's results are lower than those of H. G. Denham. The hydrolyses calculated from the effect on the inversion of cane sugar for soln. with $v=5$ and 10, are respectively 8·39 and 6·84 per cent., but the results are not so trustworthy. H. T. S. Britton calculated that a violet $0{\cdot}0050M$-soln. of chromic sulphate was hydrolyzed to the extent of 2·16 per cent., and a green $0{\cdot}0067M$-soln., 28·7 per cent. The electrometric titration curve is shown in Fig. 79. W. J. Chater and J. S. Mudd found a change in the p_H value at 2·3 and basicity 124. T. Svensson observed that a cell of chromic sulphate soln. gives an increased e.m.f. when illuminated. The change owing to the presence of neutral salt is dependent on the basicity. The difference in acidity caused by the neutral salt is a minimum at basicity 124. N. Demassieux and J. Heyrovsky obtained analogous polarization curves with chromic sulphates as were obtained with the chlorides (*q.v.*).

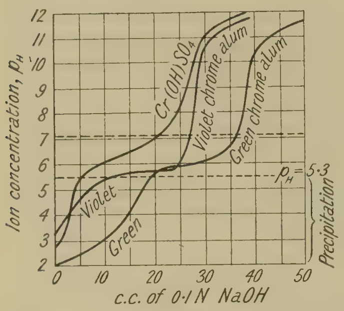

FIG. 79.—The Electrometric Titration Curves of Chromic Sulphate Solutions.

The penetration of gelatin jelly by chromium sulphate soln. is greater the greater the acidity. From his observations of the physical properties of the soln., and on those of T. W. Richards and F. Bonnet, H. G. Denham inferred that when the violet soln. is heated, the salt undergoes hydrolysis in the ordinary way; it is assumed that two mols. of the salt unite to form a complex: $2Cr_2(SO_4)_3 = [Cr_4(SO_4)_4](SO_4)_2$, and that the complex then hydrolyzes: $[Cr_4(SO_4)_4](SO_4)_2 + 2H_2O \rightleftharpoons [Cr_4(SO_4)_4]SO_4(OH)_2 + H_2SO_4$ with up to $\frac{1}{40}M$-soln., and on further dilution: $[Cr_4(SO_4)_4](SO_4)_2 + 4H_2O = 2H_2SO_4 + [Cr_4(SO_4)_4(OH)_4]$. D. M. Yost studied the rate of oxidation of soln. of chromic sulphate by potassium persulphate (*q.v.*). F. Hans found that chromic salts and silver salts (if soluble enough) react in accord with $Cr_2O_3 + 3Ag_2O = 2CrO_3 + 6Ag$. J. Poizat studied the action of chromic sulphate on the decomposition of hydrogen dioxide. W. R. Hodgkinson and C. C. Trench observed that chromium sulphate is reduced to a mixture of oxide and sulphide when heated in ammonia. F. Feigl found that a boiling soln. of chromic sulphate in alkali-lye is oxidized to chromate by charcoal (with oxygen in the pores); and G. Fuseya and co-workers discussed the formation of complex cations with chromic sulphate and glycine. W. Manchot and co-workers showed that soln. with 22·356 and 44·712 grms. $Cr_2(SO_4)_3$ per 100 c.c. dissolve respectively 31·8 and 18·2 c.c. of nitrous oxide per 100 c.c. of soln., and respectively 56·7 and 32·4 c.c. of acetylene.

L. N. Vauquelin, J. J. Berzelius, A. Schrötter, M. Siewert, H. Schiff, R. Bunsen, and C. R. C. Tichborne obtained precipitates of basic salts by the action of water on soln. of chromic hydroxide in sulphuric acid. In some cases the composition of the product approximated to $3Cr_2O_3.2SO_3$; H. Schiff obtained one approximating $3Cr_2O_3.4SO_3.12H_2O$; and M. Siewert, precipitates approximating to $5Cr_2O_3.8SO_3$, and to $5Cr_2O_3.12SO_3$. There is nothing to show that these products are anything more than arbitrary stages in the progressive hydrolysis of chromic sulphate. H. Schiff also obtained **chromic dioxysulphate,** $Cr_2O_2SO_4.nH_2O$, by dissolving a precipitated basic salt in dil. hydrochloric acid, and after diluting the soln., boiling it for some hours. A. Werner regarded it as **chromic dihydroxytetraquosulphate,** $[Cr(OH)_2(H_2O)_4]_2SO_4$, and obtained it by adding 10 grms. of pyridine to a soln. of 20 grms. of chrome-alum and 30 grms. of sodium sulphate in 300 grms. of water. The pale green, silky needles are but slightly soluble in water, and with organic and mineral acids form hexaquo-salts of the type $[Cr(H_2O)_6]X_3$. O. Grimm's observations on the chlorides are also applicable here.

A. Schrötter found that when dil. sulphuric acid sat. with hydrated chromic oxide is boiled for a long time and concentrated it furnishes a green soln. which is acidic to test-paper, and leaves on drying a green, amorphous mass from which the whole of the sulphate is expelled by ignition. H. Schiff added that at 100°, four mols. of water are given off and at a higher temp., one mol. A. Schrötter gave the formula of the compound dried at 50° to 60°, $2Cr(OH)SO_4.4H_2O$, but H. Schiff, in agreement with H. Löwel, gave $Cr_2(OH)_4SO_4.4H_2O$, **chromic tetrahydroxysulphate.** A. Schrötter found that a soln. of the salt appears ruby-red viewed by transmitted sunlight, or candle-light; and H. F. Talbot added that if the soln. which appears green by day-light, and red by candle-light be introduced into a prism with a refracting angle of 5° or 10°, and then placed between the eye and the candle-flame, red and blue images of the candle appear, and the rest of the visible spectrum is absorbed so that a kind of double refraction is produced. If the soln. be placed in a bottle and viewed by transmitted light, the two images overlap, the green predominates by daylight, and the red, by candle-light. A conc. soln. of the sulphate is rendered turbid by the addition of water, depositing the more basic 3 : 2-sulphate, and becoming paler in proportion to the amount of water added. On evaporation, however, the precipitate redissolves—when the dil. soln. filtered from the precipitate is heated, it deposits more of the 3 : 2-sulphate, which again disappears on boiling. A soln. of sp. gr. 1·219 and upwards deposits nothing when heated; a soln. of sp. gr. 1·166 becomes turbid at 57°; a soln. of sp. gr. 1·037—1·031, at 64°; one of sp. gr. 1·002, at 45°; and one of sp. gr. 1·001, at 55°; while still more dil. soln. remain clear when boiled. According to H. Löwel, if the green soln. be treated with as much acid as it already contains, ammonia then produces a dark green precipitate which is only slightly soluble in ammonia. M. Siewert found that when soln. of the violet salt is boiled with an excess of hydrated chromic oxide, and the green soln. evaporated almost to the point of solidification, it becomes turbid when water is added, but clarifies again on evaporation. Absolute alcohol precipitates from the soln. a green syrup of the 1 : 2-sulphate, and it forms a clear soln. with water. The soln. does not become turbid when boiled, but gives the 1 : 2-sulphate as a precipitate when alcohol is added. B. Cabrera and S. P. de Rubies studied the magnetic qualities of green and violet **chromic oxydisulphate,** $Cr_2O(SO_4)_2.nH_2O$, and found that they change when the soln. is kept for some time. It is suggested that this is due to the changes: $[Cr_2(SO_4)_2O] \rightarrow [Cr_2(SO_4)O]SO_4 \rightarrow [Cr_2O](SO_4)_2$. According to L. and P. Wöhler and W. Plüddemann, the oxydisulphate, obtained by heating the basic sulphate to 280° in a current of carbon dioxide, has a dissociation press. of 91 mm. at 340°, and 191 mm. at 372°; and the heat of dissociation is 21·97 Cals. Likewise, **chromic trioxytrisulphate,** $Cr_4O_3(SO_4)_3$, obtained by heating the basic sulphate to 450° or 460° in a current of carbon dioxide, has a dissociation press. of 146 mm. at 640°, and 400 mm. at 660°; the heat of dissociation is 61·62 Cals.

According to A. Colson, **chromic oxypentasulphate,** $Cr_4O(SO_4)_5.nH_2O$, with *two masked* SO_4*-radicles* is obtained by treating a cold soln. of 100 grms. of chrome-alum in 4 litres of water of ammonia; digesting an excess of the washed precipitate in sulphuric acid; and evaporating the soln. in vacuo. Only three of the five sulphate radicles are precipitated from a soln. of the salt by barium chloride. The salt in alcoholic soln. has the same composition as the solid. If the soln. of this salt is slowly crystallized, by evaporation in dry air, it yields the oxypentasulphate, $Cr_4O(SO_4)_5.12H_2O$, with *three masked* SO_4*-radicles.* A. Colson said that when a soln. of the violet sulphate is heated, it forms the oxypentasulphate, $HSO_4(CrSO_4)_2.O.(CrSO_4)_2.O.CrSO_4$, in which there are *four masked* SO_4*-radicles.* If the soln. is boiled and suddenly cooled, it yields the sulphate with all its sulphate radicles masked.

According to P. Nicolardot, when a violet soln. is boiled, and the resulting green liquor is heated with barium sulphate, part of the sulphuric acid is precipitated, and when the filtrate is allowed to evaporate spontaneously, there remains chromic oxypentasulphate, $Cr_2O_3.2{\cdot}5SO_3.7{\cdot}5H_2O$, that is, $Cr_4O(SO_4)_5.15H_2O$, with *all five* SO_4*-radicles masked.* This salt appears as a non-crystalline solid, readily soluble in water to form a green soln., but insoluble in alcohol or acetone, and precipitated from aq. soln. by these liquids. Soln. of the salt do not yield precipitates with barium chloride or with sodium phosphate; it differs in this respect from the sulphate of sulphochromyl hydroxide described, but not isolated, by A. Recoura. According to A. Colson, the equilibrium indicated in the following equation, $2Cr_2(SO_4)_3+H_2O \rightleftharpoons H_2SO_4+Cr_4O(SO_4)_5$, is only relatively stable, and the pentasulphate, $Cr_4O(SO_4)_5$, is acted on by boiling water with momentary production of a fresh quantity of acid, thus: $Cr_4O(SO_4)_5+H_2O \rightleftharpoons Cr_4O_2(SO_4)_4+H_2SO_4$. This is proved by the repeated boiling of a 0·1N-soln. of the normal green sulphate, $Cr_2(SO_4)_3.10H_2O$, cooling very rapidly, and then adding baryta-soln. The amount of heat developed in the reaction shows that each successive boiling after the first liberates sulphuric acid according to the second equation.

C. F. Cross and A. F. Higgin obtained an acid salt approximating $4Cr_2O_3.6SO_3.7H_2SO_4$, by heating chromic oxide with conc. sulphuric acid. The grey powder is insoluble in water, and is attacked with difficulty by alkali-lye. According to M. Traube, and A. Schrötter, a pale puce or grey powder is formed when a green mush of conc. sulphuric acid and a basic chromic sulphate or hydrated oxide is heated until sulphuric acid begins to volatilize: if a large proportion of sulphuric acid is employed, a green soln. is obtained, which when heated becomes colourless, and deposits the puce or grey powder. The product is washed with water and dried. A. Schrötter regarded it as the normal sulphate, but M. Traube, and M. Siewert showed that it is rather **chromic dihydroheptasulphate,** $2Cr_2(SO_4)_3.H_2SO_4$. A. Étard supposed the compound to be constituted $Cr_2(SO_4)_6Cr_2.H_2SO_4$, or $HSO_4.Cr_2(SO_4)_5Cr_2.HSO_4$; and G. N. Wyrouboff, $[Cr_2O_3(SO_2)_4O_4Cr_2O_3(SO_2)_3O_2(OH)_2]_3$. M. Traube also obtained the same salt contaminated with some potassium salt by the action of conc. sulphuric acid on potassium dichromate and chrome-alum; and T. Klobb, by the action of the acid on the ammonium chromic sulphate. M. Traube said that the powder is sometimes so fine that it will pass through filter-paper; and will remain suspended in water a considerable time, but can be rapidly precipitated by the addition of various salts—*e.g.* ammonium carbonate, potassium sulphate, etc. The powder appears grey by daylight, and green by candle-light; and A. Schrötter said that the powder may appear a very light red by diffused daylight; pale green by sunlight; and verdigris-green by candle-light. Every time it is heated, it appears puce-coloured. When heated to redness, it gives off all its sulphuric acid; and, according to M. Traube, a pyrophoric mixture of chromic sulphide and oxide may be formed. When heated in hydrogen it yields water, hydrogen sulphide, sulphur, and chromic oxide; while a current of hydrogen sulphide converts the heated salt into black chromic sulphide, with the formation of water, sulphur, and sulphur dioxide. It is insoluble in cold water, but when boiled for a long time with water, or when allowed to stand for a long time in contact with water, some of it passes into soln. It is insoluble in aq. ammonia and in strong mineral acids—*e.g.* hydrochloric, sulphuric, and nitric acids, or in aqua regia. The salt is readily decomposed by fused alkali hydroxide, or by a boiling soln. of the hydroxide or carbonate.

R. F. Weinland and R. Krebs prepared **chromic dihydrotetrasulphate,** $Cr_2(SO_4)_3.H_2SO_4.nH_2O$, by the action of an excess of conc. sulphuric acid on a soln. of chrome-alum. The *hexadecahydrate* separates in the *violet form* if the mixture is made with well-cooled liquids; columnar crystals separate from a soln. of 100 mols of sulphuric acid and one of chrome-alum when evaporated in vacuo, while if the mixture is made with warm soln., the *green form* is produced in acicular crystals. Only with the violet soln. is all the sulphuric acid precipitated by barium chloride. The salt loses no water if the salt be kept over sulphuric acid in vacuo. A soln. of a mol of the violet sulphate in 124·7 litres of water has a conductivity of 116, and this value does not change with time; on the other hand, a soln. of the green salt of nearly the same conc. has a conductivity of 76·5 which in 2 hrs. rises to 80·8, in 5 hrs. to 93·2, and in 24 hrs. to 101·8. It is therefore inferred that the violet salt is to be formulated $[Cr_2(H_2O)_{16}](SO_4)_3(H_2SO_4)$, and that with the green salt, some sulphate is contained within the co-ordinated group. If the original components interact at —15°, long, tabular, violet crystals of the *tetracosihydrate* are formed, $[Cr_2(H_2O)_{16}](SO_4)_3(H_2SO_4).8H_2O$, or $[Cr(H_2O)_8](SO_4(HSO_4).4H_2O$. This salt can be regarded as being related to chrome-alum since both contain the same number of water mols., and in both the sulphate-radicle is all precipitated by barium sulphate: $HCr(SO_4)_2.12H_2O$, and $KCr(SO_4)_2.12H_2O$. Chrome-alum loses 6 mols. of water over sulphuric acid in vacuo, while hydrochromodisulphuric acid loses 4 mols., yielding the hexadecahydrate. Still further, if 140 mols of sulphuric acid be employed to one mol of sulphate, **chromic tetrahydropentasulphate,** $Cr_2(SO_4)_3.2H_2SO_4.18H_2O$, or $[Cr_2(H_2O)_{18}](SO_4)_3(H_2SO_4)_2$, is formed in rectangular plates. This *violet form* of the salt becomes greyish-green when heated to 100°, with the loss of some water. Barium chloride does not precipitate all the sulphate from the green aq. soln., but it does so from the violet soln. Consequently, some sulphate radicle is contained within the co-ordination group of the green salt.

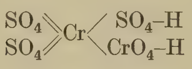
According to A. Recoura, green chromic sulphate can unite with one, two, and three mols. of sulphuric acid, or metal sulphates to form complex **chromisulphuric acids,** or their salts. The acids are prepared by evaporating to dryness on a water-bath a soln. of a mol of green chromic sulphate with one, two, or three mols of sulphuric acid, and heating the green product for a long time to 110° to 120°. No sulphate is precipitated when barium chloride is first added to aq. soln. of the acids. There are thus obtained **chromitetrasulphuric acid,** $Cr_2(SO_4)_3.H_2SO_4.nH_2O$, or $H_2[Cr_2(SO_4)_4]nH_2O$, or, according to W. R. Whitney, $[Cr_2(H_2O)_4(SO_4)]H_2$; **chromipentasulphuric acid,** $Cr_2(SO_4)_3.2H_2SO_4.nH_2O$, or $H_4[Cr_2(SO_4)_5].nH_2O$, or, according to W. R. Whitney, $[Cr_2(H_2O)_2(SO_4)_5]H_4$; and **chromihexasulphuric acid,** $Cr_2(SO_4)_3.3H_2SO_4.nH_2O$, or $H_6[Cr(SO_4)_6].nH_2O$, or, according to W. R. Whitney, $[Cr(SO_4)_6]H_6$. G. N. Wyrouboff regarded these acids as esters of the green sulphate in which two hydroxyl radicles are replaced by chromosulphuric acid. These acids are accordingly represented respectively by $[Cr_2O(OH)_4(SO_2)_4]O(OH)_6$; by $[Cr_2O(OH)_4(SO_2)_5]O_2(OH)_6$; and by $[Cr_2O(OH)_4(SO_2)_6]O_3(OH)_6$. According to A. Recoura, the proportion of contained water is dependent on the duration of the heating at 110° to 120°, and they lose no sulphuric acid below 170°. E. Moles and M. Crespi gave for the sp. gr. of the acid $HCr(SO_4)_2$, 2·724 at 25°/4°, and 90·5 for the mol. vol.; for the acid $HCr(SO_4.H_2O)_2$, they found the sp. gr. 2·516, and the mol. vol. 111·5; and for $H[Cr(H_2O)_6](SO_4.H_2O)_2$, respectively 2·009 and 195. They also observed that the acid $H[Cr(H_2O)_6](SO_4.H_2O)_2$ loses 6·03 mols. of water at 120°, and $HCr(SO_4.H_2O)_2$, 1·91 mols. at 350°. According to A. Recoura, the acids are stable when dry, and they are freely soluble in water forming green soln. The basicity of the acids just indicated accords with the thermal values of the neutralization of soln. of the respective acids with 2, 4, and 6 mols. of a soln. of sodium hydroxide—one mol per 20 litres: $(H_2[Cr_2(SO_4)_4],2NaOH)=33{\cdot}3$ Cals.; $(H_4[Cr(SO_4)_5],4NaOH)=2\times33$ Cals.; and $(H_6[Cr(SO_4)_6],6NaOH)=3\times32$ Cals. When $(H_2SO_4,2NaOH)=30{\cdot}8$ Cals. under similar conditions. The formulæ are also in accord with the fact that freshly prepared soln. do not show the reactions of chromium or sulphates with mild reagents like sodium phosphate and barium chloride. In course of time, particularly when heated, or when treated with stronger reagents like sodium hydroxide, the soln. do give the reactions of chromium and of sulphuric acid. W. R. Whitney found the electrical conductivity, λ mhos, of soln. a gram-equivalent in *v* litres at 0° to be close to the values for sulphuric acid of the same conc.,

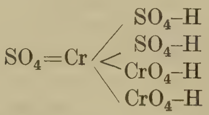
v	. . . . .	202	404	808	1616	3232
λ	$\frac{1}{2}H_2SO_4$	210·7	223·7	236·0	245·5	249·2
	$\frac{1}{2}H_2[Cr_2(SO_4)_3(H_2SO_4)]$	210·6	223·1	232·5	241·0	250·9
	$\frac{1}{4}H_4[Cr_2(SO_4)_3(H_2SO_4)_2]$	210·9	222·9	231·5	240·6	260·5
	$\frac{1}{6}H_6[Cr_2(SO_4)_3(H_2SO_4)_3]$	210·7	222·3	236·0	244·0	250·8

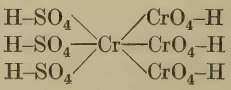
Consequently, W. R. Whitney inferred that the ionization, the velocities of transport of the anions, and the strengths of the four acids are approximately the same; similar conclusions were drawn from the action of the four acids on the hydrolysis of methyl acetate. Determinations of the f.p. show that the number of molecules in soln. of these acids is conditioned by the free sulphuric acid present in the soln. The f.p. of sulphuric acid is the same as that of one of these acids with the same content of free sulphuric acid—*i.e.* acid not bound to the chromium. Hence, chromic sulphate does not act as individual compound, but it forms complexes in agreement with the results deduced from the chemical behaviour of the complexes. When the soln. are kept for some time, the f.p. data show that there is an increase in the number of molecules. For an isomeric form of chromic tetrasulphuric acid, *vide infra.*

A. Recoura attempted to prepare chromisulphuric acids with more than three mols of sulphuric acid per mol. of chromic sulphate, but found that the products have quite a different character. Thus, when a soln. of a mol of the green sulphate with 4, 5, or 6 mols. of sulphuric acid is evaporated on a water-bath, and the resulting dark green syrup is heated for some days at 115°, **chromipolysulphuric acids**—respectively **chromiheptasulphuric acid,** $Cr_2(SO_4)_3.4H_2SO_4$; **chromioctosulphuric acid,** $Cr_2(SO_4)_3.5H_2SO_4$; and **chromienneasulphuric acid,** $Cr_2(SO_4)_3.6H_2SO_4$—are obtained in the form of transparent, green glasses which form yellowish-green soln. with water. These soln. form transparent, gelatinous masses after standing a few days; they are coagulated at 100°; on the addition of strong acids they furnish green flecks; and they give green, insoluble, flocculent precipitates when treated with soln. of the salts of the metals. In this reaction the complex is reduced to a chromitetrasulphate, $MSO_4.Cr_2(SO_4)_3$ or $Cr(SO_3)_4O_2(OH)_2$ and the excess sulphate is set free as sulphuric acid; thus, chromiheptasulphuric acid reacts with cupric chloride: $[Cr_2(SO_4)_3(H_2SO_4)_4]+CuCl_2=3H_2SO_4+2HCl+[Cr_2(SO_4)_4]Cu$. A. Recoura also prepared the chromitetrasulphuric acid by heating chromiheptasulphuric acid to 140°–150° until it no longer loses weight, and has lost 3 mols. of sulphuric acid. The grey powder is an isomeric form of the chromitetrasulphuric acid indicated above. It forms a greenish-yellow, opalescent or colloidal soln. with water, and with soln. of the metal salts, insoluble chromitetrasulphates. Chromitetrasulphuric acid, $Cr_2O_2(SO_3)_4(OH)_2$, or $[Cr_2(SO_4)_4]H_2$, is dibasic, and it is a stronger acid than sulphuric acid. Strong acids precipitate it as a gelatinous mass from soln. of its salts. The acid can be transformed into its isomeric form by boiling with water; and with boiling alkali-lye, chromites are formed. G. N. Wyrouboff believed that these chromipolysulphuric acids are not chemical individuals, but mixtures of sulphuric acid with the chromitetrasulphuric acid.

A. Recoura showed that the green chromic sulphate can unite with one, two, or three mols. of chromic acid to form **chromitrisulphatochromic acids.** These are analogous to the chromisulphuric acids. Thus, there is **chromitrisulphatochromic acid,** $Cr_2(SO_4)_3.H_2CrO_4$, or $H_2[Cr_2(SO_4)_3(CrO_4)]$; **chromitrisulphatodichromic acid,** $Cr_2(SO_4)_3.2H_2CrO_4$, or $H_4[Cr_2(SO_4)_3(CrO_4)_2]$; and **chromitrisulphatotrichromic acid,** $Cr_2(SO_4)_3.3H_2CrO_4$, or $H_6[Cr_2(SO_4)_3(CrO_4)_3]$. The constitutions may also be represented respectively by the formulæ:







These acids form dark brown amorphous masses which, in freshly prepared, dil. soln. exhibit the characteristic reactions of neither SO_4''—nor CrO_4''—radicles, slowly decompose when they do show the reactions of these radicles. Arguing by analogy, and from some observations on the heats of neutralization, it is inferred that the constitution of the chromisulphatochromic acids resembles that of the chromisulphuric acids. If the alkali chromates are employed in place of chromic acid in the preparation of these products then the corresponding chromisulphatochromates are formed. J. Poizat studied the action of chromimono-, -di-, and tri-sulphuric acids on hydrogen dioxide.

According to G. N. Wyrouboff, when an aq. soln. of chromisulphuric acid is heated, a coagulum is formed which he called *chromium sulphochromate*, $[Cr_2O_2(OH)_4(SO_2)_4O_2(OH)_2]Cr_2(OH)_6$, and which is identical with that obtained by precipitating a violet salt of chromium in the cold with sulphochromic acid. If this is maintained for some time in contact with boiling water, it becomes hydrated, dissolves slowly, and finally passes entirely into a soln. of the green sulphate. Chromium sulphochromate, when heated at 120°, becomes soluble in water and the soln. yields insoluble precipitates with metallic salts, *chromosulphochromates* being formed. When chromium sulphochromate is treated with hydrochloric acid, what he called *chromosulphochromic acid*, $[Cr_2O_2(OH)_4(SO_2)_4O_3.Cr_2O(OH)_2(SO_2)_3(OH_6][(OH)_2$, is precipitated as a dark green, gelatinous mass which dissolves in water, yielding an opalescent soln. On adding 2 mols of sulphuric acid and a little water to 1 mol of chromium sulphochromate, evaporating on the water-bath, and heating for some hours at 120°, *chromodisulphochromic acid*, $[Cr_2O_2(OH)_4(SO_2)_4O_3]_2Cr_2O(OH)_2(SO_2)_3(OH)_4(OH)_4.H_2O$, is obtained, which yields an insoluble salt with iron. With sulphochromic acid, chromium sulphochromate yields a chromosulphodichromate. If chromium sulphate is heated with an excess of sulphuric acid to a temp. not exceeding 150°, a clear green, gelatinous precipitate of sulphochromic acid is formed; on continuing the heating and at the same time allowing the temp. to rise, the green precipitate gradually changes into a heavy, greyish-yellow powder, soluble in water, yielding a milky, strongly acid soln. The same substance is obtained by heating sulphochromic acid for some time at 250°, and is the first anhydride of a polymeride of chromosulphochromic acid. Although sulphochromic acid forms insoluble compounds with the metals, it does not give precipitates with all the salts of the metals. Thus, it gives a precipitate with a soln. of mercuric nitrate or acetate, but not with mercuric bromide. This is explained by saying that the last-named salt is an anhydride and not a normal salt.

The products obtained by J. L. Gay Lussac[3] by the action of sulphuric acid on chromic anhydride, were shown by J. Fritzsche, and P. Plantamour to be mechanical mixtures. J. Meyer and V. Stateczny found the f.p. of mixtures of chromic acid and water-free H_2SO_4 to be:

CrO_3 .	0	0·16	1·2	2·02	3·13	4·17	5·37	8·66 per cent.
F.p. .	10·45°	10·2°	8·6°	5·8°	7·6°	8·8°	9·6°	9·8°

The eutectic at 5·5° corresponds with 2·2 per cent. CrO_3. A. W. Rakowsky and D. N. Tarassenkoff found that the compound decomposes at ordinary temp. with a marked change of colour when the humidity exceeds 1·7 per cent. W. Ipatieff and A. Kisseleff obtained **potassium trisulphatodichromate,** $2KCrO_4.Cr_2(SO_4)_3.H_2O$, by the action of hydrogen under press. on a soln. of potassium dichromate (*q.v.*). P. A. Bolley added chromium trioxide to conc. sulphuric acid, until no more dissolved, the resulting dark brown oil forms a pale brown, granular mass in a few days. A. Schrötter obtained a yellowish-brown substance to which he gave the formula $CrO_3.3SO_3$; and A. Pictet and G. Karl heated a mixture of sulphur and chromium trioxides in a sealed tube and obtained a yellowish-brown mass of $CrO_3.SO_3$, sometimes regarded as **chromyl sulphate,** $CrO_2(SO_4)$. The products are unstable in air, and liberate chromium trioxide by the action of moisture. The observations of L. F. Gilbert and co-workers, and A. W. Rakowsky and D. N. Tarassenkoff on the solubility of chromium trioxide in soln. of sulphur trioxide at 25° and 45° were discussed in connection with chromium trioxide. The results of L. F. Gilbert and co-workers are shown graphically in Fig. 80, for the ternary system: CrO_3–SO_3–H_2O at 25°. There are three solid phases CrO_3; $CrO_3.SO_3$; and what is thought to be the *monohydrate*, $CrO_3.SO_3.H_2O$. Chromyl sulphate is usually brown and minutely crystalline, and sometimes amorphous; the hydrate is also amorphous. Both compounds are very hygroscopic, and liberate scarlet chromium trioxide on exposure to air.

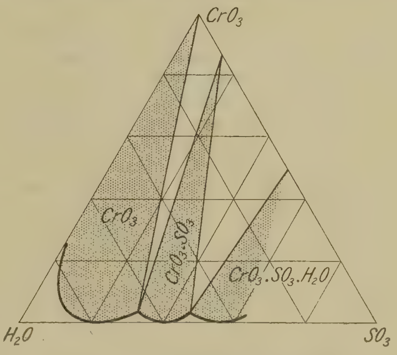


FIG. 80.—The Ternary System: CrO_3–SO_3–H_2O at 25°.

J. Meyer and V. Stateczny said that the orange precipitate which gradually forms from soln. of chromium trioxide in 95 to 100 per cent. H_2SO_4 is **chromatosulphuric acid,** H_2CrSO_7, or $H_2[CrO_3(SO_4)]$, and that it appears as a dark orange powder which reacts very energetically with water to form a brick-red soln. of chromic and sulphuric acids. The acid can be preserved over phosphorus pentoxide, or in a sealed tube. It is decomposed in light. It is insoluble in carbon disulphide and similar liquids; it is gradually reduced by ether, ligroin, and benzene. It darkens in colour when heated, it sinters at 168°–170°, and at 190° forms a blood-red liquid and then decomposes with the evolution of oxygen. It is a powerful oxidizing agent—a drop of alcohol is inflamed by the acid; and it forms chromic oxide with the evolution of sulphur dioxide when treated with aldehyde. Naphthalene, and phenol are carbonized; anthracene yields acetic acid; and a mixture of sugar and potassium chlorate is exploded by the acid. It does not form salts by direct neutralization. H. Schiff prepared **potassium chromatosulphate,** K_2CrSO_7, or $K_2[CrO_3(SO_4)]$, by melting potassium sulphate or hydrosulphate with potassium chlorochromate; and J. Meyer and V. Stateczny, by the reaction $K_2Cr_2O_7+2KHSO_4=H_2O+2K_2CrSO_7$. They also prepared **ammonium chromatosulphate,** $(NH_4)_2[CrO_3(SO_4)]$, and **sodium chromatosulphate,** $Na_2[CrO_3(SO_4)]$, in a similar manner. By heating a mixture of barium chromate and sulphur trioxide in a sealed tube for 3 hrs. at 120°, **barium chromatosulphate,** $Ba[CrO_3(SO_4)]$, was obtained; and **strontium chromatosulphate,** $Sr[CrO_3(SO_4)]$, by heating to 160° for 3 hrs. a mixture of strontium sulphate and chromium trioxide; and similarly with **calcium chromatosulphate,** $Ca[CrO_3(SO_4)]$. B. Cabrera and S. P. de Rubies studied the magnetic properties of the products formed by the addition of sulphuric acid to the oxychromic salts.

§ 30. The Complex Salts of Chromic Sulphates

The most important complex sulphates are the chrome-alums in which tervalent chromium replaces aluminium in the ordinary alums, so that the general formula for the series is $R'_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $R'Cr(SO_4)_2.12H_2O$. A. Mitscherlich[1] prepared **ammonium chromium sulphate,** or **ammonium disulphatochromiate,** $(NH_4)_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $(NH_4)Cr(SO_4)_2.12H_2O$, by mixing a sulphuric acid soln. of violet chromic sulphate with ammonia; A. Schrötter, by adding ammonium sulphate to a conc. soln. of violet chromic sulphate when crystals of the ammonium chrome-alum are precipitated, and J. L. Howe and E. A. O'Neal, by the electrolysis of a soln. of ammonium chromate in sulphuric acid—this salt collects at the negative pole. J. Hertkorn prepared it as in the case of the potassium salt—*vide infra.* A. Mitscherlich found that the crystals are regular octahedra, with surfaces of cubes and dodecahedra. The cleavage on the octahedral face is indistinct. T. Klobb prepared solid soln. of ammonium chromic alum with ammonium ferric and with ammonium aluminium alums. W. Haidinger found the crystals to be violet-blue passing into columbine-red; and, added A. Schrötter, they are ruby-red by transmitted light. They are moderately transparent, and have a sweetish saline taste. A. Schrötter gave 1·736 for the sp. gr. at 21°; O. Pettersson, 1·728 at 20°; and J. H. Gladstone, 1·719. G. T. Gerlach found the sp. gr. of violet soln. containing 2·195, 4·390, and 6·585 per cent. $(NH_4)Cr(SO_4)_2$ are respectively 1·0200, 1·0405, and 1·0610 at 15°/15°; and with green soln. at 15°/15°,

$(NH_4)Cr(SO_4)_2$	5·487	10·974	16·461	27·435	38·409	49·383 per cent.
Sp. gr. . .	1·044	1·091	1·142	1·255	1·384	1·532

The sp. gr. of the sat. violet soln. is 1·070 at 15°/15°. P. A. Favre and C. A. Valson studied the change in vol. which occurs when this alum passes into soln. H. C. Jones and E. Mackay found the lowerings of the f.p. produced by ammonium chrome alum for 0·097, 0·0484, and 0·0291 per cent. soln. are, respectively, 7·92, 8·26, and 9·14, and these values are about 0·8 less than the sum of the values of the constituents. This means that the f.p. of the soln. confirm the evidence from the conductivity data, that alum molecules exist to some extent in the more conc. soln. According to A. Schrötter, the salt effloresces superficially in air, and becomes covered with a pearl-grey powder. The m.p. is 100°. J. Locke gave 94° for the m.p. A. Schrötter observed that three-fourths of the water of crystallization is evolved when the salt melts, and the liquid shows no signs of dichroism; it solidifies to a pale green mass which gives off its remaining water above 300°. G. D. van Cleeff said that half its combined water is lost over sulphuric acid, and at 100°, five-sixths is given off. F. Ephraim and P. Wagner found that the vap. press., p mm., of the salt is:

	50°	60·5°	72°	80°	80·5°	86°
p . .	40	80	162	244	260	326 mm.

H. C. Jones and E. Mackay found that the f.p. of soln. with 92·740, 27·822, and 5·564 grms. of $(NH_4)Cr(SO_4)_2.12H_2O$ per litre are, respectively, 0·768°, —0·266°, and —0·064°. P. A. Favre and C. A. Valson gave for the heat of soln. of a mol of the sulphate —9·628 Cals. at 8° to 10°; and —9·889 Cals. at 19° to 21°. They also found for the heat of precipitation of a fresh violet soln. of a mol of ammonium chrome-alum, 14·636 Cals., and after the lapse of 14 days, 13·9 Cals. The corresponding value for a green soln. is 7·641 Cals. C. Soret gave for the index of refraction, μ, between 7° and 14°, for light of different wave-lengths, λ,

λ .	*G*-line	*F*-line	*B*-line	*E*-line	*D*-line	*C*-line	*B*-line	*A*-line
μ .	1·49594	1·49040	1·48794	1·48744	1·48418	1·48125	1·48014	1·47911

J. H. Gladstone gave $(\mu-1)/D=0·2781$ for the sp. refraction for the A-line; and $(\mu_A-\mu_G)/D=0·0104$ for the sp. dispersion. J. M. Hiebendaal, and H. Sauer studied the absorption spectrum of ammonium chrome-alum.

H. C. Jones and E. Mackay measured the mol. electrical conductivity, μ mhos, of the violet soln.; and H. H. Hosford and H. C. Jones gave for soln. with a mol of the violet salt in v litres between 0° and 35°, and S. F. Howard and H. C. Jones, between 35° and 65°,

v		8	16	32	128	512	1024	2048	4096
μ	0°	82·4	94·6	107·1	137·6	176·0	198·8	—	259·0
	12·5°	113·1	181·0	149·1	194·5	253·0	289·3	—	378·0
	25°	145·9	169·6	193·8	255·7	341·2	395·3	—	523·5
	35°	169·8	197·9	228·6	302·7	410·2	483·1	577·4	671·2
	65°	245·0	288·8	333·5	459·1	649·0	754·8	897·3	1050·3
α	35°	25·3	29·5	34·1	45·1	61·1	72·0	86·0	100·0
	65°	23·3	27·5	31·7	43·7	61·8	71·9	85·4	100·0

The values at the higher temp. are of course affected by the presence of x per cent. of the green salt. α refers to the calculated percentage ionization. The corresponding values for green soln. were:

v		8	16	32	128	512	1024	2048	4096
μ	0°	103·6	119·7	136·4	172·3	202·6	215·6	222·0	234·4
	12·5°	133·2	155·4	178·2	228·4	274·4	294·2	313·5	328·4
	25°	162·9	190·6	220·8	288·1	355·7	386·2	414·0	458·1
	35°	194·0	229·8	268·0	355·6	446·1	492·2	537·1	589·8
	65°	250·7	299·6	352·2	489·8	673·8	789·6	924·3	1061·7
α	35°	32·9	39·0	45·4	60·3	75·6	83·4	91·1	100·0
	65°	23·6	28·3	33·2	46·1	63·5	74·4	87·1	100·0

According to A. Schrötter, ammonium chrome-alum dissolves in cold water forming a bluish-violet soln. Alcohol precipitates the alum from its violet soln. At about 75° or 80°, the bluish-violet aq. soln. assumes a grass-green colour owing to some molecular change, so that the soln. on evaporation does not yield crystals, but dries to a green mass; nor does the green soln. give a precipitate with alcohol, but it either mixes with it, or forms a substratum with the alcohol floating on the surface. If the green soln. is diluted with water, and left to stand for ten days, the violet alum is gradually reproduced. When a soln. of the violet alum is mixed with an excess of sulphuric acid, then treated with alcohol, the green soln. decanted from the precipitated blue salt, and mixed with so much ammonia that it still remains slightly acid, a dark green, highly acid soln. settles to the bottom. When this soln. is allowed to stand for a long time, it decolorizes, and a light green salt is deposited. It has the composition $14(NH_4)_2SO_4.Cr_2(SO_4)_3.3H_2SO_4.33H_2O$. J. Locke found that at 25° a litre of water dissolves 212·1 grms. of $(NH_4)Cr(SO_4)_2.12H_2O$, or 107·8 grms., *i.e.* 9·75 per cent. of $(NH_4)Cr(SO_4)_2$. As in the case of the chromium salts previously discussed, the soln. of the violet salt in water involves a state of equilibrium between the green and the violet forms, and this is dependent on the temp. The time required for equilibrium is represented by the following observations of I. Koppel on the solubilities, S grams of $(NH_4)Cr(SO_4)_2$ per 100 grms. of soln., after the lapse of the stated intervals of time:

Time		2·5	20	50	100	200	300	400	∞ hrs.
S	0°	3·82	3·68	3·73	—	—	—	—	3·77
	30°	10·6	11·9	13·12	16·25	15·2	15·7	16·0	16·00
	40°	15·5	19·3	21·6	22·8	24·5	—	24·8	24·70

He inferred from conductivity and f.p. determinations that at 0° a sat. soln. of the violet alum has 3·8 per cent. of $(NH_4)Cr(SO_4)_2$; and at 40°, after the elapse of 20 days the same soln. is in equilibrium when about 52 per cent. of the solute is in the violet form and 48 per cent. in the green form; while at 55°, equilibrium occurs when 39 per cent. of violet alum and 61 per cent. of green alum are present. Similar data were obtained with conc. soln. The calculations assume that only one variety of the green salt is produced.

Anhydrous or dehydrated ammonium chrome-alum was obtained by M. Traube by melting chromic oxide or a chromic salt with an excess of ammonium sulphate. It was also prepared by T. Klobb—*vide infra,* the ammonium trisulphatochromiate. The salt appears in hexagonal plates, or as a pale green powder which, according to P. A. Favre and C. A. Valson, had a sp. gr. of 2·472 at 21·9°. M. Traube found that the salt does not melt nor yet decompose at 350°. It reddens when heated. It is insoluble in cold water; and it is not attacked by boiling water, dil. boiling alkali-lye, or acids, or by conc. hydrochloric acid. T. Klobb said that it is isomorphous with the dehydrated potash-alum and soda-alums and with the corresponding aluminium and ferric salts. A. Recoura obtained what he regarded as a pentahydrate, by dehydrating ammonium chrome-alum.

W. Meyeringh obtained **hydroxylamine chromium sulphate,** or **hydroxylamine disulphatochromiate,** $(NH_3OH)_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $(NH_3OH)Cr(SO_4)_2.12H_2O$, in cubic crystals, from a soln. of the component salts. H. Sauer studied the absorption spectrum of this salt and of the methylamine. F. Sommer and K. Weise prepared **hydrazine chromium sulphate,** or **hydrazinium disulphatochromiate,** $(N_2H_5)Cr(SO_4)_2.12H_2O$, which furnishes dark violet octahedral crystals, freely soluble in water. G. Canneri prepared **guanidine disulphatochromiate,** $(C_6H_5N_3)_2.H_2SO_4.Cr_2(SO_4)_3.12H_2O$; it is isomorphous with the corresponding sulphatodialuminate.

A. Schrötter prepared **sodium chromium sulphate,** or **sodium disulphatochromiate,** $Na_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $NaCr(SO_4)_2.12H_2O$, by gradually mixing a mol of sodium dichromate with 3 mols of conc. sulphuric acid so as to avoid much heating; adding alcohol, and then allowing the soln. to stand. Definite crystals were not obtained. E. I. Orloff prepared the salt in crystals by the following process:

> Add 100 grms. of xylene, in small portions at a time and with constant stirring, to a sealed flask containing 300 grms. of sulphuric acid of sp. gr. 1·84; when the xylene has dissolved, add 295 grms. more of the acid, and pour the mixture into a large porcelain dish containing a litre of water, and add 375 grms. of finely powdered sodium dichromate in small portions at a time. The reduction takes place in the cold, and it is completed by warming the liquid which then turns green. The soln. is then evaporated to 1339 grms., and the product poured into flat porcelain dishes, covered, and left to crystallize at room temp. The small crystals can be recrystallized from water by slowly evaporating sat. soln.

A. Schrötter found that the salt loses 16 mols. of water at 100°; and it weathers more rapidly in air than the ammonium or potassium salt. F. Ephraim and P. Wagner found the vap. press., p mm., of the hydrate to be:

	51°	63°	71°	76°	80°	82·5°	90°
p . .	43	83	122	162	241	250	382 mm.

T. Klobb obtained mixed crystals of the anhydrous sodium and ammonium chromium sulphates, $(NH_4,Na)SO_4.Cr_2(SO_4)_3$, by melting together chromic sulphate or chrome-alum with ammonium and sodium sulphates. The hexagonal crystals are isomorphous with the anhydrous alums. A. N. Bach found the transition temp. to be between 60° and 70°.

Crystals of potassium chrome-alum, **potassium chromium sulphate,** or **potassium disulphatochromiate,** $K_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $KCr(SO_4)_2.12H_2O$, were first obtained by A. Mussin-Puschkin; and J. J. Berzelius obtained the violet crystals by the spontaneous evaporation of a soln. of a mixture of the component salts. A. Schrötter, and F. A. Rohrman and N. W. Taylor obtained it by sat. with sulphur dioxide a sat. soln. of potassium dichromate and conc. sulphuric acid prepared in the cold; N. W. Fischer, M. Traube, and H. Löwel used a modification of the process with alcohol as reducing agent; A. Lielegg used oxalic acid as reducing agent, and, added E. A. Werner, if too little water be present, a complex oxalate is formed. G. Städeler obtained chrome-alum as a by-product in the preparation of acetaldehyde. The manufacture of chrome-alum was described by P. Hasenclever, etc.—*vide supra,* the extraction of chromium. J. Hertkorn obtained it by treating a soln. of chromic sulphate in water or sulphuric acid with potassium sulphite or hydrosulphite—with or without the addition of a little nitrate or nitrite, and then subjecting it to the action of sulphur dioxide under ordinary and an increased press. H. C. Starck described the preparation of a soln. from ferrochromium, where the sulphuric acid soln. of the alloy is treated with potassium dichromate, heated to the b.p. at atm. press., preferably with the addition of sodium carbonate, or at a higher press. The iron compounds are thus precipitated, and the filtered soln. is treated with potassium sulphate for chrome alum. Processes were also described by A. W. Gregory, and O. Nydegger. H. Chaumat prepared the salt by the electrolysis of a soln. of potassium dichromate mixed with sulphuric acid. The liquor is circulated in the cathode compartment, which is separated from the anode by a porous vessel, the cathode preferably consisting of graphite powder packed round a carbon core. Dil. sulphuric acid is circulated in the anode compartment, and to utilize the SO_3-ion, which is disengaged at the anode, the latter may take the form of a copper electrode surrounded by copper shavings, whereby copper sulphate is formed in the course of electrolysis. A. Stiassny, H. N. Warren, F. A. Rohrman and N. W. Taylor, and A. Polis discussed the formation of large crystals of the salt. E. S. Hedges and J. E. Myers studied the periodic crystallization of this salt. Analyses were made by N. W. Fischer, and P. de Boissieu. E. J. Maumené found that the analyses indicated between 23·9 and 24·1 mols. of water, and V. A. Jacquelain, 22 mols.—but this number probably refers to the partly effloresced salt. T. Ishikawa studied the reciprocal salt pair $\{K_2,(NH_4)_2\}-\{(SO_4),(CrO_4)\}$ at 25° ; and A. Fock, and G. Tammann and A. Sworykin, isomorphous mixtures with potash-alum. R. Hollmann's observations on the composition of the solid soln. and mother-liquor for potassium chromium and potassium aluminium alums are summarized in Fig. 81, and his observations on the vap. press. of the solid soln. in Fig. 82. There are two minima, and one maximum in the curve.

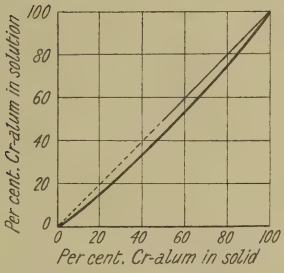

FIG. 81.—Composition of Solution and Solid Mixtures of Potassium Chromium and Potassium Aluminium Alums.

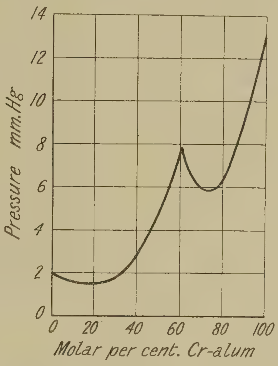

FIG. 82.—Vapour Pressures of Mixtures of Potassium Chromium in Potassium Aluminium Alums.

The octahedral, cubic crystals are violet to black in colour, and appear ruby-red in thin layers ; and J. H. Kastle found that the intensity of the colour is very much reduced at liquid air temp. F. Klocke, C. F. Rammelsberg, C. von Hauer, and J. W. Retgers showed that the crystals are isomorphous with other alums, for they show similar corrosion figures. E. Dittler obtained overgrowth with potassium aluminium sulphate. T. V. Barker found a close connection between parallel overgrowths in chrome-alum, potash-alum, and ammonia-alum and the mol. vols which are respectively 542·2, 541·6, and 552·2. C. von Hauer found that with the introduction of a crystal of iron-alum in a sat. soln. of chrome-alum nearly all the latter separates out ; while L. de Boisbaudran found that a sat. soln. of basic ammonium aluminium alum does not affect the octahedral faces of the crystal, but the cubic faces are slowly attacked. K. Grinakowsky found that different faces of the crystal do not all possess the same solubilities, and that the degree of supersaturation has different values for the different faces of the polyhedron, and is dependent on the temp. At low temp., the edges and angles are the less soluble; and at high temp., the faces; the edges of obtuse angles are more stable than the summits of four-faced angles at low temp., whilst at high temp. the reverse applies. P. N. Pawloff's statement, that the surface layer of a crystalline substance is vectorial in character and influences the direction and general course of the deformation, applies to some extent, especially in the case of twinning deformation. The latter indicates the existence of a temperature-limit for a possible equilibrium of the system crystal-mother liquor, the surface energy being, for a given crystallographic form, a maximum. The direction and course of the deformation of crystals of chrome-alum show that the octahedron is the most stable form, and is followed in order by the rhombic dodecahedron, cube, and trapezohedron. The crystals were studied by E. S. von Fedoroff.

L. Vegard and H. Schjelderup obtained X-radiograms of the alums, and deduced probable arrangements for the metal, sulphur, and oxygen atoms in the space-lattice. They added that the crystal model divides the 24 mols. of water into six groups, which groups are cubically disposed with reference to the four tetrahedrally arranged atoms of sulphur. The model makes no distinction between the water of crystallization and the other constituents of the alum. Any hypothesis which would distinguish the water of crystallization from water of constitution could not be reconciled with the observed relations between the high-frequency reflection spectra. The removal of the water of crystallization is necessarily accompanied by the destruction of that structure which is characteristic of the hydrated salt. The unit hexagonal cells of the anhydrous salt furnished $a=4{\cdot}737$ A., and $c=8{\cdot}030$ A., and each unit cell contains one mol. of $KCr(SO_4)_2$. J. M. Cork found that the unit cubic cell has $a=12{\cdot}20$ A., and that there are four mols. per cell. The eight metal atoms take positions at the corners, centre, centre of faces, and mid-points of the edges of the cell making a rock salt arrangement of the univalent and tervalent metals. C. Schaefer and M. Schubert, L. Vegard and E. Esp, L. Vegard and A. Maurstad, and L. Vegard discussed this subject.

H. Schiff found the sp. gr. to be 1·845; L. Playfair and J. P. Joule, 1·856; H. Kopp, 1·848; J. Dewar, 1·834 at −188°, and 1·82 at 17°; O. Pettersson, 1·842 at 20·8°; J. H. Gladstone, 1·817; while W. Spring gave

	0°	10°	20°	30°	40°	50°	60°
Sp. gr. .	1·8308	1·8282	1·8278	1·8274	1·8269	1·8259	1·8202

According to E. Moles and M. Crespi, the sp. gr. and mol. vol., at 25°/4°, of $KCr(SO_4)_2$ are 2·548 and 111 respectively; of $KCr(SO_4)_2.H_2O$, respectively 2·482 and 120; of $K[Cr(H_2O)_6](SO_4)_2$, respectively 2·17 and 180; and of $K[Cr(H_2O)_6](SO_4)_2.6H_2O$, 1·834 and 272. B. Franz found the sp. gr. of soln. with the following number of grams of $KCr(SO_4)_2.12H_2O$ per 100 grms. of soln., to be at 17·5°,

Salt .	5	10	20	30	40	50	60	70 per cent.
Sp. gr. .	1·0174	1·0342	1·0746	1·1274	1·1896	1·2894	1·4566	1·6362

while G. T. Gerlach gave for violet soln. with 2·84, 5·68, and 8·52 per cent. of the anhydrous salt, respectively 1·0275, 1·055, and 1·0835 at 15°/15°; and for the green soln.:

$KCr(SO_4)_2$	5·68	11·36	17·03	22·71	28·39	34·07	39·74	45·42	51·10
Sp. gr. .	1·050	1·103	1·161	1·225	1·295	1·371	1·453	1·451	1·635

so that the sp. gr. of the violet soln. is greater than is the case with the green soln. M. A. Rakuzin and co-workers found that a sat. soln. of the green alum has 114·19 parts of salt per 100 parts of water at 20°, and the sp. gr. of the sat. soln. is 1·6683. For a concentration C per cent.,

C	5	10	20	40	60	80	100	114·19 per cent.
Sp. gr.	1·0378	1·0641	1·1076	1·1623	1·2531	1·3524	1·4404	1·6683

The sp. gr. of the soln. does not increase proportionally with concentration, and soln. of the same conc. made with different samples of alum have different sp. gr. This is attributed to differences in the relative proportions of the green and violet salts in the different soln. K. Grinakowsky found a transition temp. at 78°; and C. Montemartini and L. Losana, at 77°. P. A. Favre and C. A. Valson, and G. Beck studied the vol. changes which occur when the alum dissolves. J. Beckenkamp found the elastic modulus of the crystals perpendicular to the cubic surface to be 1608 kgrms. per sq. mm.; perpendicular to the dodecahedral surface, 1771 kgrms. per sq. mm.; and perpendicular to the octahedral surface, 1832 kgrms. per sq. mm. A. Ferrero observed that for a 13·75 per cent. soln., at 20·5°, the viscosity is 0·01261 G.G.S. units for the violet soln., and 0·1185 for the green soln. prepared at 80°; similarly for a 20·5 per cent. soln. at 20·5°, 0·01417 for the violet soln. and 0·01294 for the green soln. prepared at 80°. The difference between the green and violet soln. decreases with increasing dilution. R. F. d'Arcy made observations on this subject. F. Rüdorff found that in dil. soln., the potassium sulphate diffuses more rapidly than the chromium sulphate; and D. M. Torrance and N. Knight, G. D. van Cleeff, and M. E. Dougal observed that in the dialysis of the green soln., more sulphuric acid passes through the membrane than is the case with the violet soln. C. Montemartini and L. Losana studied the viscosity of the soln. P. W. Bridgman gave for the compressibility of chrome-alum at 30°, $-\delta v/v_0=64{\cdot}86\times10^{-7}p-112{\cdot}5\times10^{-12}p^2$.

W. Spring gave for the thermal expansion the linear coeff. $0{\cdot}0_4246$ between 0° and 60°. H. Kopp found the sp. ht. to be 0·324. A. Eucken and G. Kuhn found the sp. ht. at −190° to be 0·00242, and the value at 0°, 0·00426. According to C. Pape, the crystals are stable in air; but uninjured crystals effloresce at 29°. N. W. Fischer added that when the salt is impure it will effloresce on the surface when exposed to air, and, if chromic sulphate be in excess, it will assume a green colour, and a violet colour if the potassium sulphate predominates. G. D. van Cleeff, and J. Juttke observed that the salt loses 12 to 13 mols. of water when confined over sulphuric acid, in vacuo; and H. Löwel added that a similar amount is lost over quicklime, or conc. sulphuric acid, at 25° to 30°, and no more is lost by the granular mass at 80° to 90°; at 100° or over, it loses more water and becomes green. J. Juttke observed that all the water can be expelled at 100° without the alum becoming insoluble or decomposing; and G. D. van Cleeff observed a loss of 21 mols. of water at 110°. W. Müller-Erzbach found that at 0·49 mm. press. and 27·8°, half the water of crystallization is given off, and the residue when kept 7 days at 30° loses very little more water. For the dissociation press., p mm. in the reaction: $KCr(SO_4)_2.12H_2O \rightleftharpoons KCr(SO_4)_2.6H_2O+6H_2O$, H. Lescœur and D. Mathurin observed p=3·7 at 10°; 6·0 at 15°; 9·1 at 20°; 12·3 at 25°; 16·7 at 30°; and 23·8 at 35°; while F. Ephraim and P. Wagner gave

	31°	40°	50°	55°	60°	70°	73°	77·5°	79°
p	15	31	63	86	119	202	224	250	260

R. Hollmann gave p=13·2 mm. at 17° to 19°; and he also obtained values for solid soln. of the chromium and aluminium alums. H. Lescœur and D. Mathurin found that over conc. sulphuric acid the alum loses half its water of crystallization and passes into a lilac-coloured powder which does not lose its colour at 75°. At 20°, the dissociation press., p mm. of the moist alum, $KCr(SO_4)_2 : nH_2O$, is 15·25 mm. for n=13·05, and 15·0 for n=12·3; for n=12·1, p=9·8, and the violet powder produced when n=11·8, has p=9·1. This value of p remains approximately constant up to n=6·01. When n=5·72, a lilac powder is formed with p=3·2, and for n=5·4, p=3·2. When n=3·92, p is less than 1·5; and when n=2·35, p is less than 1·0. The n=6-hydrate was found by A. Recoura to lose no water between 80° and 90°, but at 110° it gives off 4 mols. and becomes green. A. Beutel found that the velocity with which water is expelled is accelerated by exposing the crystals to visible and ultra-violet light. Observations on the dissociation of the alums were also made by E. J. Maumené, and P. de Boissieu. When the salt is heated to 200°, N. W. Fischer, and C. Hertwig found that 22 mols. of water are given off, and the remainder between 300° and 400°. E. Moles and M. Crespi found that the salt $K[Cr(H_2O)_6](SO_4)_2.6H_2O$ loses about 5·9 mols. of water at 18°, and at 60°; while $K[Cr(H_2O)_6](SO_4)_2$ loses 5·30 mols. of water at 140°; and $KCr(SO_4)_2.H_2O$ loses 0·9 mol. at 350°. According to H. Löwel, when the salt is gradually heated between 300° and 350° it furnishes the anhydrous soluble salt; but over 350°, without losing much weight, it forms the yellowish-green insoluble salt. F. Krauss and co-workers' observations on the effect of heat on potash-chrome-alum can be represented by Fig. 83. The anhydrous salt begins to lose sulphur trioxide at 612°.

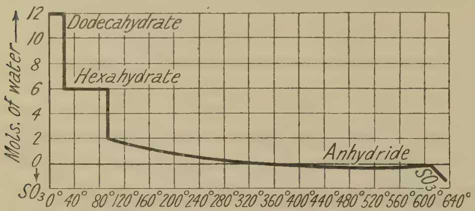

FIG. 83.—The Action of Heat on Potassium Chrome-alum.

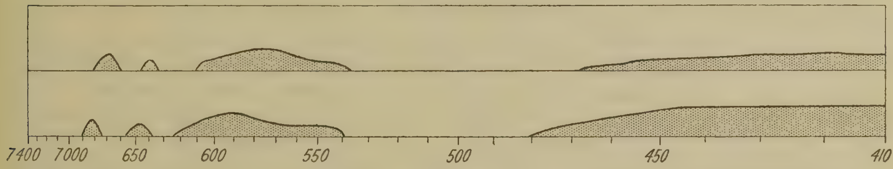
The salt melts in its water of crystallization at 80° to 90°. W. A. Tilden, and J. Locke gave 89° for the m.p. H. C. Jones and E. Mackay found for the f.p. of soln. of 117·44, 29·36, and 5·872 grms. of $KCr(SO_4)_2.12H_2O$ in a litre of water, the respective values —0·888°, —0·267°, and —0·065°.

J. Thomsen found the heat of soln. for a mol of $KCr(SO_4)_2.12H_2O$ to be —9·564 Cals. at 8° to 11°; and P. A. Favre and C. A. Valson, —9·651 Cals. at 8° to 11°; and —9·499 Cals. at 19° to 21°. Conc. soln. were found to give almost the same numbers, but the partially dehydrated salt gave 3·825 Cals. H. Löwel, and W. R. Whitney found that barium chloride precipitates all the sulphate from the violet soln. in the cold; and P. A. Favre and C. A. Valson observed that for a mol of $KCr(SO_4)_2$, the heat of precipitation is 14·767 Cals. The heat required for precipitation of the first half of the SO_4 is 7·514 Cals., and for the second half, 7·388 Cals.; similarly, for successive quarters, the heats of precipitation are respectively 3·680, 3·702, 3·665, and 3·699 Cals. P. A. Favre and C. A. Valson, and W. R. Whitney found that only half the sulphate is precipitated at once from the green, modified soln. The total heat of precipitation was found by P. A. Favre and C. A. Valson to be 8·251 Cals. per mol of $KCr(SO_4)_2$, and for the first and second halves 8·142 Cals and 0·204 Cals. respectively; while for the first, second, and third quarters, the values were 4·104 Cals., 4·102 Cals., and 0·146 Cal. respectively. The heat of precipitation for $\frac{1}{2}K_2SO_4$ is 3·3 Cals.; for $\frac{1}{2}Cr_2(SO_4)_3$, 4·9 Cals.; and for $\frac{1}{2}H_2SO_4$, 5·053 Cals. This shows that only half the contained sulphate is precipitable at once by barium chloride from a freshly prepared soln. of the salt.

C. Soret observed that the index of refraction, μ, at 0° to 17°, for light of different wave-lengths, λ, is:

λ .	*G*-line	*F*-line	*b*-line	*E*-line	*D*-line	*C*-line	*B*-line	*A*-line
μ .	1·49309	1·48753	1·48513	1·48459	1·48137	1·47805	1·47738	1·47642

C. Soret and co-workers found that refractive indices of the green soln. to be less than those of violet soln. J. H. Gladstone gave for the sp. refraction for the *A*-line, $(\mu-1)/D$=0·2616; and for the sp. dispersion $(\mu_A-\mu_G)/D$=0·0098. J. Formanek observed that the absorption spectrum of the violet soln., Fig. 84, has a weak band at 671·8, and a stronger one between 610 and 540 with a maximum at 578; at 470, the absorption of short waves begins; J. M. Hiebendaal observed a weak band at 658, and a stronger one between 590 and 535; A. Étard found bands between 678 and 670, and between 654 and 633. O. Knoblauch observed a band between 610 and 558; and W. Böhlendorff, strips at 672, and 640, and a band between 609 and 568. Observations were also made by W. N. Hartley, H. Sauer, G. D. Liveing and J. Dewar, and K. Vierordt. H. W. Vogel found with a violet soln., a strong line at 665, a feebler one at 656, and a broad band with a maximum at 589, and an absorption in the violet begins at 489. The solid salt does not show the first line, and the band is more towards the red. J. Formanek found that the green soln. has a strip at 681, and a second one at 640 which is connected with a band extending as far as 540 with a maximum at 591. The absorption in the violet begins at 480, Fig. 85. J. M. Hiebandaal found with thick layers of soln. a band between 660 and 523, and an absorption beginning at 469; with thinner layers of soln., there are bands between 673 and 667, and between 632 and 544; while with still thinner layers, there is a band between 613 and 535. Observations were also made by W. N. Hartley, and W. Böhlendorff. H. W. Vogel found a small strip at 686, and a band between 656 and 530, while absorption begins at 486. The solid salt, and the alcoholic soln. have different spectra. H. C. Jones and W. W. Strong, K. Grinakowsky, and A. Byk and H. Jaffe studied the violet and ultra-violet spectra of the soln.; H. Sauer, the absorption spectrum. S. Higuchi, the ultra-red spectrum; and H. du Bois and G. J. Elias, the influence of magnetization and temp. on the spectra of the solid salts. H. M. Vernon estimated the ionization from the colour of aq. soln. M. Bamberger and R. Grengg found that the colour fades as the temp. approaches —190°. C. Doelter observed that radium radiations change the crystals into a pale violet powder.



Figs. 84 and 85.—Absorption Spectra of Solutions of Potassium Chrome-Alum.

H. C. Jones and E. Mackay, K. Grinakowsky, F. Schmidt, and F. S. Svenson measured the electrical conductivity, μ mhos, of soln. of the salt; H. H. Hosford and H. C. Jones obtained the accompanying values between 0° and 35°, and S. F. Howard and H. C. Jones between 35° and 65°, for violet soln. containing a mol of $KCr(SO_4)_2.12H_2O$ in v litres. The computed values for the percentage degree of ionization, α, are affected by the formation of x per cent. of the green salt.

v		8	16	32	128	512	1024	2048	4096
μ	0°	75·8	87·3	99·0	127·0	161·1	186·6	212·3	245·8
	12·5°	105·0	121·2	138·1	179·5	232·0	271·6	314·2	364·8

	65°	22·35	25·55	31·39	43·15	60·84	72·52	85·73	100·0

V. Monti found that the conductivity of the green soln. is greater than that of the violet soln. H. C. Jones and E. Mackay found that the change from violet to green corresponds with the change in the conductivity of the soln. H. H. Hosford and H. C. Jones, and S. F. Howard and H. C. Jones, obtained the following results for green soln. for the temp. indicated in connection with the violet soln. :

v		8	16	32	128	512	1024	2048	4096
μ	0°	107·4	126·8	146·5	188·9	224·2	244·4	—	290·2

	65°	24·39	27·47	34·67	47·78	68·76	75·90	88·81	100·0

H. T. S. Britton found that, at 18°, a 0·0050*N*- and 0·0067*N*-soln. of the violet and green salts have respectively an e.m.f. of 0·467 and 0·395 volt against a *N*-calomel electrode ; the $H^{\cdot}$-ion concentrations are $p_H=3·19$ and 1·94 ; and the percentage hydrolysis is 2·16 and 28·7. In the electrometric titration with sodium hydroxide, precipitation began with the e.m.f. respectively 0·591 and 0·587 volt, when the $H^{\cdot}$-ion conc. was $p_H=5·30$ and 5·27 ; or when 1·00 and 1·21 eq. of alkali per eq. Cr had been added ; and precipitation was complete when 2·75 and 2·71 eq. of alkali had been added. F. L. S. Jones studied the formation of complex anions in soln.—*vide supra*, chromic sulphate. According to N. Demassieux and J. Heyrovsky, the polarization curves obtained in the electrolysis of tervalent chromium soln. show inflexions corresponding with either $Cr^{\cdots}\rightarrow Cr^{\cdot\cdot}+\oplus$ or $Cr^{\cdots}\rightarrow Cr+3\oplus$. The curves show that the less hydrated chromium ions in the green salts are reduced and discharged at potentials which are more positive than those at which the more hydrated chromium ions in the violet salts become reduced. This is true of the chloride and sulphate soln., although with the latter the abnormally great displacements of the potentials at which reduction occurs indicate that the complexity of the ions varies with dilution in passing from the green to the violet form. The potentials at which reduction occurs in potassium and rubidium chrome alum soln. are coincident, and indicate the progressive dissociation of the anion complexes. No reduction occurs in alkaline chromium hydroxide soln., which is regarded as proof of the colloidal nature of the hydroxide, in contrast with soln. of zincates and plumbites in which reduction has been observed.

C. Montemartini and L. Losana studied the e.m.f. of soln. of the salt. A. Hagenbach made observations on the thermoelectric force of the soln. E. Feytis found the magnetic susceptibility of the powdered salt to be $11·83\times10^{-6}$ mass units ; J. G. Königsberger found for the soln., 13×10^{-6} mass units at 22° ; and O. Liebknecht and A. P. Wills, 22×10^{-6} mass units at 18°. P. Pascal found the mol. magnetic susceptibility to be $2\times629\times10^{-5}$. L. A. Welo's measurements of the magnetic susceptibility of solid and molten alum are summarized in Fig. 86. The Curie point, $C=\chi(T-\theta)$, for the solid and molten potassium chromic alum are $C_s=2·02$, $C_l=1·67$; $\theta_s=-37°$; and $\theta_l=17°$.

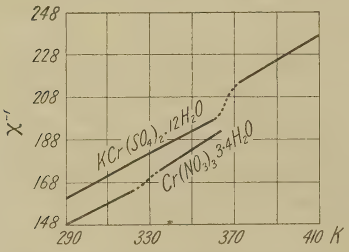

FIG. 86.—The Magnetic Susceptibilities of Hydrated Chromium Salts—Solid and Molten.

N. W. Fischer observed that 100 parts of cold water dissolve 16·7 parts of the chrome alum. J. Locke found that a litre of water dissolves 243·9 grms. of $KCr(SO_4)_2.12H_2O$, or 125·1 grms. of $KCr(SO_4)_2$. The aq. soln. of the violet salt has an acidic reaction, and when the salt has been precipitated many times by alcohol from its aq. soln. H. Baubigny and E. Péchard found that a soln. neutralized by ammonia with methyl-orange as indicator, gave crystals which had an acidic reaction ; and the soln. also reacts acidic after standing a little while. F. P. Venable and F. W. Miller also found that the green modified soln. is also acidic. A. and L. Lumière and A. Seyewetz found that a considerable quantity of alkali-lye can be added to the violet soln. without giving a precipitate ; a soln. of 100 grms. of the alum will take up alkali-lye eq. to 8·435 grms. of H_2SO_4, at ordinary temp. or at 50°, before it yields a permanent turbidity ; at 100°, alkali-lye eq. to 12·8 grms. of H_2SO_4 is similarly taken up. F. Ulffers observed that a cold, conc., aq. soln. of the alum takes up nearly a mol of alkali per gram-atom of chromium, and at the same time the soln. becomes green. According to E. J. Mills and R. L. Barr, a turbidity appears in a soln. of chrome-alum when 2 mols of Na_2CO_3 per mol of $Cr_2(SO_4)_3$ have been added ; and L. Meunier and P. Caste found that chrome alum soln. undergo hydrolysis and the basic chromic salts so formed polymerize under the action of heat and more slowly on keeping. The neutralization of the sulphuric acid formed by the hydrolysis by the sodium carbonate, is accompanied by the liberation of carbon dioxide, and this is expelled from the soln. by increase of temp. or agitation. The precipitation is due to the sodium carbonate acting as a neutralizing agent and also as a coagulating agent on the colloidal soln. of the chromium hydroxide or the polymerized basic chromium salts. For W. J. Chater and J. S. Mudd's observations on the $H^{\cdot}$-ion conc., *vide supra,* chromium sulphate. The electrometric titration curves of H. T. S. Britton for violet and green soln. of chrome-alum are shown in Fig. 79. N. W. Fischer observed that by the spontaneous evaporation, of the violet soln., the salt may be recovered unchanged ; if the soln. be heated between 50° and 75°, it becomes green, and furnishes, on evaporation, a green soluble, amorphous mass or else it yields crystals of potassium sulphate leaving green chromic sulphate in soln. ; but H. Löwel added that the chromic sulphate hinders the crystallization of the potassium sulphate. H. Löwel also observed that if the chrome-alum in a sealed tube be melted in its water of crystallization, and cooled to —20°, there remains a viscid liquid, which, when evaporated at 25° to 30°, loses about 18 mols. of water ; if allowed to stand 2 or 3 weeks under a bell-jar over water, it takes up 15–20 per cent. of the original quantity. If a soln. of alum be dissolved in twice or thrice its weight of water, the green soln. very slowly deposits crystals of chrome-alum. D. Gernez observed that seeding the green liquid with crystals of alum favours the formation of crystals of chrome-alum. V. A. Jacquelain said that the re-formation of crystals of chrome-alum from the green soln. occurs at 2° ; and H. Löwel, at 20° to 30°. H. Löwel also found that if chrome-alum be melted in a sealed tube, or if a soln. of chrome-alum in one or two parts of water be boiled in a flask which is closed while the soln. is boiling, no crystallization occurs even if the vessels be shaken after standing for a year ; but the crystallization of the undercooled or supersaturated liquid starts immediately the vessel is opened.

L. de Boisbaudran observed that the violet soln. prepared in the cold gradually becomes greener ; while the green soln. prepared by heat, slowly becomes blue. In the former case, the soln. increases in vol. owing to the salt giving up combined water ; and in the latter case the soln. decreases in vol. owing to the salt taking up water. K. Grinakowsky said that the absorption spectra, and the electrical conductivities of the soln. indicated that 78° is the transition temp. for the violet to the green soln. The transformation has been discussed by G. D. van Cleeff, M. E. Dougal, W. R. Whitney, A. Recoura, F. P. Venable and F. W. Miller, etc. —*vide supra,* chromic chloride. A. Mitscherlich observed that if the soln.—with or without admixture with potassium sulphate—be heated to 200°, an amorphous precipitate is formed which is supposed to be *chromium-löwigite,* or the *enneahydrate,* $K_2SO_4.Cr_2(SO_4)_3.9H_2O$. F. P. Venable and F. W. Miller said that the same salt is precipitated by adding alcohol to a freshly prepared soln. of the violet salt. According to C. R. C. Tichborne, if a soln. of chrome-alum be heated in sealed tubes for 2 or 3 hrs. at 177°, a basic sulphate is precipitated ; and a dil. soln. of chrome-alum is instantly dissociated, or hydrolyzed when dropped into a flasko of biling water, for the contents of the flask become turbid and opaque. The precipitate redissolves on cooling, and even during boiling if the chrome-alum is gradually added. He concluded that "the green colour of chromic salts is due to the basylous condition"—*vide supra,* H. T. S. Britton's observations. H. Löwel found that barium chloride precipitates all the SO_4 from a cold, freshly prepared, violet soln., but only part of the SO_4 is precipitated from the green soln., so that when the filtrate is heated, the addition of barium chloride precipitates more SO_4. C. Montemartini and L. Losana studied the solubility of the salt in sulphuric acid. According to M. Krüger, alcohol precipitates from the violet soln. the unchanged violet salt—*vide supra*—but the green soln. furnishes a green oily liquid which gradually solidifies, and which contains three-fourths of the SO_4-radicle, the remaining quarter remains dissolved in the alcohol; and M. Siewert added that the oily precipitate contains $K_2O : Cr_2O_3 : SO_3 = 6 : 5 : 18$, and the soln. 2 : 3 : 14. G. N. Wyrouboff observed that the same amount of chromic oxalate is precipitated by the addition of alkali oxalate to the freshly prepared violet soln. as to a soln. which has been kept at 30° for some time. H. Löwel observed that zinc and iron react with a soln. of the salt as in the case of chromic chloride (*q.v.*).

As indicated above, H. Löwel found that if chrome-alum be heated gradually between 300° and 350°, it is transformed into green, anhydrous, $K_2SO_4.Cr_2(SO_4)_3$, which is a pseudomorph after the hydrate, and quickly dissolves in boiling water. If chrome-alum be heated a little above 350°, or, according to C. Hertwig, between 300° and 400°, until all the water is expelled, the anhydrous, green, insoluble salt is formed. This salt, said N. W. Fischer, is lilac-coloured when hot, yellowish-green when cold. C. Hertwig, and H. Löwel found that if the salt be heated just below redness it loses 5·8 per cent. of sulphur trioxide, and at a full red-heat, the chromic sulphate forms chromic oxide. The potassium sulphate can be removed by washing with water. The salt is decomposed if boiled for a long time with alkali-lye with the separation of chromic oxide. The salt is not decomposed by cold or boiling water, hydrochloric acid, sulphuric acid, nitric acid, or aq. ammonia. M. Traube heated potassium dichromate with a large excess of conc. sulphuric acid, and at 160° to 180° obtained a mush of a green, insoluble double salt, and a green liquid; at 240°, there is produced a greyish-red substance. These products contain the more potassium sulphate the lower the temp., and the shorter the time of contact with the acid. W. Wernicke obtained some analogous products.

According to N. W. Fischer, and C. Hertwig, a *dihydrate,* $K_2SO_4.Cr_2(SO_4)_3.2H_2O$, is formed when potassium chrome-alum is heated to 200° so long as it continues to lose water. The dark green, porous residue slowly dissolves when boiled for a long time with water, and more rapidly if hydrochloric acid be present. Water and dil. sulphuric or hydrochloric acid do not act on the salt at ordinary temp. in the course of several days. The salt is decomposed by warm, aq. ammonia which separates as dark-green chromic oxide, soluble in hydrochloric acid. P. N. Pavloff studied the action of soln. of chrome-alum on leather. The *enneahydrate,* $K_2SO_4.Cr_2(SO_4)_3.9H_2O$, and the *tetracosihydrate,* ordinary chrome-alum, have been discussed above. F. Fichter and E. Brunner observed that fluorine is a powerful oxidizing agent. They showed that a soln. of chromium alum, acidified with very dil. sulphuric acid, is not altered by the passage of fluorine for several hours, but if the conc. of free acid is as high as $1{\cdot}5N$, a regular oxidation to chromic acid sets in, and is easily recognized by the change of colour from violet to orange-yellow. Higher conc. of sulphuric acid up to $7{\cdot}5N$ have the same effect. The oxidation is certainly indirect, for if the amount of chromic acid is determined by titration, the fresh soln., which evolves ozone, has about 1·5 times the possible oxidizing power. After standing overnight or heating on a water-bath, the excess of oxidizing substances is destroyed, and the soln. has an oxidizing value corresponding exactly to the theoretical amount of chromic acid. The oxidizing substance must be sulphuric tetroxide, for it is effective at 0°, whereas persulphate oxidizes chromic salts only at higher temp. The conc. sulphuric acid is assumed to exert two functions: (i) to furnish sulphur tetroxide as an intermediate compound; and (ii) to prevent the formation of hydrogen dioxide and hence of perchromic acid which would lead to reduction. According to L. Meunier and P. Caste, the amount of sodium carbonate necessary to produce a permanent precipitate in a soln. of chrome-alum varies with the age and method of preparation of the soln. Immediately after the soln. has been prepared, there is a relatively short period during which the amount of sodium carbonate required increases with the time up to a maximum which varies with the dilution and the temp. This period is longer and more marked the more conc. is the soln. and the lower the temp. After this maximum, there is a relatively long second period, which may last several months during which the amount of sodium carbonate required decreases slowly with the time. At high temp., and particularly at 100°, the two periods are of such short duration that the end of their combined action is almost immediate. It is supposed that immediately on its dissolution in water, chromium sulphate undergoes a partial hydrolysis. The chromium hydroxide and chromium sulphate interact to give a less ionized complex more stable towards sodium carbonate. This process predominates at first. This immediate hydrolysis progresses and is slowly accentuated and the ionic conc. is increased until the second process gradually predominates, with the consequent requirement of less sodium carbonate for the precipitation of the chromium hydroxide. F. E. Brown and J. E. Snyder observed that a crystal of chrome-alum blackens when boiled with vanadium oxytrichloride.

T. Klobb obtained hexagonal crystals of **ammonium potassium chromium sulphate,** $(NH_4,K)_2SO_4.Cr_2(SO_4)_3$, as solid soln. isomorphous with the anhydrous alums, by fusing a mixture of potassium chrome-alum with ammonium sulphate. The salt is not attacked by boiling water. By operating in an analogous manner, **ammonium aluminium chromium sulphate,** $(NH_4)_2SO_4.(Cr,Al)_2(SO_4)_3$, and **ammonium ferric chromium sulphate,** $(NH_4)_2SO_4.(Cr,Fe)_2(SO_4)_3$, were obtained as isomorphous mixtures.

J. H. Gladstone, and H. Erdmann prepared **rubidium chromium sulphate,** or **rubidium disulphatochromiate,** $Rb_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $RbCr(SO_4)_2.12H_2O$, from a soln. of the component salts. It furnishes violet octahedra which, according to O. Pettersson, have the sp. gr. 1·968 at 16·8°. J. H. Gladstone gave 1·946 for the sp. gr. J. Locke said that the salt melts at 107° in its water of crystallization. F. Ephraim and P. Wagner found the vap. press., *p* mm., of the hydrate to be:

	40°	51°	61·5°	71°	79·5°	84°	90°
p . .	25	42	86	166	250	355	414

C. Soret found the index of refraction, μ, for the wave-length, λ at 12° to 17°, to be:

λ .	*G*-line	*F*-line	*b*-line	*E*-line	*D*-line	*C*-line	*B*-line	*A*-line
μ .	1·49323	1·48775	1·48522	1·48486	1·48151	1·47868	1·47756	1·47660

J. H. Gladstone gave for the sp. refraction for the *A*-line $(\mu-1)/D=0·2444$; and for the sp. dispersion $(\mu_A-\mu_G)/D=0·0090$. H. Sauer studied the absorption spectrum. H. Erdmann found that the salt is sparingly soluble in cold water, and that the soln. becomes green when heated. J. Locke gave for the solubility in a litre of water at 25°, 43·4 grms. of the hydrated and 25·7 grms. of the anhydrous salt. N. Demassieux and J. Heyrovsky studied the polarization curves—*vide supra.*

J. H. Gladstone, and C. Soret prepared **cæsium chromium sulphate,** or **cæsium disulphatochromiate,** $Cs_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $CsCr(SO_4)_2.12H_2O$, from a soln. of the component salts. J. H. Gladstone gave 2·043 for the sp. gr. J. Locke found the m.p. to be 116°. F. Ephraim and P. Wagner gave for the vap. press., *p* mm.,

	44°	71·8°	80°	81·5°	90°	95°
p . .	14	119	224	250	411	512

C. Soret observed the index of refraction, μ, for light of wave-length, λ, at 6° to 12°, to be:

λ .	*G*-line	*F*-line	*b*-line	*E*-line	*D*-line	*C*-line	*B*-line	*A*-line
μ .	1·49280	1·48723	1·48491	1·48434	1·48100	1·47836	1·47732	1·47627

J. H. Gladstone gave for the sp. refraction for the A-line $(\mu-1)/D=0\cdot2326$; and for the sp. dispersion, $(\mu_A-\mu_G)/D=0\cdot0086$. H. Sauer studied the absorption spectrum. J. Locke found for the solubility in a litre of water at 25°, 9·4 grms. for the hydrated, and 5·7 grms. for the anhydrous salt. The soln. becomes green above 95°.

E. Carstanjen, J. E. Willm, and O. Pettersson prepared **thallium chromium sulphate,** or **thallium disulphatochromiate,** $Tl_2SO_4.Cr_2(SO_4)_3.24H_2O$, or $TlCr(SO_4)_2.12H_2O$, from a soln. of the component salts. The octahedral crystals appear almost black ; they appear red by transmitted light. J. H. Gladstone gave 2·388 for the sp. gr. ; J. Locke, 92° for the m.p. ; and F. Ephraim and P. Wagner, for the vap. press., p mm.,

	33°	50°	68°	78·5°	87·5°	94°	102°
p . .	8	44	155	250	394	507	672

The index of refraction, μ, for light of wave-length λ at 9° to 25°, was found by C. Soret to be :

λ .	G-line	F-line	b-line	E-line	D-line	C-line	B-line	A-line
μ .	1·53808	1·53082	1·52787	1·52704	1·52280	1·51923	1·51798	1·51692

J. H. Gladstone found the sp. refraction for the A-line to be $(\mu-1)/D=0\cdot2161$; and the sp. dispersion, $(\mu_A-\mu_G)/D=0\cdot0092$. H. Sauer studied the absorption spectrum. J. Locke observed that a litre of water at 25° dissolves 163·8 grms. of the hydrated or 104·8 grms. of the anhydrous salt.

A series of salts of the type $3R_2SO_4.Cr_2(SO_4)_3$, or $R_3Cr(SO_4)_3$, or $R_3[Cr(SO_4)_3]$, has been prepared in the dry way, but not by wet processes. The salts may be identical with A. Recoura's chromotrisulphuric acid. T. Klobb found that when chromic oxide, chloride, or sulphate is fused with ammonium sulphate, **ammonium trisulphatochromiate,** $(NH_4)_3Cr(SO_4)_3$, is formed in pale green, acicular crystals, which become rose-coloured when heated. If the fusion is prolonged, anhydrous ammonium chrome-alum is formed. Ammonium trisulphatochromiate is insoluble in cold water, and it is slightly attacked by boiling water, dil. acids, and dil. alkali-lye. It is not changed at 350°, but it decomposes at a red-heat forming chromic oxide. W. Wernicke prepared **lithium trisulphatochromiate,** $Li_3[Cr(SO_4)_3]$, by fusing chromic oxide with lithium hydrosulphate, adding conc. sulphuric acid to the cold mass, and fusing the mixture again. The properties resembled those of the potassium salt. W. Wernicke obtained **sodium trisulphatochromiate,** $Na_3[Cr(SO_4)_3]$, in a similar manner ; and C. Pagel, by melting a mixture of sodium hydrosulphate, and ammonium and chromic sulphates (5 : 2.5 : 1) as in the case of the potassium salt ; and also by heating sodium dichromate and chloride in the presence of an organic reducing agent, and treating the product with sulphuric acid. The salt forms prismatic or acicular crystals, and behaves like the potassium salt. W. Wernicke obtained **potassium trisulphatochromiate,** $K_3[Cr(SO_4)_3]$, by melting potassium pyrosulphate with anhydrous chrome-alum, or chromic sulphate or oxide, and extracting the cold mass with hot water. A. Étard prepared it by melting chromic chloride and potassium hydrosulphate at a red-heat ; and T. Klobb, by melting a mixture of chrome-alum, and ammonium and potassium sulphates (1 : 4 : 4). The green powder was found by W. Wernicke to appear violet-red when hot ; it consists of six-sided rhombic or hexagonal needles. C. Pagel said that the crystals are hexagonal ; and T. Klobb added that they are probably isomorphous with the corresponding ammonium salt. The compound loses SO_3 when heated to redness, and, according to W. Wernicke, it is insoluble in water, acids, and dil. alkali-lye, but it is decomposed by boiling with conc. potash-lye.

A. Recoura obtained **potassium chromitetrasulphate,** $K_2[Cr_2(SO_4)_4]$, by evaporating on the water-bath a mol of green chromic sulphate with a mol of potassium sulphate ; and the *tetrahydrate,* $K_2[Cr_2(SO_4)_4].4H_2O$, by dehydrating chrome-alum slowly at 110°. The former compound is dark green, and it is soluble in water.

The soln. gives no immediate precipitation with barium chloride, showing that all the SO_4-radicles are masked. The isomeric $(KO)_2Cr_2O_2(SO_3)_4$, or $K_2[Cr(SO_4)_4]$, was obtained from the chromipolysulphuric acid (*q.v.*); and similarly also with **sodium chromitetrasulphate.** A. Recoura obtained **potassium chromipentasulphate,** $K_4[Cr_2(SO_4)_5]$, by evaporating on a water-bath a mol of green chromic sulphate with 2 mols of potassium sulphate; if 3 mols of potassium sulphate are employed, **potassium chromihexasulphate,** $K_6[Cr_2(SO_4)_6]$, is formed. Both these green compounds are soluble in water; and all the SO_4-radicles are masked. G. N. Wyrouboff discussed the composition of these salts—*vide supra*, the corresponding acids.

The mixed crystals of potassium sulphate and chromate were discussed in connection with potassium chromate. A. Recoura obtained **potassium chromitrisulphatochromate,** $K_2[Cr_2(SO_4)_3(CrO_4)]$, by evaporating on a water-bath a soln. of a mol of the green sulphate with a mol of potassium chromate. The dark brown, amorphous product forms a green or brown soln. with water; the aq. soln. readily decomposes into chromic sulphate and potassium chromate. A. Recoura also prepared **potassium chromitrisulphatodichromate,** $K_4[Cr_2(SO_4)_3(CrO_4)_2]$, by using a mol of green chromic sulphate and 2 mols of potassium chromate; with three mols of potassium chromate, **potassium chromitrisulphatotrichromate,** $K_6[Cr_2(SO_4)_3(CrO_4)_3]$, is formed. The properties of these salts are similar. According to A. Étard, a soln. of a mol of potassium chromate and 2 mols of magnesium sulphate furnishes monoclinic prisms of **potassium magnesium disulphatochromate,** $K_2CrO_4.2MgSO_4.9H_2O$, which lose 5 mols. of water at 100°, and all the water at 250°. C. von Hauer said that a third of the SO_4-radicles in $K_2SO_4.MgSO_4.6H_2O$ can be replaced by the CrO_4-radicle without change of form. A. Duffour showed that A. Étard's salt is an arbitrary stage in a series of isomorphous mixtures of $nK_2Cr(SO_4)_2.6H_2O.(1-n)K_2Mg(CrO_4)_2.6H_2O$.

S. M. Jörgensen[2] prepared **chromic hexamminosulphate,** $[Cr(NH_3)_6]_2(SO_4)_3.5H_2O$, by triturating the hexamminobromide with freshly precipitated silver oxide and water; the filtrate was treated with dil. chromic sulphate, and the salt precipitated by alcohol. The yellow needles lose 4 mols. of water over sulphuric acid; and at 100°, the water is expelled in a few hrs. The salt is freely soluble in hot water. It forms a complex chloroplatinate. S. M. Jörgensen, and O. T. Christensen obtained **chromic aquopentamminosulphate,** $[Cr(NH_3)_5(H_2O)]_2(SO_4)_3.3H_2O$, and as in the case of the preceding salt, the prismatic crystals are freely soluble in water; they lose 4 mols. of water between 98° and 100°. The salt forms a complex chloroplatinate. A. Werner and J. L. Klein obtained **chromic tetraquodiamminosulphate,** $[Cr(NH_3)_2(H_2O)_4]_2(SO_4)_3$, by dissolving the bromide in a little dil. hydrobromic acid, adding 8 vols. of absolute alcohol, then adding dil. sulphuric acid, and washing the crystals with alcohol and ether. The reddish-violet plates are very hygroscopic. P. Pfeiffer prepared **chromic tetraquodipyridinosulphate,** $[CrPy_2(H_2O)_4]_2(SO_4)_3.3H_2O$, and also the **hydrosulphate,** $[CrPy_2(H_2O)_4]HSO_4.2H_2O$. For the hexaquo-salts, see the chlorosulphates, and the alums $M[Cr(H_4O_2)_6](SO_4)_2$.

H. J. S. King prepared **chromic hydroxypentamminosulphate,** $[Cr(NH_3)_5(OH)]SO_4$, by the action of a soln. of chloropentamminochloride on ammonium sulphate in conc. aq. ammonia, and precipitation by the addition of alcohol. He gave for the conductivity, μ mhos, of a mol of the salt in v litres:

v . .	32	64	128	256	512	1024	2048
μ 0° .	59·4	69·5	82·0	94·1	108·3	118·9	132·3
25° .	117·6	132·9	158·3	181·2	208·2	234·0	254·2

A. Werner and J. L. Klein, and A. Werner and J. V. Dubsky obtained **chromic hydroxytriaquodiamminosulphate,** $[Cr(NH_3)_2(H_2O)_3(OH)]SO_4.H_2O$, by the action of sulphuric acid on chromic dihydroxydiaquodiamminochlorobromide. The pale red needles were insoluble in water, and soluble in dil. acetic and propionic acids. The acetic acid soln. with potassium thiocyanate forms dihydroxydiaquodiamminothiocyanate. P. Pfeiffer and M. Tapuach, and P. Pfeiffer and W. Osann prepared **chromic hydroxytriaquodipyridinosulphate,** $[CrPy_2(H_2O)_3(OH)]SO_4$. O. T. Christensen obtained **chromic nitritopentamminosulphate,** $[Cr(NH_3)_5(NO_2)]SO_4.H_2O$, by the action of silver sulphate on the chloride of the series. The yellow crystals lose water with decomposition at 100° ; they are freely soluble in water ; and are decomposed by dil. sulphuric acid. S. M. Jörgensen obtained **chromic chloropentamminosulphate,** $[Cr(NH_3)_5Cl]SO_4.2H_2O$, by treating an aq. soln. of the chloride with silver carbonate, and adding dil. sulphuric acid and afterwards alcohol to the filtrate. The carmine-red prisms are freely soluble in water. All the water is expelled in the presence of conc. sulphuric acid, or at 100°, a **hydrosulphate,** $[Cr(NH_3)_5Cl]_4(SO_4)(HSO_4)_6$, was also prepared. A. Benrath found that the chloropentamminosulphate, $[Cr(NH_3)_5Cl]SO_4$, is stable in the presence of 0 to 70 per cent. sulphuric acid, but with more conc. acid, $4[Cr(NH_3)_5Cl]SO_4.3H_2SO_4$ is formed. P. T. Cleve, P. Pfeiffer and S. Basci, P. Pfeiffer and M. Tilgner, and S. M. Jörgensen obtained **chromic chloroaquotetramminosulphate,** $[Cr(NH_3)_4(H_2O)Cl]SO_4$, by the action of cold conc. sulphuric acid on the chloride of the series. The rose-red or dark violet rhombic plates are sparingly soluble in cold water, and freely soluble in warm water. The salt is decomposed by boiling in acidic soln. Y. Shibata measured the absorption spectrum. A. Werner and A. Miolati gave 171·5, 195·1, 226·4, and 262·6 mhos for the conductivity of soln. with a mol of the salt respectively in 250, 500, 1000, and 2000 litres of water at 25°. The pale violet precipitate is hygroscopic. For A. Recoura's, R. F. Weinland and R. Krebs', and R. F. Weinland and T. Schumann's observations on **chromic chloropentaquosulphate,** $[Cr(H_2O)_5Cl]SO_4$, *vide infra.* P. T. Cleve also prepared **chromic bromoaquotetramminosulphate,** $[Cr(NH_3)_4(H_2O)Br]SO_4$, by treating an aq. soln. of the bromide of the series with sodium sulphate and sulphuric acid, and then adding alcohol. The rose-red, crystalline powder is freely soluble in water ; and when the aq. soln. is boiled the salt is decomposed with the deposition of hydrated chromic oxide, and the evolution of ammonia. E. H. Riesenfeld and F. Seemann treated a soln. of chlorodiaquotriamminodichloride with conc. sulphuric acid, and obtained pale violet, hygroscopic crystals of **chromic chlorodiaquotriamminosulphate,** $[Cr(NH_3)_3(H_2O)Cl]SO_4$. S. Guralsky, and A. Werner prepared violet **chromic bromodiaquotriamminosulphate,** $[Cr(NH_3)_3(H_2O)_2Br]SO_4$, by the action of sulphuric acid on the chloride of the series followed by alcoholic precipitation ; and A. Werner and R. Huber, N. Bjerrum and G. H. Hansen prepared **chromic bromopentaquosulphate,** $[Cr(H_2O)_5Br]SO_4.H_2O$, or $CrBrSO_4.6H_2O$.

P. Pfeiffer and M. Tapuach prepared **chromic dihydroxydiaquodipyridinosulphate,** $[CrPy_2(H_2O)_2(OH)_2]_2SO_4.12$ or $14H_2O$; and P. Pfeiffer and P. Koch, **chromic cis-dichlorobisethylenediaminohydrosulphate,** $[Cr\ en_2Cl_2](HSO_4)$. E. Rosenbohm obtained **chromic dichlorotetramminosulphate,** $[Cr(NH_3)_4Cl_2]_2SO_4$, with the magnetic susceptibility $20·68 \times 10^{-6}$ mass units. A. Werner obtained **chromic dichloraquotriamminosulphate,** $[Cr(NH_3)_3(H_2O)Cl_2]_2SO_4$, by treating the chloride of the series with sulphuric acid. The blue needles form a blue soln. with water ; and the salt is reprecipitated by the addition of sulphuric acid. A. Werner, and S. Guralsky prepared dark green crystals of **chromic dibromoaquotriamminosulphate,** $[Cr(NH_3)_3(H_2O)Br_2]_2SO_4$, by the action of sulphuric acid on the bromide of the series. For A. Werner and R. Huber's observations on **chromic dibromotetraquosulphate,** *vide infra.* P. Pfeiffer and P. Koch prepared **chromic cis-dithiocyanatobisethylenediaminohydrosulphate,** $[Cr\ en_2(SCy)_2]HSO_4.1\frac{1}{2}H_2O$; and P. Pfeiffer, the **trans-salt.**

S. M. Jörgensen prepared both the rhodo- and the erythro-salts of **chromic hydroxydecamminosulphate,** $[Cr_2(OH)(NH_3)_{10}]_2(SO_4)_5.2H_2O$, by adding sulphuric acid to an aq. soln. of the thiocyanate of the series. The carmine-red, quadratic or rectangular plates are sparingly soluble in cold water. S. M. Jörgensen prepared carmine-red prismatic crystals of **chromic trihydroxyaquohexamminosulphate,** $[Cr_2(OH)_3(H_2O)(NH_3)_6]_2SO_4.3H_2O$, as well as the **hydrosulphate,** $[Cr_2(OH)(H_2O)(NH_3)_6]HSO_4.\frac{1}{2}H_2O$. P. T. Cleve prepared **chromic decahydroxy-**

tetramminosulphate, $Cr_4(OH)_{10}(SO_4)(NH_3)_4.19H_2O$, by the action of ammonia on ammonium chrome-alum. P. Pfeiffer and W. Vorster prepared **chromic hexahydroxysexiesethylenediaminosulphate,** $[Cr_4(OH)_6en_6](SO_4)_3.10H_2O$. M. Z. Jovitschitsch treated a chromium salt with a little aq. ammonia, and about a gram of the light grey hydroxide treated with just enough sulphuric acid to dissolve it, diluted to about 25 c.c., and mixed with the same vol. of ammonia. A grey precipitate is formed which redissolves in an hour or two. When the soln. is treated with alcohol, the red oil which is formed, when freed from ammonium sulphate, solidifies to a red mass of **chromic dioxyhexamminodisulphate,**

$$\begin{array}{l}(NH_3)_2{=}Cr.O.NH_3.Cr{=}SO_4\\(NH_3)_2{=}\dot{C}r.O.NH_3.\dot{C}r{=}SO_4\end{array}\quad 10H_2O$$

When dried over sulphuric acid, it loses $4H_2O$, but when left in contact with water, it gradually suffers hydrolysis and becomes paler, the acid radicles being partly replaced by hydroxyl groups. It is stable in absolute alcohol, but absorbs carbon dioxide when exposed to the air. D. Strömholm prepared **platinic dihydroxysulphatoctamminochromatodichromate,** $[Pt_2(NH_3)_8(OH)_2SO_4]Cr_2O_7(CrO_4)$, as well as **platinic hydroxysulphatotetramminodichromate,** $[Pt(NH_3)_4(OH)(SO_4)]_2Cr_2O_7$, previously obtained by P. T. Cleve.

H. Schiff prepared the monohydrate of **green chromic chlorosulphate,** $CrClSO_4.H_2O$, by evaporating at about 50° a soln. of basic chromic sulphate in cold hydrochloric acid. A. Recoura, and A. Werner and R. Huber obtained the *hexahydrate* by boiling for a quarter of an hour 60 grms. of violet chromic sulphate with 50 c.c. of fuming hydrochloric acid, and allowing the mixture to stand for some days. R. F. Weinland and R. Krebs obtained the *octohydrate* by evaporating at 10° over conc. sulphuric acid a mixture of a conc. aq. soln. of the green chloride with an eq. quantity of sulphuric acid; and R. F. Weinland and T. Schumann, and N. Bjerrum also obtained it from one of the chromic chlorides and sulphuric acid. H. Schiff described his monohydrate as a green, hygroscopic, amorphous mass; A. Werner and R. Huber described his hexahydrate as a bluish-green mass of tabular crystals; and R. F. Weinland and co-workers found the octohydrate forms pale green masses of tabular crystals. A. Recoura, and R. F. Weinland and co-workers said that a *pentahydrate* is formed by heating the higher hydrate at 85°, or exposing it in vacuo over sulphuric acid. A soln. of the salt gives no immediate precipitation with silver nitrate, but a precipitate with barium chloride is formed at once showing that the chloride radicle is masked, but not so with the sulphate radicle. The lowering of the f.p. is rather greater than would correspond with that for the non-oxidized molecule; and the mol. conductivity 76·5 for $v=125$ at 1° corresponds with the dissociation of the salt into two ions. The conductivity gradually increases when the soln. is allowed to stand showing that the salt is gradually resolved into three ions as it is transformed into the violet salt. The formula for **chromic chloropentaquosulphate,** $[Cr(H_2O)_5Cl]SO_4nH_2O$, fits the facts very well; and this, changing to the violet salt, forms $[Cr(H_2O)_6](SO_4)Cl.nH_2O$. N. Bjerrum discussed the case where the sulphate radicle is not immediately precipitable. L. A. Welo gave $19{\cdot}86\times10^{-6}$ for the magnetic susceptibility of $[Cr(H_2O)_6]ClSO_4.2H_2O$, and $19{\cdot}62\times10^{-6}$ for $[Cr(H_2O)_5Cl]SO_4.3H_2O$.

R. F. Weinland and R. Krebs obtained the *octohydrate* of **violet chromic chlorosulphate,** $CrClSO_4.8H_2O$, by mixing 26·6 grms. of the greyish-blue $CrCl_3.6H_2O$ dissolved in 28 grms. of water, with 10 grms. of conc. sulphuric acid mixed with 18 grms. of water, all well cooled. Violet acicular crystals of the salt separate in a few days as the mixture is evaporated in a desiccator; if 11 grms. of water and 10 grms. of conc. sulphuric acid are used tabular crystals are formed. If the octohydrate is kept over sulphuric acid in vacuo it forms the *hexahydrate*. An aq. soln. of the salt evaporated over sulphuric acid yields violet chromic sulphate. An acidified soln., at 0°, gives an immediate precipitation of silver chloride when treated with silver nitrate, but barium sulphate is not at once precipitated by barium chloride. The mol. conductivity is 116 for $v=125$ at 1°, showing that the salt is not all ionized into three ions. The lowering of the f.p. also gives values rather larger than those required for the non-ionized molecule. The facts are considered to fit the formula for **chromic hexaquochlorosulphate,** $[Cr(H_2O)_6](SO_4)Cl.nH_2O$. A. del Campo and co-workers obtained the violet salt by the action of hydrogen chloride on a cold, conc. soln. of the violet chromic sulphate. E. Moles and M. Crespi gave 1·799 for the sp. gr. of $[Cr(H_2O)_6]Cl(SO_4).H_2O$, at 25°/4°, and 171 for the mol. vol. According to A. Werner and R. Huber, by mixing conc. soln. of violet chromic sulphate, and green chromic chloride, and adding conc. sulphuric acid while the mixture is cooled with iced water, green crystals of the bimolecular, green chlorosulphate, $(CrClSO_4.6H_2O)_2$, thought by A. Werner and R. Huber, and N. Bjerrum to be **chromic dichlorotetraquochromihexaquodisulphate,** $[Cr(H_2O)_6](SO_4)_2[Cr(H_2O)_4Cl_2].2H_2O$. The aq. soln. does not give an immediate precipitation with silver nitrate, but, it does give one with barium chloride. A 1 : 10-soln. of the salt in dil. hydrochloric acid, when sat. with hydrogen chloride, precipitates half the chromium as blue chromic chloride. N. Bjerrum and G. H. Hansen likewise prepared **chromic dichlorotetraqualuminohexaquodisulphate,** $[Cr(H_2O)_4Cl_2][Al(H_2O)_6(SO_4)_2.2H_2O$; and **chromic dichlorotetraquovanadihexaquodisulphate,** $[Cr(H_2O)_4Cl_2][V(H_2O)_6](SO_4)_2.2H_2O$, by the electrolytic reduction of vanadyl sulphate in the presence of chromic chloride. A. Werner and R. Huber, and N. Bjerrum and G. H. Hansen obtained **chromic dibromotetraquochromihexaquodisulphate,** $[Cr(H_2O)_6](SO_4)_2[Cr(H_2O)_4Br_2].2H_2O$, by the action of hydrogen bromide as in the analogous case of the preceding salt. The dark green plates are soluble in water; and are precipitated from the aq. soln. by sulphuric acid. N. Bjerrum and G. H. Hansen likewise prepared **chromic dibromotetraquoaluminohexaquodisulphate,** $[Cr(H_2O)_4Br_2][Al(H_2O)_6](SO_4)_2.2H_2O$, as well as the corresponding **chromic dibromotetraquoferrihexaquodisulphate,** $[Cr(H_2O)_4Br_2][Fe(H_2O)_6](SO_4)_2.2H_2O$; and dark green crystals of **chromic dibromotetraquovanadihexaquodisulphate,** $[Cr(H_2O)_4Br_2][V(H_2O)_6](SO_4)_2.2H_2O$, by the electrolysis of vanadyl sulphate in the presence of chromic bromide. The corresponding titanium and manganese salts could not be prepared.

S. M. Jörgensen prepared yellow octahedral crystals of **chromic hexamminoiodosulphate,** $[Cr(NH_3)_6](SO_4)I$, by adding ammonium iodide and sulphate to an ammoniacal soln. of the chloride of the series.

N. Larsson prepared **ammonium chromic chloropentaquodichlorosulphate,** $[CrCl(H_2O)_5]Cl_2.(NH_4)_2SO_4.H_2O$, by adding ammonium sulphate to a well-cooled soln. of chromic chloropentaquodichloride; **ammonium chromic chloropentaquodisulphate,** $[CrCl(H_2O)_5]SO_4.(NH_4)_2SO_4$, by adding alcohol to a cold soln. after boiling a mixture of soln. of chromic chloropentaquodichloride and ammonium sulphate; if the soln. contains sulphuric acid, **ammonium chromic chloropentaquosulphatohydrosulphate,** $[CrCl(H_2O)_5]SO_4(NH_4)HSO_4$, is formed; likewise with **hydroxylamine chromic chloropentaquochlorosulphate,** $[CrCl(H_2O)_5]Cl(SO_4).(NH_4O)_2SO_4.2H_2O$; and **hydroxylamine chromic chloropentaquosulphatohydrosulphate,** $[CrCl(H_2O)_5]SO_4.(NH_4O)HSO_4$. Complexes were also prepared with sulphates of *organic* bases—methylammonium, dimethylammonium, tetramethylammonium, ethylammonium, pyridinium, and strychnine.

R. F. Weinland and T. Schumann observed that a soln. of green hydrated chromic chloride and ammonium sulphate in equimolar proportions deposits crystals of **ammonium chromic trichlorodisulphate,** $CrCl_3.2(NH_4)_2SO_4.6H_2O$, or **ammonium chromic trichlorotetraquodisulphate,** $[Cr(H_2O)_4Cl_2]Cl.2(NH_4)_2SO_4.2H_2O$, in the form of large, green, four- or six-sided plates when kept a short time in a desiccator. Only one-third of the chlorine is precipitated immediately by silver nitrate from an acidified soln. of the salt at 0°, whereas all the sulphate is thrown down immediately by barium chloride. N. Larsson prepared this salt as well as **ammonium chromic dichlorotetraquochlorotrisulphate,** $[CrCl_2(H_2O)_4]Cl.3(NH_4)_2SO_4.2H_2O$; and

N. Larsson, and R. F. Weinland and T. Schumann found that **ammonium chromic dichlorohydrosulphatotrisulphate,** $[Cr(H_2O)_4Cl_2]_2SO_4.2(NH_4)_3SO_4(HSO_4)$, separates in green needles from a soln. containing a mol of green hydrated chromic chloride, a mol of ammonium sulphate, and 1 to 3 mols of sulphuric acid. In an acidified soln. of the salt at 0°, silver nitrate does not produce an immediate precipitate, but all the sulphate is at once thrown down by barium chloride. N. Larsson found that chromium dichlorotetraquosulphate forms complex salts with the sulphates of organic bases—methylammonium, tetramethylammonium, ethylammonium, tetraethylammonium, guanidinium, and pyridinium.

J. Meyer and V. Stateczny[3] obtained indications of the existence of **chromyl sulphuryl chloride,** $CrSO_5Cl_2$, formed by the action of sulphur trioxide on a well-cooled soln. of chromyl chloride in carbon tetrachloride, and the mixture heated in a sealed tube at 120°. The brown product fumes in air, it is decomposed by water into sulphur trioxide and chromyl chloride.

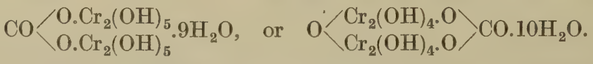
§ 31. Chromium Carbonates

According to A. Moberg,[1] the precipitate produced by adding an alkali carbonate to a soln. of chromous chloride is supposed to be **chromous carbonate,** $CrCO_3$, which is similar in many respects to magnesium, zinc, and ferrous carbonates. When chromous chloride is added to a boiling soln. of potassium carbonate, the reddish-brown precipitate gradually acquires a bluish-green colour provided air be excluded, and the supernatant liquor becomes yellow, and deposits brown-yellow plates, which, when exposed to air, become opaque and green. If these be now placed in water, a yellow soln. and a greenish-blue residue are formed. Again, if a cold soln. of potassium carbonate, freed from air, is employed, a dense yellow powder may be precipitated, or bluish-green flakes—of the same composition—may appear. If the yellow or brownish-red liquid be exposed to air, it turns green, and deposits a green substance; if the liquid be kept in closed vessels, carbon dioxide is evolved and the liquid becomes turbid, and deposits a green, flocculent precipitate which also gives off carbon dioxide, and hydrogen, forming brown, hydrated chromosic oxide. The precipitate obtained with the cold soln. of potassium carbonate, on boiling, gives off carbon dioxide, and then dissolves in acids without effervescence. If potassium hydrocarbonate be employed, a similar product is obtained but containing more carbon dioxide, while the liquid retains more chromous carbonate in soln. H. Moissan obtained the carbonate of a high degree of purity, by adding sodium carbonate to a soln. of chromous chloride while air is excluded. The amorphous, greyish-white carbonate takes up oxygen from air, and when heated it forms chromic oxide and carbon monoxide; it is sparingly soluble in water sat. with carbon dioxide; if allowed to stand in water exposed to air, it becomes red and then changes to bluish hydrated chromic oxide.

G. Baugé prepared a series of double carbonates by the action of a carbonate on moist chromous acetate or tartrate in an atm. of carbon dioxide. He obtained **ammonium chromous carbonate,** $(NH_4)_2CO_3.CrCO_3.H_2O$, by passing a current of carbon dioxide through an ammoniacal soln. of chromous acetate, and washing the precipitate successively with aq. ammonia, alcohol, and ether, and dried in a current of hydrogen charged with ammonia. The same salt was obtained by boiling a soln. of chromous acetate in ammonia with sodium carbonate in a current of hydrogen. The yellow, crystalline powder, when thoroughly dried, is fairly stable in dry air. It is very active chemically. In air, it forms chromic hydroxide, with chlorine it forms chromic chloride; it dissolves in hydrochloric or sulphuric acid forming a blue soln. if air be absent; and hydrogen sulphide converts it into chromic sulphide. G. Baugé obtained impure **lithium chromous carbonate** by adding lithium carbonate to chromous acetate suspended in water. According to G. Baugé, when well washed and moist chromous acetate is mixed with a soln. of sodium carbonate, it first dissolves, and after a time a reddish-brown compound separates; this is washed with water, and afterwards with 98 per cent. alcohol, all the operations being conducted in an atm. of carbon dioxide. When dried in a current of the same gas, the resulting *decahydrate* of **sodium chromous carbonate,** $Na_2CO_3.CrCO_3.10H_2O$, forms microscopic, tabular lozenge-shaped crystals which lose water in vacuo at the ordinary temp. or at 100°. It is very soluble in cold water, but the solubility gradually diminishes, probably in consequence of polymerization. It is a powerful reducing agent, and decomposes water at a little below

100° with liberation of hydrogen. When exposed to dry air, it effloresces, and is afterwards converted into a mixture of sodium carbonate and chromic hydroxide; in moist air, it oxidizes rapidly with development of heat. Chlorine converts it into chromic oxide with liberation of carbon dioxide; hydrogen and hydrogen sulphide have no action on it in the cold, and when heated at 100° in a current of these gases, it yields the monohydrate. Dil. hydrochloric and sulphuric acids dissolve the salt, forming blue soln. The *monohydrate*, $Na_2Cr(CO_3)_2.H_2O$, obtained by the action of a current of an inert gas at 100°, is a yellow powder which becomes brown when heated in vacuo or in a current of hydrogen, but regains its yellow colour on cooling. At 300°, it decomposes into sodium carbonate and chromic oxide. When heated in air, it is converted into sodium chromate; when heated in chlorine it yields chromyl dichloride and chromic oxide; in hydrogen sulphide at about 240°, it yields the red, crystalline chromic sulphide—otherwise it resembles the decahydrate. When chromous acetate is treated with a 20 per cent. soln. of potassium carbonate, **potassium chromous carbonate,** $K_2CO_3.CrCO_3.3H_2O$, is formed in yellow, hexagonal prisms, which at first dissolve in water, but gradually polymerize, whether in soln. or in the solid state, and become less soluble. It is a powerful reducing agent, and decomposes water below 100°; when heated out of contact with air, it becomes brown, but regains its original colour on cooling; at about 280°, it decomposes. When heated in air, it is converted into potassium chromate. If the yellow, complex carbonate is suspended in water and treated with a current of carbon dioxide, or if the chromous acetate is treated with a dil. soln. of potassium carbonate, a less soluble, red double carbonate is formed; it is partially decomposed by water, and decomposes water at 100°. The carbonates of barium, strontium, and calcium have no action on chromous acetate, but magnesium hydrocarbonate converts chromous acetate into reddish-brown **magnesium chromous carbonate** which could not be obtained free from magnesium carbonate, and which decomposes water at 100°.

According to M. Z. Jovitschitsch, chromic hydroxide freed from all traces of alkali and ammonia, absorbs carbon dioxide from the atm. until the saturation limit corresponding with **chromic pentahydroxycarbonate,** $[Cr_2(OH)_5]_2CO_3.8H_2O$, is attained. This substance can be dried at 100° without losing carbon dioxide, but it is decomposed by acids. The graphic formula is supposed to be either



$$CO\begin{array}{l}\diagup O.Cr_2(OH)_5 \\ \diagdown O.Cr_2(OH)_5\end{array}.9H_2O, \quad \text{or} \quad O\begin{array}{l}\diagup Cr_2(OH)_4.O\diagdown \\ \diagdown Cr_2(OH)_4.O\diagup\end{array}CO.10H_2O.$$

According to H. Rose, alkali carbonates precipitate from soln. of chromic salts a pale green hydroxide containing more or less carbonate, which on standing becomes blue in daylight, and violet in artificial light. An excess of the precipitant dissolves the precipitate, and the soln. gives no precipitate when boiled; potassium or ammonium hydrocarbonate behaves similarly; but barium carbonate slowly precipitates hydrated chromic oxide completely from cold soln. J. N. von Fuchs made a similar observation with respect to calcium carbonate; and H. Demarçay, with respect to strontium and magnesium carbonates. K. F. W. Meissner, J. Lefort, and T. Parkman obtained basic chromic carbonates by the action of alkali or ammonium carbonate on a soln. of a chromic salt. M. Hebberling added that the freshly-formed precipitate is soluble in soln. of alkali carbonate or borax. The composition of the precipitate depends on the conditions; thus, K. F. W. Meissner gave $10Cr_2O_3.7CO_2.8H_2O$; J. J. Berzelius, $4Cr_2O_3.CO_2.H_2O$; and C. Langlois, $2Cr_2O_3.CO_2.6H_2O$.

T. Parkman dropped a cold, aq. soln. of chrome-alum into a soln. of sodium carbonate with constant stirring until the mixture had only a slight alkaline reaction. The unwashed, moist precipitate corresponded with **chromic oxydicarbonate,** $Cr_2O(CO_3)_2$. If the mixing be done in the reverse way, the precipitate is contaminated with sulphate. J. Lefort treated a violet soln. of a chromic salt with a moderate excess of sodium carbonate and, after washing and drying the product, obtained **chromic dioxycarbonate,** $Cr_2O_2(CO_3)$. It loses carbon dioxide at 300°. T. Parkman obtained a similar product by adding sodium carbonate to a boiling soln. of chrome alum; and W. Wallace by adding sodium or ammonium carbonate to a cold dil. soln. of chromic chloride. The washed precipitate was dried at ordinary temp.

O. T. Christensen prepared **chromic nitritopentamminocarbonate,** $[Cr(NH_3)_5(NO_2)]CO_3$, by triturating an excess of silver carbonate with the chloride of the series, and treating the filtrate with alcohol. The yellow, crystalline product could not be obtained pure. It is easily decomposed; is freely soluble in water; and the soln. gives the characteristic reactions of the carbonates.

According to N. J. Berlin, chromic carbonate dissolves sparingly in an aq. soln. of potassium carbonate, forming a pale-green soln. which separates on prolonged boiling. If chromic chloride is supersaturated with a conc. soln. of potassium carbonate, very little precipitate is redissolved; dissolution occurs on mixing more dil. soln. The soln. of hydrated chromic carbonate in a boiling soln. of potassium hydrocarbonate deposits on cooling a complex **potassium chromic carbonate** in pale green crystalline scales, while a soln. of potassium carbonate under similar conditions deposits a pulverulent complex salt on evaporation. A mineral associated with the serpentine and chromite of Dundas, Tasmania, was called **stichtite**—after R. Sticht—by W. F. Petterd,[2] and *chromobrugnatellite*, by L. Hezner. Its composition is that of a **magnesium chromic hydroxycarbonate,** $2MgCO_3.5Mg(OH)_2.2Cr(OH)_3.4H_2O$, like brugnatellite, with chromium in place of iron; or hydrotalcite with chromium in place of aluminium. The mineral occurs in micaceous scales of a lilac colour. The cleavage is good; the sp. gr. is 2·16; the refractive index, 1·542; it is optically uniaxial or feebly biaxial; the optical character is negative; and it is feebly pleochroic. Observations on the mineral were made by W. F. Foshag, L. Hezner, and A. Himmelbauer.

The mineral **beresowite,** *beresovite*, or *berezovite* was found by J. Samoiloff[3] in Berezov, Urals. associated with the galena and cerussite. It is a **lead carbonatochromate,** $6PbO.3CrO_3.CO_2$; and it occurs in deep red, birefringent plates of sp. gr. 6·69.

§ 32. Chromium Nitrates

F. Allison and E. J. Murphy[1] reported the examination of the magneto-optic properties of a soln. of **chromous nitrate,** $Cr(NO_3)_2$. A. A. Hayes observed that a soln. of hydrated chromic oxide in an excess of nitric acid; or, according to H. Löwel, of a basic nitrate in that acid forms a soln. which is blue by reflected and red by transmitted light. According to J. R. Partington and S. K. Tweedy, a soln. of chromic hydroxide—freshly precipitated from chrome-alum in the cold, and washed with hot water—in cold $4N$-NHO_3 is green, but in a few days it becomes violet. When kept in a stoppered bottle, it deposits reddish-violet crystals of **chromic nitrate,** $Cr(NO_2)_3.12\frac{1}{2}H_2O$. The *hemipentacosihydrate* melts at 104° to 105°. J. M. Ordway found that the soln. furnishes purple, rhombic prisms of chromic nitrate, $Cr(NO_3)_3.9H_2O$. J. R. Partington and S. K. Tweedy obtained the crystals of the enneahydrate by allowing a soln. of violet chromic chloride in nitric acid to crystallize in a vacuum desiccator. The *enneahydrate* melts at 36·5°, and decomposes at 100°. It is soluble in alcohol. J. R. Partington and S. K. Tweedy gave 66° to 66·5° for the m.p., and there is no sign of a transition at this temp. to a second hydrate. O. M. Halse said that a soln. of hydrated chromic oxide in dil. nitric acid, when evaporated very slowly, deposits violet crystals of the *hemipentadecahydrate*, $2Cr(NO_3)_3.15H_2O$, which melt at 100°, and decompose during dehydration; but J. R. Partington and S. K. Tweedy said that O. M. Halse's salt is really the hemipentacosihydrate. M. Z. Jovitschitsch found that by dissolving chromic oxide in hot, conc. nitric acid, of sp. gr. 1·4, the soln. on crystallization furnish dark brown, monoclinic prisms of the hemipentadecahydrate, $2Cr(NO_3)_3.15H_2O$, with the axial ratios $a:b:c=1{\cdot}4250:1:1{\cdot}1158$, and $\beta=93°\ 10'$. In contact with dry air, the grey coloured *hemienneahydrate*, $2Cr(NO_3).9H_2O$, is formed. The crystals are red by transmitted light; they are not changed by air; and dissolve in water, and alcohol. M. Z. Jovitschitsch found that the evaporation of a nitric acid soln. of chromic oxide yields a dark brown mass which, when dissolved in water and the soln. evaporated, furnishes a dark green, crystalline mass of anhydrous chromic nitrate, $Cr(NO_3)_3$. This is stable in light, and takes up moisture from the air to form the *trihydrate*, $Cr(NO_3)_3.3H_2O$.

I. Traube gave for the sp. gr. of the violet aq. soln. with 3·389, 7·550, 16·536, and 29·082 per cent. of $Cr(NO_3)_3$, respectively 1·02699, 1·06252, 1·14602, and 1·28163 at 15° when the mol. soln. vol. are respectively 47·9, 50·2, 53·7, and 57·7. C. Montemartini and L. Losana studied the viscosity of the soln. H. C. Jones and F. H. Getman measured the sp. gr. and the f.p. of soln. of chromic nitrate. For soln. with 0·0934, 0·3736, 1·1208, and 1·8680, the respective sp. gr. were 1·021, 1·069, 1·203, and 1·334; and the respective f.p. were —0·280°, —2·493°, —11·57°, and —29·50°. J. R. Partington and S. K. Tweedy found the viscosities, η dyne per cm. of soln. containing W grms. of $Cr(NO_3)_3$ per 100 grms. of water to be:

W . .	29·11	23·62	15·07	7·16	3·55
η 18° . .	0·01948	0·01669	0·01373	0·01172	0·01102
η 25° . .	0·01498	0·01122	0·01050	0·00999	0·00993

C. Montemartini and L. Losana observed a break in the expansion curve of soln. of chromium nitrate. L. R. Ingersoll found for Verdet's constant for the electromagnetic rotatory power for light of wave-length 0·8, 1·0, and 1·25μ, respectively 0·0066, 0·0041, and 0·0025 for soln. of chromic nitrate of sp. gr. 1·087. W. N. Hartley found that two violet soln. of the nitrate showed absorption bands respectively between 5880 and 5570, and 5650 and 5070. The violet soln. becomes green when heated. According to O. Knoblauch, the absorption spectrum of the soln. has a faint band at 6670, and a band between 6160 and 5770, with a small absorption at 513. When the soln. is diluted the band moves to 6180 to 5920. J. M. Hiebendaal observed a band between 6130 and 5320, and absorption from 4540. The addition of ammonium chloride weakens the band, and produces a narrow band at 6370; in alcoholic soln., there is a narrow band at 6370; a band between 6550 and 5350, with a maximum between 6130 and 5500; and absorption from 4600. A. Étard found bands between 6780 and 6700, and between 6540 and 6330. The spectrum was also examined by A. Byk and H. Jaffe. The electrical conductivity of soln. of the nitrate was measured by H. C. Jones and co-workers, and by N. Bjerrum. H. C. Jones and C. A. Jacobson found the mol. conductivity, μ mhos, of soln. with a mol of the salt in v litres between 0° and 35°; and A. P. West and H. C. Jones, and E. J. Shaeffer and H. C. Jones, between 35° and 65°:

	v	2	8	16	32	128	512	1024	2048
μ	0°	92·9	125·3	138·3	147·6	158·8	201	216	224
	10°	119·5	163·2	180·9	193·9	212	270	292	315
	25°	164·9	228	254	275	305	395	440	467
	35°	192·3	279	312	343	417	504	549	595
	65°	297	445	504	560	705	869	539	1032
α	0°	41·4	55·9	61·6	65·8	70·8	89·7	96·5	100·0
	35°	38·0	46·6	52·2	56·8	63·7	83·6	93·4	100·0

The values for the percentage ionization, α, were calculated by H. C. Jones and C. A. Jacobson; and H. M. Vernon calculated the degree of ionization from the colour. N. Bjerrum calculated the percentage hydrolysis, 100β, and the hydrolysis constant K for $Cr(NO_3)_3+H_2O \rightleftharpoons Cr(NO_3)_2OH+HNO_3$, from $K=[H]^{\cdot}[Cr(OH)^{\cdot\cdot}]/[Cr^{\cdot\cdot\cdot}]=m\beta^2/(1-\beta)$, from the conductivity, μ mhos, for soln. with m mols per litre at 19·8°:

m	0·02	0·01	0·005	0·0025	0·00125	0·00625
μ	265·7	299·1	316·0	345·2	374·8	406·5
100β	5·0	7·2	9·0	14·2	18·6	26·0
K	$0{\cdot}0_452$	$0{\cdot}0_456$	$0{\cdot}0_445$	$0{\cdot}0_449$	$0{\cdot}0_453$	$0{\cdot}0_457$

so that the average value of K is 0·00054. G. Herrmann said that his attempt to reduce a soln. of chromic nitrate, electrolytically, *wie nicht anders zu erwarten war*, were unsuccessful. L. A. Welo measured the magnetic susceptibility of the solid and molten hydrate, $Cr(NO_3)_3.3{\cdot}4H_2O$, and the results are summarized in Fig. 86. The Curie points, $C=\chi(T-\theta)$, are for the solid and liquid states, $C_s=1{\cdot}90$; $C_l=1{\cdot}50$; $\theta_s=-85°$; and $\theta_l=5°$. P. Philipp found the magnetic susceptibility to be $24{\cdot}09\times10^{-6}$ and $22{\cdot}75\times10^{-6}$ for soln. respectively of sp. gr. 1·3295 and 1·02706.

According to J. M. Ordway, when alkali hydroxide is added to a soln. of chromic nitrate, chromic hydroxide is precipitated. The precipitate appears when more than two-thirds of the acid has been neutralized. This proves that nitric acid can dissolve more chromic hydroxide than corresponds with the normal nitrate. C. Montemartini and L. Losana studied the e.m.f. of the soln. N. Bjerrum and C. Fourholt determined the masked hydroxide, $Cr(H_2O)_6^{\cdots}$, by precipitation as cæsium alum. With soln. of chromic nitrate they obtained the results indicated in Table V.

TABLE V.—THE HYDROLYSIS OF SOLUTIONS OF CHROMIC NITRATE.

M-Molar Soln.	Eq. of base present.	Days heated to 75°.	Per cent. latent chromium.	Masked OH-radicles per 100 Cr-atoms.	Masked OH-radicles per Cr-atom in latent basic Cr.
0·01	—	3 to 4	17·6	20	1·14
0·05	—	7	20·1	25	1·24
0·01	—	5	31·4	40	1·27
0·05	0·5	1 to 5	47·3	57	1·21
0·05	1·0	2 to 9	67·0	103	1·54
0·05	2·0	2 to 3	89·0	179	2·01

A. A. Hayes observed that when a soln. of an excess of chromic oxide in nitric acid is evaporated, it does not furnish crystals, but dries up to a gummy, fissured mass which appears dark green by reflected and transmitted light. J. J. Berzelius, and F. Brandenburg made some observations on this subject. H. Löwel assumed that the green soln. obtained by dissolving hydrated chromic oxide in hot nitric acid contains **chromic hydroxydinitrate,** $Cr(OH)(NO_3)_2$. J. M. Ordway obtained what he regarded as the *hexahydrate*, $Cr(OH)(NO_3)_2.6H_2O$, by keeping crystals of the normal nitrate on the water-bath. The dark green residue is soluble in water, forming a dark brown liquid which contains chromic nitrate and chromate. H. Schiff said that by digesting the warm nitric acid soln. for a long time, the precipitate which is formed contains Cr_2O_3 and 1 or $2N_2O_5$. M. Siewert also said that a sat. blue soln. of hydrated chromic oxide in cold nitric acid contains $Cr(OH)(NO_3)_2$; and the green soln. in hot nitric acid, $2Cr_2O_3.3N_2O_5$ or $Cr(OH)_3Cr(NO_3)_3$. J. M. Ordway assumed that the sat. soln. of hydrated chromic oxide in nitric acid contains $8Cr_2O_3.3N_2O_5$, or $3Cr_2O_3.5Cr(NO_3)_3$. By treating chromic acid, or chromates with nitric acid, F. Brandenburg, H. Moser, and K. F. W. Meissner obtained chromic acid associated with nitric acid. J. E. Howard and W. H. Patterson examined the effect of chromic nitrate on the critical soln. temp. of water and isobutyric acid. For V. Ipatieff and B. Mouromtseff's observations on the action of hydrogen under press., *vide supra*, hydrated chromic oxide.

L. Darmstädter [2] heated potassium chromate with two parts of conc. nitric acid and obtained crimson tabular crystals of what he regarded as **potassium nitritodichromate,** $KCr_2O_5(NO_2)$, or

$$\left.\begin{matrix}KO\\NO_2\end{matrix}\right\rangle CrO_2.CrO_3$$

and an excess of nitric acid was said to convert it into **potassium nitritotrichromate,** $KCr_3O_9(NO)_2$. The aq. soln. furnishes potassium dichromate. The salt melts to a dark brown liquid, and at the same time gives off red fumes. G. N. Wyrouboff, and G. C. Schmidt questioned the existence of these salts—*vide supra.*

H. Schiff treated the hydroxydichloride with nitric acid, and on evaporating the soln. obtained **chromic dichloronitrate,** $CrCl_2(NO_3)$, in hygroscopic plates. When heated, it decomposes: $2CrCl_2(NO_3)=2NO_2Cl+Cr_2O_2Cl_2$. The sol. has an acidic reaction; and the salt is soluble in alcohol. If the soln. of the dihydroxychloride in dil. nitric acid be evaporated, **chromic hydroxychloronitrate,** $Cr(OH)(NO_3)Cl$, is formed as a hygroscopic mass. H. Schiff also obtained **chromic sulphatonitrate,** $Cr(NO_3)SO_4$, as a green, hygroscopic mass, by the action of nitric acid on chromic oxydisulphate; and **chromic tetranitratosulphate,** $Cr_2(NO_3)_4SO_4$, as a brown soluble, hygroscopic mass by evaporating a soln. of the basic sulphate in nitric acid at 80°–90°.

S. M. Jörgensen [3] prepared **chromic hexamminotrinitrate,** $[Cr(NH_3)_6](NO_3)_3$, by reducing a soln. of potassium dichromate first by alcohol and hydrochloric acid, and then by the addition of zinc; adding ammonium chloride and ammonia; and allowing the mixture to stand 24 hrs. W. R. Lang and C. M. Carson, and O. T. Christensen treated with nitric acid the product of the action of liquid ammonia on anhydrous chromic chloride. The orange-yellow plates dissolve in water—100 parts of water dissolve 2·5 to 3 parts of the salt. A. Werner and A. Miolati found soln. with a mol of salt in 125, 250, 500, 1000, and 2000 litres at 25° had the respective conductivities $\mu=341{\cdot}2$, 374·1, 401·1, 425·3, and 444·2 mhos. H. J. S. King also measured the electrical conductivity of soln. of this salt. E. Rosenbohm gave $20{\cdot}42\times10^{-6}$ mass unit for the magnetic susceptibility. The salt is decomposed by boiling water; and the aq. soln. gives precipitates with hydrobromic, hydriodic, hydrofluosilicic, hydrochloroplatinic, and hydrochloroauric acids, potassium chromate, dichromate, triiodide, and ferricyanide, and sodium dithionate. F. Ephraim and W. Ritter observed that while the hexammine absorbs ammonia gas at low temp., the dissociation curves show no breaks corresponding with the formation of definite ammines. A. Benrath found that in the presence of conc. nitric acid, $[Cr(NH_3)_6](NO_3)_3.HNO_3$ is formed. S. M. Jörgensen also prepared the **hydrotetranitrate,** and a chloroplatinate. P. Pfeiffer prepared **chromic terethylenediaminotrinitrate,** $[Cr\ en_3](NO_3)_3$. O. T. Christensen obtained **chromic aquopentamminotrinitrate,** $[Cr(NH_3)_5(H_2O)](NO_3)_3$, as in the case of the bromide or iodide. The yellowish-red salt is freely soluble in water; it loses water at 100°; and detonates at a higher temp. A. Benrath found that in the presence of nitric acid $[Cr(NH_3)_6](NO_3)_3$ is formed. P. Pfeiffer prepared the **hydrotetra-**

nitrate. P. Pfeiffer treated the hydroxyaquotetramminodithionate with conc. nitric acid, and obtained **chromic diaquotetramminohydrotetranitrate,** $[Cr(NH_3)_4(H_2O)_2](NO_3)_4H$, as an orange powder. E. H. Riesenfeld and F. Seemann obtained red crystals of **chromic triaquotriamminodichloronitrate,** $[Cr(NH_3)_3(H_2O)_3]Cl_2(NO_3)$, by treating an aq. soln. of the trichloride with conc. nitric acid, and **chromic nitratodiaquotriamminodinitrate,** $[Cr(NH_3)_3(H_2O)_2(NO_3)](NO_3)_2$, from a soln. of chromium triamminotetroxide in conc. nitric acid. P. Pfeiffer and W. Osann prepared **chromic tetraquodipyridinotrinitrate,** $[CrPy_2(H_2O_4)](NO_3)_3$. M. Kilpatrick studied **chromic hexaureatrinitrate,** $[Cr(NH_2.CO.NH_2)_6](NO_3)_3$. R. Weinland and W. Hübner studied other complexes with organic radicles.

O. T. Christensen obtained **chromic nitritopentamminodinitrate,** $[Cr(NH_3)_5(NO_2)](NO_3)_2$, by the action of ammonium nitrate on a soln. of the chloride. The yellow octahedral crystals are sparingly soluble in water 100 parts of which dissolve 0·67 part of the salt. The salt detonates when heated. F. Ephraim and W. Ritter observed that **chromic aquopentamminotrinitrate,** $[Cr(NH_3)_5(H_2O)](NO_3)_3$, absorbs ammonia gas at a low temp., the decomposition curve shows that possibly a monammine is formed. Ammonia converts the salt into the hydroxypentamminonitrate, $[Cr(NH_3)_5(OH)](NO_3)_3$. F. Ephraim and W. Ritter found that ammonia gas is absorbed by chromic nitritopentamminonitrate, but the decomposition curve shows no breaks. H. J. S. King obtained **chromic hydroxypentamminodinitrate,** $[Cr(NH_3)_5(OH)](NO_3)_2.\frac{1}{2}H_2O$, by the action of the hydroxide on a soln. of ammonium nitrate, and precipitation with alcohol and ether. He gave for the conductivity, μ mhos, of a mol of the salt in v litres,

v	32	64	128	256	512	1024	2048
μ 0°	106·4	115·7	124·7	132·0	138·9	141·4	152·7
μ 25°	201·5	219·4	233·6	244·3	254·2	260·8	279·9

A. Werner and J. von Halban prepared **chromic nitratopentamminodinitrate,** $[Cr(NH_3)_5(NO_3)](NO_3)_2$, by the action of fuming nitric acid on chromic thiocyanatopentamminonitrate, or of nitric acid on aquopentamminohydroxide. The pale flesh-coloured powder is sparingly soluble in water, and the soln. is liable to decompose. A. Benrath found that with nitric acid, $[Cr(NH_3)_5(H_2O)](NO_3)_2$ may be formed. A. Werner and J. von Halban prepared **chromic nitratopentamminodiiodide,** $[Cr(NH_3)_5(NO_3)]I_2$, by shaking up the nitrate with solid potassium iodide and water. E. H. Riesenfeld and F. Seemann prepared **chromic nitratodiaquotriamminodinitrate,** $[Cr(NH_3)_3(H_2O)_2(NO_3)](NO_3)_2$, by the action of conc. nitric acid on the cold on chromic triamminotetroxide. A. Hiendlmayr prepared **chromic fluopentamminodinitrate,** $[Cr(NH_3)_5F](NO_3)_2$, by the action of calcium nitrate on the difluoride. S. M. Jörgensen prepared **chromic chloropentamminodinitrate,** $[Cr(NH_3)_5Cl](NO_3)_2$, by the action of nitric acid on a cold soln. of the chloride of the series. The carmine-red octahedra are soluble in water; at 17·5°, 100 parts of water dissolve 1·4 parts of salt. A. Werner and A. Miolati found that a mol of the salt in 125, 250, 500, 1000, and 2000 litres of water at 25° have the electrical conductivities μ=250·2, 265·9, 279·0, 288, 299·1 mhos respectively. P. T. Cleve, and S. M. Jörgensen prepared **chromic chloroaquotetramminodinitrate,** $[Cr(NH_3)_4(H_2O)Cl](NO_3)_2$, by the action of nitric acid on the chloride of the series. The carmine-red, or purple-red rhombohedral crystals lose no water over sulphuric acid; at 100°, the salt blackens. A. Werner and A. Miolati found that the soln. of a mol of the salt in 125, 250, 500, 1000, and 2000 litres of water at 25° has the electrical conductivity 206·5, 226·4, 244·7, 260·3, and 282·5 mhos respectively. S. M. Jörgensen prepared violet, octahedral crystals of **chromic bromopentamminodinitrate,** $[Cr(NH_3)_5Br](NO_3)_2$, by the action of nitric acid on the chloride of the series; and also reddish-violet crystals of **chromic iodopentamminodinitrate,** $[Cr(NH_3)_5I](NO_3)_2$. A. Werner and J. von Halban prepared **chromic thiocyanatopentamminodinitrate,** $[Cr(NH_3)_5(SCy)](NO_3)_2$.

S. Guralsky prepared **chromic dibromoaquotriamminonitrate,** $[Cr(NH_3)_3$-

$(H_2O)Br_2]NO_3$; P. Pfeiffer and W. Osann, **chromic dihydroxydiaquodipyridinonitrate,** $[CrPy_2(H_2O)_2(OH)_2]NO_3$; P. Pfeiffer and T. G. Lando, and A. Werner **chromic cis-dichlorobisethylenediaminonitrate,** $[Cr\,en_2Cl_2]NO_3$, and P. Pfeiffer and P. Koch, the **trans-salt.** A. Werner obtained greyish-blue needles of **chromic dichlorodiaquotriamminonitrate,** $[Cr(NH_3)_3(H_2O)_2Cl_2]NO_3$, by the action of nitric acid on the chloride of the series. Y. Shibata measured the absorption spectrum. P. Pfeiffer and M. Tapuach prepared **chromic dichlorodiaquodipyridinonitrate,** $[CrPy_2(H_2O)_2Cl_2]NO_3.2H_2O$; P. Pfeiffer and M. Tapuach, **chromic trans-dibromobisethylenediaminonitrate,** $[Cr\,en_2Br_2]NO_3$; **chromic dibromodiaquodipyridinonitrate,** $[CrPy_2(H_2O)_2Br_2]NO_3$; P. Pfeiffer and M. Tilgner, **chromic dithiocyanatotetramminonitrate,** $[Cr(NH_3)_4(SCy)_2]NO_3$; P. Pfeiffer and P. Koch, **chromic cis-dithiocyanatobisethylenediamine,** $[Cr\,en_2(SCy)_2]NO_3$; and P. Pfeiffer, the **trans-salt.** P. Pfeiffer and S. Basci also obtained **chromic oxalatotetramminonitrate,** $[Cr(NH_3)_4(C_2O_4)]NO_3.H_2O$.

S. M. Jörgensen prepared rose-red or pale carmine-red aggregates of needles of **chromic hydroxydecamminopentanitrate,** $[Cr_2(OH)(NH_3)_{10}](NO_3)_5$, by the action of nitric acid on the chloride or bromide of the series. The rhodo-salt so obtained is sparingly soluble in water. S. M. Jörgensen also prepared the erythro-salt in an analogous way. He also obtained **chromic trihydyroxyaquohexamminotrinitrate,** $[Cr_2(OH)_3(H_2O)(NH_3)_6](NO_3)_3$, in pale carmine-red needles sparingly soluble in cold water; and the soln. is liable suddenly to precipitate hydrated chromic oxide. The salt decomposes at 100°; and over sulphuric acid, it gives off a mol. of water. R. F. Weinland and E. Gussmann prepared **chromic dihydroxyhexacetatotripyridinonitrate,** $[Cr_3(CH_3COO)_6Py_3(OH)_2]NO_3.5H_2O$; and P. Pfeiffer and W. Vorster, **chromic hexahydroxysexiesethylenediaminohexanitrate,** $[Cr_4(OH)_6en_6](NO_3)_6.6H_2O$.

P. T. Cleve reported the salts **chromic diamminodihydroxydinitrate,** $Cr(OH)_2(NO_3)_2(NH_3)_2.\frac{1}{2}H_2O$; **chromic diamminopentahydroxynitrate,** $Cr_2(OH)_5(NO_3)(NH_3)_2.nH_2O$; and also **ammonium chromic heptamminoctonitrate,** $2Cr(NO_3)_3.2NH_4NO_3.(NH_3)_7.4\frac{1}{2}H_2O$; and **chromic oxalatohemienneamminonitrate,** $Cr(NO_3)(C_2O_4).4\frac{1}{2}NH_3.1\frac{1}{2}H_2O$. M. Z. Jovitschitsch dissolved a gram of hydrated chromic oxide in enough nitric acid, diluted the liquid to 25 c.c., added the same vol. of ammonia, and found that alcohol precipitated a soluble, scarlet mass of **chromic dioxyheptamminotrinitrate,**

$$\begin{array}{l}(NH_3)_2{=}Cr.O.NH_3.Cr{=}(NO_3)_2\\(NH_3)_2{=}\dot{C}r.O.NH_3.\dot{C}r(NO_3)(NH_3)\end{array}\quad 10H_2O$$

R. Weinland and co-workers prepared complex salts of the nitrate with pyridine, *o*-toluidine, guanidine, and aniline.

§ 33. Chromium Phosphates

A. Moberg [1] added sodium dihydrophosphate to a soln. of chromous salt and obtained a blue amorphous precipitate of **chromous phosphate,** $Cr_3(PO_4)_2.nH_2O$, which rapidly turns green on exposure to air forming, according to H. Moissan, a chromic salt. The precipitate is soluble in acids—*e.g.* in acetic, tartaric, and citric acids. It is insoluble in water, and a little soluble in water containing carbon dioxide. When heated under press. at 100° it remains amorphous. C. U. Shepard found it occurring naturally in green masses ; and he called it *phosphorchromite*. A. Colani was unable to prepare **chromous metaphosphate,** $Cr(PO_3)_2$, by the action of fused metaphosphoric acid on chromium or chromous salts, although the method is applicable for the corresponding ferrous salt.

L. N. Vauquelin [2] found that hydrated chromic oxide dissolves in an aq. soln. of phosphoric acid, forming an uncrystallizable, emerald-green liquid. When a soln. of chromic chloride is mixed with potassium phosphate, a green precipitate is obtained, which appears bluish-black after ignition, and yields a greenish-brown powder. If a hot soln. of chrome-alum is treated with an excess of sodium hydrophosphate, hydrated chromic phosphate is precipitated, and when this is heated, it yields brown **chromic orthophosphate,** $CrPO_4$. A. F. Joseph and W. N. Rae observed that the brown anhydrous salt is formed when any of the hydrates is heated to dull redness—*vide infra*. It is very resistant towards chemical agents being insoluble in hydrochloric acid or aqua regia, and only attacked by sulphuric acid when nearly boiling. It is then converted into an earthy-coloured powder, insoluble in water and acids, which appears to be a compound of chromium phosphate and sulphate of indefinite composition. The anhydrous phosphate requires calcining with lime before it can be dissolved by alkali-lye. W. Lapraik found that a soln. of hydrated chromic oxide in phosphoric acid shows an absorption band in the green. H. T. S. Britton studied the electrometric titration of soln. of chromic sulphate with sodium phosphate. W. J. Sell dialyzed a soln. of chromic phosphate in an ammoniacal soln. of ammonium hydrophosphate, and obtained **colloidal chromic phosphate.** N. R. Dhar and co-workers studied the adsorption of calcium salts by colloidal chromic phosphate. The electrical conductivity of the sol shows that there are no free ions exist in soln., and this is confirmed by the fact that the sol coagulates. J. A. Hedvall and J. Heuberger found that chromic phosphate begins to react with baryta: $2CrPO_4+3BaO=Ba_3(PO_4)_2+Cr_2O_3$ at 342°; with strontia at 464°; and with lime at 517°.

Some green pigments are composed essentially of chromic phosphate. Thus, J. Arnaudon obtained a green pigment by heating to 170°–180° for half an hour a mixture of 128 parts of normal ammonium phosphate and 149 parts of potassium dichromate, and washing the product with hot water. E. Mathieu-Plessy, and G. Köthe, by boiling 10 kgrms. of potassium dichromate in 100 litres of water, and 30 litres of a soln. of monocalcium phosphate, and 2·5 kgrms. of cane sugar; and G. Schnitzer, by melting 36 grms. of crystalline sodium phosphate, 15 grms. of potassium dichromate, and 6 grms. of tartaric acid and washing the product with cold hydrochloric acid, and then with hot water. J. Dingler employed a similar process. A. Carnot boiled a mixture of an alkali chromate, and sodium thiosulphate in the presence of phosphoric acid. W. Muthmann and H. Heramhof recommended chromic phosphate as a more stable pigment than chromic oxide for high temp. work.

C. F. Rammelsberg showed that when a cold soln. of sodium dihydrophosphate is added drop by drop to an excess of chrome-alum, the precipitate is lavender or violet, amorphous *hexahydrate;* and if this be allowed to remain in contact with the soln. for, say, 48 hrs., it furnishes the dark violet, crystalline hexahydrate. It may be washed by decantation, filtered, and dried in air. If the chrome-alum be not in excess, a violet powder is formed which does not crystallize if allowed to stand for days. H. Schiff added that this compound is formed only in acidic soln. when the chrome-alum is in excess. The triclinic crystals have a sp. gr. of 2·121 at 14°; A. F. Joseph and W. N. Rae gave 2·12 for the sp. gr. of the hexahydrate at 32·5°. All the hydrates at a low red-heat form the black anhydride, which has a sp. gr. 2·94 at 32·5°. The sp. gr. increases during a prolonged ignition owing to the loss of phosphoric oxide. The following data denote respectively the percentage losses and sp. gr.: heated over a bunsen burner for 1 hr., 1·2, and 3·16, and for 3 hrs., 2·4, and 3·29; heated 36 hrs. at 1100°, 4·4, and 3·42; and when heated 36 hrs. in a draught-furnace, 9·8, and 3·66; and for 50 hrs., 11·7, and 3·78. A. Étard stated that the hexahydrate lost 3·5 mols. of water at 100°. H. Schiff said that the hexahydrate forms a green pseudomorph at 100°, and loses 3 mols. of water, and a fourth mol. is not all expelled when kept for 4 days at this temp. H. Schiff said that when the hexahydrate is boiled with acetic anhydride it forms a green salt. C. F. Rammelsberg said that a green phosphate is formed if the chrome-alum soln. be added to an excess of a soln. of sodium dihydrophosphate. C. L. Bloxam acidified the soln. with acetic acid, and boiling the mixture—*vide infra;* and A. Carnot worked with a boiling acid soln. in the presence of sodium acetate—if a chromate soln. is used, it is reduced to the chromic state by the simultaneous addition of sodium thiosulphate. There is some difference of opinion as to the composition of the green hydrate dried at 100°. C. L. Bloxam, and A. Étard regarded it as a *hemipentahydrate;* and C. F. Rammelsberg, and A. Carnot, as a *trihydrate;* while H. Schiff found that the salt obtained by the action of boiling acetic anhydride on the violet hexahydrate is the green *dihydrate.* A. F. Joseph and W. N. Rae who observed no evidence of the existence of the hemipentahydrate or of the trihydrate, but, in agreement with H. Schiff, they observed the formation of the dihydrate, and found that the dehydration does not proceed any further if the boiling be prolonged. If the dry hexahydrate be heated, A. F. Joseph and W. N. Rae observed that the first break occurs when the dihydrate appears. The dihydrate has a sp. gr. of 2·42 at 32·5°; and H. Schiff represented it by the formula $(HO)_2=PO.O.Cr(OH)_2$. If the hexahydrate be left in contact with its mother-liquor, or with water, it forms a green, amorphous powder of the *tetrahydrate.* This change occurs if the crystals of the hexahydrate be left in contact with water, or with a soln. of sodium phosphate or of chrome-alum. The change is slow at low temp., for at 5° signs of the change appear only after 30 days, whereas at 100°, half an hour's boiling with water suffices for the production of the green, crystalline tetrahydrate. The violet crystals also passed into the green tetrahydrate when kept for 2 years at room temp. in air. The sp. gr. of the tetrahydrate is 2·10 at 32·5°. According to A. Carnot, the green hydrate is sparingly soluble in boiling water, and in soln. of ammonium nitrate, or acetate. C. L. Bloxam found it to be slowly dissolved by boiling conc. hydrochloric acid in sulphuric and hydrochloric acids, but the dihydrate is rather difficult to dissolve in the latter. C. L. Bloxam found that chromic phosphate is oxidized when boiled with nitric acid of sp. gr. 1·4 assisted by a little potassium chlorate. J. Dowling and W. Plunkett stated that the hydrated phosphate is not soluble in acetic acid, but is soluble in mineral acids from which it is precipitated unchanged by ammonia or ammonium sulphide. The hydrated phosphate is readily dissolved by alkali-lye, from which soln. it is deposited by boiling; but, added H. Kämmerer, much of the phosphoric acid remains in soln. A. F. Joseph and W. N. Rae said that chromite soln. are formed by the action of conc. alkali-lye, and that a soln. of sodium carbonate immediately converts the violet hexahydrate into a green basic salt, which retains alkali too tenaciously to be removed by washing. J. A. Hedvall observed that chromic phosphate reacts with barium oxide at 342°, forming barium phosphate and chromic oxide; and it reacts in an analogous manner with strontium oxide at 464°, and with calcium oxide at 517°.

S. M. Jörgensen prepared **chromic hexamminophosphate,** $[Cr(NH_3)_6]PO_4.4H_2O$, by adding sodium dihydrophosphate to a soln. of the hexamminotrinitrate, and then conc. ammonia. The yellow needles are sparingly soluble in water, and freely soluble in dil. acids, from which soln. the salt is precipitated unchanged by ammonia. It loses water slowly when confined in a desiccator over sulphuric acid; and rapidly when heated to 100° in air.

K. Haushofer obtained an acid salt—**chromic trihydrodiphosphate,** $CrH_3(PO_4)_2.8H_2O$—from a soln. of chromic phosphate in phosphoric acid; the triclinic crystals have the colour of chrome-alum, and are stable in air. A. Schwarzenberg obtained pale green hydrated **chromic pyrophosphate,** $Cr_4(P_2O_7)_3$, by adding sodium pyrophosphate to a soln. of chrome-alum; and L. Ouvrard, by melting sodium metaphosphate with chromic oxide. The pale green hydrate darkens at 100°, and loses nearly 3 mols. of water when heated. L. Ouvrard found that the monoclinic prisms obtained by his fusion process have a sp. gr. of 3·2 at 20°. The salt is soluble in soln. of sodium pyrophosphate, in strong mineral acids, in sulphurous acid, and in potash-lye. J. Persoz said that the pyrophosphate is not attacked by ammonium sulphide. A. Rosenheim and T. Triantaphyllides obtained salts of what they regarded as **chromipyrophosphoric acid,** $H(CrP_2O_7)$. Thus, by dropping into a sat. soln. of sodium pyrophosphate soln. a cold, conc. soln. of chromic chloride in conc. hydrochloric acid, grey **sodium chromipyrophosphate** is formed as an *octohydrate,* $Na(CrP_2O_7).8H_2O$, which becomes a pale green *pentahydrate* in a few days. Similarly, there were obtained pale green **potassium chromipyrophosphate,** $K(CrP_2O_7).5H_2O$; and grey, microscopic columns of **ammonium chromipyrophosphate,** $NH_4(CrP_2O_7).6H_2O$.

According to R. Maddrell, if a soln. of hydrated chromic oxide in an excess of dil. phosphoric acid be evaporated to dryness, and the product heated to 360°, **chromic metaphosphate,** $Cr(PO_3)_3$, is formed. K. R. Johnsson obtained it by heating chromic sulphate with metaphosphoric acid so as to drive off all the sulphuric acid; and P. Hautefeuille and J. Margottet, by melting chromic oxide or phosphate with four times its weight of metaphosphoric acid. The salt was prepared by J. Müller by treating 8 grms. of sodium metaphosphate with 300 c.c. of a conc. soln. of chrome-alum, with constant stirring at 70°; this soln. remains clear when boiled, or diluted with its own vol. of water. If this soln. be stirred for 4 days at ordinary temp. with 9 grms. of sodium metaphosphate, and the dark green solid be washed, and heated to 350°, chromic metaphosphate is produced. P. Hautefeuille and J. Margottet observed that the green, rhombic crystals are isomorphous with the metaphosphates of iron, aluminium, and uranium; K. R. Johnsson found the sp. gr. to be 2·974, and the mol. vol. 195. A. F. Joseph and W. N. Rae found that if heated for some time over a meker burner, it becomes brown, but regains its green colour on cooling; its sp. gr. is then 2·96, whilst the salt prepared by R. Maddrell's process had a sp. gr. of 2·93. The salt is insoluble in water and in mineral acids. P. Glühmann found that a violet crystalline or green amorphous **chromic triphosphate** is produced by the action of sodium triphosphate on a chromic salt—*vide* **8**. 50.

L. J. Cohen could not prepare **ammonium chromium phosphate,** by adding ammonium dihydrophosphate to a strongly acidic soln. of chromic chloride, but by reducing the acidity, a green, gelatinous precipitate with the composition $(NH_4)_2HPO_4.2CrPO_4.3H_2O$ was obtained; but if no hydrochloric acid or only a very small proportion was present **ammonium chromium hydroxyphosphate,** $5NH_4(H_2PO_4).2CrPO_4.4Cr(OH)_2$, was produced. L. J. Cohen found that the precipitate obtained on boiling soln. of chromic salts with sodium phosphate and acetic acid, is not, as C. L. Bloxam supposed, an impure chromic phosphate, but rather **sodium chromium phosphate,** $Na_2HPO_4.2CrPO_4.5H_2O$, which, when repeatedly washed with water, is converted into a basic salt. H. Grandeau obtained pale violet crystals of **potassium chromium phosphate,** $3K_2O.2Cr_2O_3.3P_2O_2$, by fusing a mixture of chromic and potassium phosphates.

K. A. Wallroth prepared **sodium chromium pyrophosphate,** $NaCrP_2O_7$, by cooling a molten mixture of microcosmic salt and chromic oxide; and L. Ouvrard obtained from a soln. of chromic oxide or chromic phosphate in molten sodium metaphosphate; or of chromic phosphate in molten sodium pyrophosphate. The green rhombic prisms have a sp. gr. 3·0 at 20°. S. M. Jörgensen treated a soln. of chromic hexamminonitrate with sodium pyrophosphate and then with ammonia. Yellow, six-sided plates of **sodium chromic hexamminopyrophosphate,** $Na[Cr(NH_3)_6]P_2O_7.11\frac{1}{2}H_2O$, were produced. The salt is insoluble in cold water; and when confined over sulphuric acid for a few months, it loses $10\frac{1}{2}$ mols. of water; at 130°, some ammonia as well as water is given off. J. Persoz treated a soln. of a chromic salt with potassium pyrophosphate, and obtained a soln. which was not precipitated by ammonium sulphide. L. Ouvrard melted potassium metaphosphate with chromic oxide, or potassium dichromate with chromic phosphate and obtained monoclinic prisms of **potassium chromic pyrophosphate,** $KCrP_2O_7$, of sp. gr. 3·5 at 20°.

C. Friedheim and I. Mozkin[3] prepared **ammonium phosphatotetrachromate,** $(NH_4O.CrO_2.O.CrO_2.O)_2 : PO.(ONH_4)$, by evaporating soln. of a mol each of ammonium dichromate and phosphorus pentoxide or from a soln. of equimolar proportions of ammonium dihydrophosphate and chromium trioxide, or by heating a mixture of 2 mols of phosphoric acid, 4 mols of chromium trioxide, 2 mols of ammonia, and a mol of ammonium dihydrophosphate. The salt forms dark red crystal aggregates; when the soln. of the salt is recrystallized from its aq. soln., ammonium dichromate, and phosphoric and chromic acids are formed. They also prepared **potassium phosphatodichromate,** $(KO.CrO_2.O.CrO_2.O)(KO) : PO.OH$, from a mixture of potassium dichromate with an excess of phosphoric acid. M. Blondel obtained it by mixing a highly conc. soln. of phosphoric and chromic acids, containing 8 mols of the latter to one mol of the former, with three-fourths of a mol of potassium carbonate. A salt of the composition $3K_2O.P_2O_5.8CrO_3$, or **potassium phosphatotetrachromate,** $(KO.CrO_2.O.CrO_2.O)_2PO(OK)_2$, is precipitated in the form of small, short prisms. If the soln. contains only two mols of chromic acid, needles of the phosphatodichromate are formed. If the latter soln., however, is mixed with some crystals of the first salt, the precipitate at first consists of phosphatotetrachromate, but, if left in contact with the liquid, it is converted into the phosphatodichromate. The phosphatotetrachromate is converted into the phosphatodichromate by treatment with water or with a sat. soln. of potassium dichromate. For some complex phosphohalides, *vide supra*, chromyl chloride.

CHAPTER LXI

MOLYBDENUM

§ 1. History of Molybdenum

The extraordinary confusion in the use of the terms plumbago, graphite, galena, and molybdena, which prevailed from the time of Aristotle, *circa* 350 B.C. to the 18th century, has been discussed in connection with carbon, and with galena. It is very difficult to pick out from the various references those which in all probability refer to molybdena. The term *molybdœna* is the Latinized form of the Greek *μολύβδαινα*, which is derived from *μόλυβδος*, lead. The term *μολύβδαινα* appears to have been applied by Aristotle,[1] Dioscorides, Galen, Pliny, etc., to various things associated with lead—plummets, sinkers for fishing nets, bullets for catapults, etc.—to lead oxide obtained as a by-product in cupellation, and to natural lead ores.

According to J. W. Evans, during the 17th century, the terms *lapis plumbarius*, *plumbago*, and *galena*, and exceptionally *molybdœna*, were employed in the sense of graphite, including, probably, molybdenite with which it was confounded. Later, molybdæna was commonly employed for graphite, and galena became identified with the mineral which now bears that name. It was soon recognized that molybdæna and graphite did not contain lead; and those who experimented on molybdæna seem to have regarded it as a kind of zinc sulphide. J. F. Henckel,[2] for instance, used the molybdæna for zinc-blende; and J. G. Hoffmann and J. B. Böhmer associated the term molybdæna with tin, and they also confused it with graphite. In his work on *nihil* or sublimed zinc oxide, I. Lawson described molybdæna, and this appears to have been molybdenite, although he believed it to be identical with graphite. J. G. Wallerius' minerals *ren Blyertz* or molybdæna pura, and *oren Blyertz* or molybdæna impura included graphite and molybdenite. In 1754, in a paper: *Rön om Blyerts*—the Swedish term for graphite, B. Qvist described some experiments on a mineral occurring in flexible plates which must have been molybdenite. A. von Cronstedt's description of *molybdena membranacea nitens* from Bispberg, Sweden, is applied to the molybdenite employed in B. Qvist's experiments. J. W. Baumer distinguished the non-combustible Wasserbley or molybdæna of Bispberg from the combustible Wasserbley or molybdæna or *plumbum scriptorum* used for making pencils. C. Linnæus referred to *molybdœnum tritura cœrulescente*, or molybdenum with a bluish streak; and this was possibly the mineral investigated by B. Qvist.

The confused ideas which prevailed up to 1778 as to the nature of graphite and molybdenite were at length dissipated by the work of C. W. Scheele described in papers entitled *Försök med Blyerts, Molybdœna* (1778), and *Försök med Blyerts, Plumbago* (1779). In his first paper, C. W. Scheele showed that the *molybdœna membranacea nitens* on which B. Qvist made his experiments, is a combination of an acid of a metallic nature with sulphur; and in his second paper, he demonstrated that the *molybdenœna textura micacea et granulata* of A. von Cronstedt, is a mineral charcoal composed of an aerial acid—carbonic acid—and phlogiston with a small proportion of pyrites. Translating C. W. Scheele's statement into modern nomenclature: aerial acid+phlogiston=carbon. It is not stated why the term molybdæna was allocated to molybdenite when, at that period, graphite was the more usual term; but afterwards, when he wanted a term for graphite, he naturally adopted the Latin term plumbago. C. W. Scheele's usage fixed the subsequent terms molybdæna and graphite or plumbago. For example, T. Bergman, W. Withering, J. Fibig, A. G. Werner, D. L. G. Karsten, and R. Kirwan followed C. W. Scheele. J. B. L. Romé de l'Isle was studying graphite at the same time as C. W. Scheele, and he expressed the belief that C. W. Scheele's molybdæna is micaceous iron ore, *mine de fer micacée grise,* and that his plumbago owed its action on nitre *au fer noirâtre phlogistiqué, en un mot à l'éthiops martial natif et à la matière grasse qui s'y rencontrent.* The subject was discussed by B. G. Sage, and P. J. Macquer.

In 1782, P. J. Hjelm[3] separated the metal from molybdæna, and called it **molybdenum.** B. Pelletier also isolated the metal which was thereafter studied by J. J. Berzelius, and C. F. Bucholz. R. Kirwan[4] applied the term **molybdenite** to the metal, but A. Brongniart's use of the term molybdenite for the mineral sulphide is in general use in England and France. In Germany, the old term *Molybdän,* as well as D. L. G. Karsten's term *Molybdänglanz,* are used for the sulphide.

M. Ogawa[5] reported that molybdenite and thorianite contain a new element closely allied to molybdenum, and probably identical with the new tin-group element reported by C. de B. Evans in thorianite. The element was said to differ from molybdenum in being soluble in hot conc. hydrochloric acid, and in giving no colour reaction when its higher oxide is reduced with tin and hydrochloric acid either in the presence or absence of potassium thiocyanate. M. Ogawa also reported another element which he called *nipponium,* to occur in molybdenite, thorianite, and reinite; this element was said to fill the gap between molybdenum and ruthenium. These results have not been confirmed. R. Nasini and E. Baschieri could find no nipponium in the molybdenite from Stilo, Calabria. G. G. Boucher[6] extracted from cast-iron and blast-furnace boiler-dust "a new element" which was shown by F. G. Ruddock, and C. H. Jones to be molybdenum mixed with iron.

M. Gerber reported that molybdenum is not a simple substance, but that it is accompanied by an isotope which is chemically and spectroscopically identical. He called this element *neomolybdenum.* He said that neomolybdenum was separated from molybdenum by fractional crystallization of a specimen of ammonium molybdate prepared from molybdenite from Glen Innis, New South Wales. The most soluble fractions, when analyzed, have for the metal an at. wt.$=99{\cdot}9$ (Mo$=96$), and, moreover, the acidic oxide obtained by heating this ammonium salt was far more volatile than ordinary molybdic acid. These statements have not been confirmed.

§ 2. The Occurrence of Molybdenum

Molybdenum does not occur in the elemental form in nature. Its compounds are among the scarcer constituents of the earth's crust. According to F. W. Clarke and H. S. Washington,[1] the average proportion of molybdenum in the igneous rocks of the earth's crust is $n \times 10^{-6}$ per cent. J. H. L. Vogt estimated $n \times 10^{-7}$ per cent. W. Vernadsky gave $0{\cdot}0_5 9$ for the percentage amount, and $0{\cdot}0_4 5$ for the atomic proportion. W. and J. Noddack and O. Berg gave 10^{-7} for the absolute abundance of molybdenum on the earth. The general subject was discussed by H. S. Washington, G. Tammann, V. M. Goldschmidt, E. Herlinger, A. von Antropoff, O. Hahn, and J. Joly. H. A. Rowland [2] included molybdenum among the elements which had been detected spectroscopically in the sun; although C. C. Hutchins and E. S. Holden failed to detect molybdenum lines in the solar spectrum. J. N. Lockyer, however, attributed certain lines in the spectrum of the sun to molybdenum; and S. Albrecht detected the lines of this element in the spectrum of γ-Geminorum.

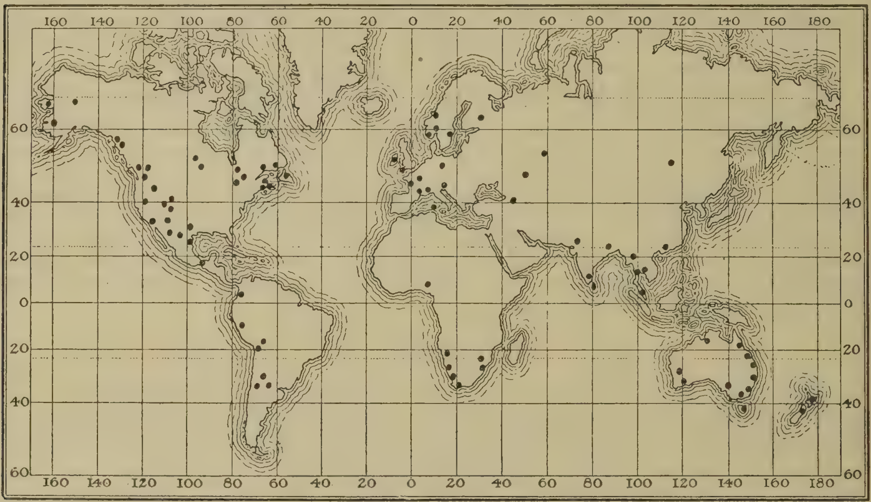

FIG. 1.—Geographical Distribution of the Molybdenum Ores.

The two minerals of practical importance are molybdenite, MoS_2, and wulfenite, $PbMoO_4$. Molybdenite—molybdenum sulphide—is a pneumatolytic product derived from granitic magmas. Most of the occurrences of molybdenite are closely associated with acidic plutonic rocks, particularly the granites. It occurs embedded in the granite itself, or along open joints or in dykes cutting the granite or the neighbouring rocks. It also occurs in deep-seated veins allied to the pegmatites, or in the fissure veins of metalliferous lodes. The mineral is here of direct magmatic origin, and is concentrated in the later solidifying portions of the magma along with tin, wolfram, and sulphides; and it is frequently associated with fluoriferous minerals—tourmaline, topaz, and fluorspar. Molybdenite is sometimes associated with crystalline limestone or lime-silicate rocks formed by the thermal metamorphism and metasomatism of calcareous deposits near the granite. This case is illustrated by some of the Canadian deposits where the molybdenite has been produced by the transfer of material from the granitic magma to the sediment, and recrystallization. In the west of the United States, the wulfenite—lead molybdate—is usually a secondary mineral which has been formed in the oxidation zone of the upper levels for both lead and molybdenum occurs as sulphides lower down. The subject was discussed by G. O. Smith,[3] A. R. Crook, J. W. Wells, W. H. Emmons, W. C. Brögger, F. Schafarzik, R. Brauns, L. W. Staples and C. W. Cook, and E. Thomson.

The geographical distribution[4] of the more important molybdenum ores is summarized in the map, Fig. 1. The chief localities are as follow:

Europe.—Small quantities of molybdenite have been reported from a number of localities in the **British Isles**[5]—*e.g.*, at Lalant, Marazion, St. Day, Guinear, etc. in Cornwall; Mount Sorrel, Leicestershire; Carrock Fell, Cumberland; Tomnadashan, Perthshire; in the granites of Galloway, Argyleshire, and Inverness; Murvey, Galway; near Lough Laragh, Inishdovey, Donegal. In no case is any deposit of commercial value. No deposits are worked in **France**[6] on a commercial scale. Molybdenite has been reported at Miséri, near Nantes; in Haute Vienne; at St. Léonard, Limoges; Chessy, in the Central Plateau; the red granite of Glacier de la Meije, Dauphiné; in the gneiss near the Mer de Glace; and in the Vosges. Molybdenum concentrates have been exported from **Spain.**[7] There are molybdenum occurrences on the Sierra de Guadarrama, Villacastin, Navacerrada, Hoyo de Manzanares, and at the Torrelodones tunnel; also at Cuevas de Salabe, Asturias; Espinabel, Gerona; Socorro mine, Linares; Madronal, San Roque, Sierra de Mijas, Málaga; Sierra Nevada and in several places in Granada. It also occurs at Vélez de Benaudella, and Güéjar, Sierra, near Albunuelas; in the Umbrua del Madronal; and in Almeria. Molybdenite occurs in a few places in **Italy**[8]—*e.g.* Traversella, Drusacco, Quittengo, Bolladore, Villaputzu, Sardinia, and at Monte Somma. In **Switzerland,**[9] occurrences of molybdenum have been observed at Binnenthal, Lucendro, Mürtschenalp, Aletsch, and Visp; and in **Austria,**[10] at Salzberg, Zillerthal, and Schmirn. Occurrences have been found in **Yugo-Slavia**[11]—*e.g.* in Carinthia (Slovenia). Molybdenite occurs in various parts of **Russia**[12]—*e.g.* near Bash Abaran, Caucasus; in the Zanguezar district, on the Ilmensky Hills, near the River Cherelipanky; there are deposits in **Finland,**[13] and at Mätäsvaara, and Pitkäranta. In **Germany,**[14] molybdenite occurs as a rare constituent of the stanniferous veins of Geyer, Erzgebirge; at Sanberge, Ehrenfriedersdorf; and at Sadisdorf, Saxony. Molybdenite occurs in **Sweden**[15] near Nörrköping; and on the Island of Ekholmen in Vestervik. There are important deposits of molybdenum ore in **Norway,**[16] which is regarded as one of the principal producers. Most of the Norwegian output is from mines in the districts of Knaben, Moi, Siredalen, Mandal, Telemarken, Drammen, and Haugesund. The ore has been worked on a small scale at Syversvolden, Ostvaago, Smölen, Langvaten, and Tjaardalskampen. Molybdenite is an accessory constituent of many of the igneous rocks of Norway—Laurvik, Frederiksvärn, Langesundfjord, Lövö, and Klokkerholmen.

Asia.—A. E. Fersman[17] reported molybdenite in the Selengan Dauria, **Transbaikalia.** Molybdenite occurs in a vein of pegmatite at Hetimulla, Kegalla, and Saffragam in **Ceylon.**[18] Considerable amounts of molybdenite are associated with wolfram and tin in **Burma**[19]—*e.g.* Yamethin, South Shan States, Thaton, Tavoy, and Mergui. In **India,**[20] molybdenite occurs in the rocks of Chota Nagpur; Rajputana; South Travancore; Madura; Trichinopoly; Kurinavaram; Mangamalai; Oregum, Mysore; Patria River, Mahabagh; and Urmi, Bengal. Molybdenum ores have been reported at Chantabun on the east coast of **Siam**;[21] in Kwang-tung in **China**; and at Gifu, Toyania, Niigata, Totori, and Hyogo in **Japan.**[22] In **Siberia,**[23] and Asiatic Russia, there are deposits in the Kirghiz Steppes, and in the Transbaikul province, etc.

Africa.—J. Barthoux[24] described the deposits of wulfenite in **Morocco**; G. Castelli, those in Portuguese **Angoli**; and R. A. Farquherson, those in **Somaliland.** Molybdenite has been reported in Nigeria[25] near Jos, and in the Jarawa Hills, as well as in the cassiterite veins of Dogon Daji. In **Southern Rhodesia,**[26] molybdenite occurs at Umtali, Hartley district, and near Bulawayo; in **South West Africa,**[27] south of Usakos; in the Kuiseb Valley; at Aus, and in the Velloor Hills, Warmbad district; at Gansberg; and Tsumeb. The ore occurs in many places in the **Union of South Africa**[28]—*e.g.* in the granite rocks near Stellenbosch, Cape Province; in various localities of the copper district of Little Namaqualand; in the Transvaal at Appingadam, Stavoreu, Enkeldoorn, and Houlenbek; and in Natal in the valley of Hlatimba, and at Umkukuse, Subeni, and in Buffalo valley.

North America.—Extensive deposits of molybdenite occur in **Canada**[29]—British Columbia, Manitoba, New Brunswick, Nova Scotia, Ontario, Quebec, and Newfoundland. Deposits occur in the **United States**[30] in Arizona, California, Colorado, South Dakota, Maine, Montana, Nevada, New Mexico, Texas, Utah, and Washington. Molybdenite occurs in Shaken in **Alaska.**[31] Molybdenite has been reported from the Leeward Islands, **West Indies**;[32] and from Hawaii.[33] Ores have been reported from a dozen states in **Mexico**[34]—San José, Tamaulipas; Nacosari, Sonora; Sahuaripa, El Poovenir, Temascaltepec, Chihuahua, Hidalgo, etc. Molybdenite also occurs in Central America.[35]

South America.—Molybdenite has been found in **Argentina,**[36] at San Virgilio, Sierra de Cordoba; and Los Coloraditos, Sierra de Velasco. In **Bolivia,**[37] the mineral occurs in the Tasna district, Oruro; and in Larecaja, La Paz. In **Chile,**[38] molybdenite has been reported at Cupane, and La Punta. In **Peru,**[39] in the Jauja province, Junin; at Runatullo, Picran; Torrioc ridge, Janchis-Jucha; Tipillapa; and Caseas, Contumaza. In **Brazil,**[40] at Vallongo. It also occurs at Santa Rita and Patagonia.[41]

Australasia.—In **New South Wales,**[42] molybdenite occurs in the New England district—Wilson's Downfall, Rock River or Wanglebung, Bolivia, Deepwater, Glen Eden, Kingsgate, Yarrow Creek, Booralong or Balderleigh, Attunga and Moonbi; in the Yetholme district—Mount Tennyson, Gemaila, and Tarana; and in the Whipstick district—Jingera, Mount Metallic, Black Range, and Tantawanglo. In the **Northern Territory,**[43] deposits occur at Yenberrie, and Hatches Creek. In **Queensland,**[44] there are large deposits of molybdenum ore, at Stanthorpe, Ballandean; in the northern area in the Chillagoe district; the Wolfram area, the Bamford Mining field; Rocky Creek area; Khartoum area; Tyrconnel; Mt. Perry; and Boomarrie. In **South Australia,**[45] molybdenum occurs in the Moonta and Walaroo areas. In **Victoria,**[46] molybdenum ore occurs at Wangrabelle, Gippslund; and at Everton, in the Beechworth district. In **West Australia,**[47] molybdenum ores occur near the Yalgoo goldfield; near Leonora; at Callie Soak; Coolgardie; in the Mount Margaret goldfield; at Southern Cross, Swan View, Wagin, Ravensthorpe, Clackline, and Blackboy Hill. In **New South Wales,**[48] mobybdenite occurs near Kingsgate. In **Tasmania,**[49] small deposits occur in various localities—*e.g.* on the West side of Mt. Stronach; in the hinterland of Scamander district; in the district of Moina; East of River Forth; King Island; and South Heemshirk. In **New Zealand,**[50] molybdenite has been reported at Ohio Creek, Thames Goldfield; at Fourteen-mile Creek, Greymouth; in the Mt. Radiant district; near Specimen Creek; at Richmond Hill, Parapara; Bravo Island; and near Dusky Sound.

Before 1914, molybdenum metal sold at about 6/– per lb.; in 1918, ferromolybdenum with 50 to 60 per cent. molybdenum sold at about 16/– per lb.; and in 1920, at about 9/6 per lb. The price of molybdenum ore in 1924 ranged from 52*s.* 6*d.* to 55*s.* 0*d.* per unit. Reliable data for estimating the world's output have been available only in comparatively recent times. Until the demand for molybdenum for the manufacture of special steels arose, the greater part of the world's output was absorbed in the manufacture of a few chemical reagents. R. H. Rastall[51] estimated for 1915–1920 the proportion of metal in metric tons contained in the concentrates produced by different countries, to be as follows:

	1915	1917	1918	1920
Australia . . .	70·8	94·4	105·1	35·5
Bolivia . . .	6·5	—	—	—
Canada . . .	8·0	89·9	102·9	nil
Chile . . .	—	20·1	—	—
China . . .	—	2·4	1·1	—
Korea . . .	—	59·2	10·7	—
Japan . . .	—	12·1	70·3	—
Mexico . . .	—	—	14·0	0·3
Norway . . .	72·3	82·1	84·9	—
Peru . . .	1·3	3·8	1·3	1·0
Spain . . .	5·2	—	—	—
Sweden . . .	—	20·3	25·1	—
United States . .	82·4	158·8	390·8	15·8

The minerals containing molybdenum include the crystalline sulphide, **molybdenite,** MoS_2, or the colloidal form, **jordisite:** the molybdates, **wulfenite,** $PbMoO_4$; **powellite,** $CaMoO_4$, associated with $CaWO_4$; **belonosite,** $MgMoO_4$; **molybdic ochre,** or **molybdite,** $MoO_3.nH_2O$, and $Fe_2(MoO_4)_3.nH_2O$—possibly a mixture; **ochrematite,** $3\{3Pb(AsO_4)_2.PbCl_2\}.4Pb_2MoO_5$; **ferrous tetramolybdite** of M. Spica;[52] **pateraite,** impure $CoMoO_4$; **ilsemannite,** or blue oxide, $MoO_2.4MoO_3$, or $Mo_3O_8.nH_2O$.

W. F. Hillebrand[53] reported on the molybdenum content of the American rocks; and M. Spica analyzed the molybdenum minerals of Stilo, Calabria. C. J. Heine discussed the molybdenum content of the copper *schists* of Mansfield, and P. Krusch, that of Rickelsdorf; K. Chuboda, that of *manganese diaspore;* C. D. Braun, that of the vanadiferous *iron ores of* Xaverloh, Harz; F. Wöhler, that of *iron*, and *iron slags;* L. A. Palmer, *clays;* C. R. Fresenius and E. Hintz, that of *hardhead tin;* H. Traube, that of *scheelite;* H. St. C. Deville, that of *rutile;* C. de B. Evans, that of *thorianite*, and W. Steinkuhler, that of *pitchblende;* A. Jorissen discussed the occurrence of molybdenum in the Liège coal-field; and H. Ramage, in the flue-dusts from South

Yorkshire coals. A. Schacci observed that a small proportion of molybdenum occurs in the crusts of the fumaroles in the craters of Vesuvius; J. B. Ferguson, in the volcanic lava of Hawaii; and F. Zambonini, in vesbine in crevices of the Vesuvian lava of 1631. T. L. Phipson showed that the so-called vesbium (**9**. 53, 1) is a mixture of copper and molybdenum.

E. Demarçay [54] observed molybdenum occurring in the ashes of some plants—Scotch fir, silver fir, vine, oak, poplar, and hornbeam; and F. von Oefele, in the excrement of animals.

§ 3. The Extraction of Molybdenum

The molybdenum ores are first concentrated.[1] In the case of wulfenite ores, this operation is comparatively simple because the mineral has a high sp. gr. and is easily wetted. Hence, water separation can be employed for removing the gangue. Pneumatic concentration has also been used when water is scarce. Molybdenite is not usually treated by water separation because the flaky mineral is not easily wetted, and it is liable to float. The ores are poor—over 2 per cent. of molybdenite is rare. The electrostatic process can be employed with ore rather coarsely crushed. The ore is dried and warmed. Other sulphides also collect with the molybdenite, and the flotation process is the most successful mode of concentrating the ore. Water flotation is used in some cases, but oil flotation—in different forms—is more generally employed.

The extraction of molybdates or molybdic acid.—F. Wöhler,[2] and J. J. Berzelius recommended roasting the sulphide in a current of air so as to collect the sublimate of molybdenum trioxide. C. Brunner roasted an intimate mixture of the sulphide with sand, with stirring until the mass became yellow. The molybdic acid was extracted with aq. ammonia; and the unoxidized residue was roasted again. The ammoniacal soln. was treated with a little ammonium hydrosulphide to precipitate the copper; the filtrate was evaporated to dryness; extracted with dil. ammonia; and the filtrate evaporated for the crystallization of ammonium molybdate. R. W. Stimson, C. Svensson, and L. F. Svanberg and H. Struve used modifications of the process. F. Luchs deflagrated a mixture of potassium nitrate and molybdenite, extracted the mass with water, and treated the product with nitric acid. A. Kissock roasted a mixture of the sulphide with lime.

K. Christl melted a mixture of powdered wulfenite and sodium carbonate, and poured out the molten mass so that the alkali molybdate was separated as much as possible from the lead oxide. The cold cake was extracted with hot water. The filtrate was treated with a little ammonia and ammonium carbonate to precipitate lead carbonate; and the filtrate was mixed with nitric acid and evaporated to dryness. The sodium nitrate was removed from the molybdic acid by extraction with water. C. Elbers modified the process by adding iron turnings or carbonized potassium tartrate to the original mixture. This reduces the lead to the metal, but not the molybdic acid. A. Kissock roasted the ore mixed with a calcium salt, so as to form calcium molybdate and, similarly, by roasting with ferric oxide or sulphide, ferric molybdate is formed. The product was then treated for molybdic acid. J. W. Weitzenkorn heated a mixture of molybdenite with manganese oxide in the presence of oxygen. F. D. S. Robertson roasted the sulphide ore to oxide, and then volatilized the molybdenum trioxide. B. Broch, and P. Schwarzkopf heated the ore at 1100°–1500° in dry oxygen to volatilize the trioxide; and S. Westberg and E. Edwin first reduced the ore with hydrogen before the oxygen treatment. E. K. Jenckes leached roasted molybdenite with aq. ammonia; precipitated iron, copper, and calcium from the soln.; and this, when crystallized, furnished ammonium molybdate. Guggenheim Bros. heated the ores in a gas containing sulphur—*e.g.* sulphur vapour, hydrogen or carbon sulphides—so as to form a volatile sulphide. G. D. van Arsdale and co-workers washed the roasted ore with dil. sulphuric acid, treated it with alkali-lye to form alkali molybdate, and regenerated the alkali-lye at the anode. F. L. Hahn and W. Franke heated the molybdate at 250° to 300° with carbon tetrachloride under press., and extracted the product with acid.

F. Ullik washed the wulfenite ore with dil. hydrochloride acid to remove carbonates, phosphates, oxides, etc. ; the washed product was digested with hot, conc. hydrochloric acid ; the soln. was concentrated and cooled to separate lead chloride ; and the remaining lead precipitated as lead sulphate ; or else the soln. was evaporated to dryness, and the molybdenum compound extracted with aq. ammonia as recommended by F. Wöhler. Basic lead chloride remained. Ammonium molybdate was crystallized from the soln. ; or else the soln. was evaporated with nitric acid, and the ammonium nitrate removed from the molybdic acid by washing with water. H. Debray purified the ammonium molybdate by heating to redness a mixture with an equal amount of ammonium chloride, and roasting the product. The purification of molybdenum salts is discussed in memoirs dealing with the at. wt. (*q.v.*). C. Elbers decomposed wulfenite by heating it with conc. sulphuric acid ; and after evaporation, the blue liquid was diluted with water. The filtrate from the lead sulphate was mixed with nitric acid and evaporated. Molybdic acid separated out, and this was washed with water acidulated with nitric acid. The filtrate was again diluted and treated with nitric acid to recover more molybdic acid. W. Delffs, and A. Rodland decomposed the mineral with nitric acid, but C. Elbers, and A. von Wich did not recommend the process.

L. A. Buchner and F. Mahla heated a mixture of wulfenite and carbon in a current of chlorine, and extracted the molybdenum chloride with alcohol. P. Nicolardot opened up the wulfenite by fusion with potassium hydrosulphate ; extracted the cold mass with water ; evaporated the soln. to dryness ; and heated the product with carbon and sulphur to form molybdenum disulphide. F. Wöhler heated a mixture of wulfenite, carbonized sodium tartrate, and sulphur ; dissolved the sodium sulphomolybdate in water, and on treating the soln. with sulphuric acid, molybdenum trisulphide was precipitated. This was washed, dried, and heated out of contact with air. The resulting molybdenum disulphide was roasted for molybdenum trioxide. G. E. Mauritii obtained the sulphomolybdate by boiling the mineral with potassium carbonate and sulphur ; F. Wöhler, with soda-lye and sulphur ; G. C. Wittstein, with sodium polysulphide ; and W. Wicke, with aq. ammonium sulphide.

According to J. P. Bonardi, when wulfenite is first concentrated, the concentrate contains 15 to 20 per cent. of MoO_3. The vanadinite, cerussite, anglesite, galena, pyromorphite and mimetite collect in the concentrate. The ore can then be treated with an acid or an alkaline leach, or fused with something which will reduce the lead to the metallic form and leave the molybdenum in the slag. The acid leach is the least favourable process. The sodium sulphide leach has proved most satisfactory. The molybdenum passes into soln. as sodium molybdate, the lead and precious metals collect in the residues. The sodium molybdate can then be used for the preparation of ferromolybdenum, etc. If the concentrate be fused with soda-ash, caustic soda, and coal, the lead is recovered as bullion, and the sodium molybdate can be leached from the slag. The subject was discussed by R. E. Head and V. Miller.

R. E. Pearson and co-workers [3] proposed an electrolytic process for extracting the molybdenum. The ore is ground and mixed to a paste with sulphuric acid, and the mixture is replaced on a lead plate which forms the anode of an electrolytic cell containing dil. sulphuric acid. On passing a current through the cell the basic impurities, *e.g.* iron, manganese, calcium or sodium oxide, in the material on the anode pass into soln., leaving a residue of tungsten or molybdenum oxides. Alternatively the anode may consist of nickel or a nickel alloy, and the electrolyte of caustic soda, whereby soluble sodium tungstate or molybdate is formed and the foreign metals are left as anode slime.

In working up molybdenum residues which collect in the determination of phosphates in the analysis of manures, steel, etc., the molybdic acid has to be separated from phosphates. J. A. Prescott[4] evaporated the soln. to dryness; dissolved the residue in aq. ammonia; and treated the soln. with magnesia mixture to precipitate the phosphoric acid. The soln. was then evaporated to allow the ammonium molybdate to crystallize, and the mother-liquors worked up with a subsequent collection of molybdenum residues. Processes were also described by C. R. Fresenius, F. Muck, O. Maschke, H. Uelsmann, E. Reichardt, A. Gawalowsky, A. Bornträger, W. D. Brown, R. Friedrich, H. Kinder, P. Rudnik and R. D. Cooke, C. G. Armstrong, H. Rubricius, E. Stamm, etc. V. Lenher and M. P. Schultz diluted the waste molybdate liquor, or treated it with alkali so that the amount of free nitric acid is reduced to 0·1–0·4 per cent. Hydrogen sulphide is then passed into the soln., preferably warm, and the precipitated molybdenum sulphide is washed and dried, after which it may be converted into the trioxide by roasting. Again, ammonium phosphomolybdate is dissolved in sufficient aq. sodium hydroxide to make a soln. just alkaline to phenolphthalein; the liquid, after filtration if necessary, is treated with hydrogen sulphide, and the molybdenum sulphide precipitated by acidifying with dil. hydrochloric acid.

The preparation of the element.—J. J. Berzelius,[5] F. Wöhler, C. F. Rammelsberg, C. W. Blake, J. H. Müller, P. Sabatier and J. B. Senderens, L. F. Svanberg and H. Strüve, and H. N. Warren, obtained the metal by heating molybdenum trioxide to a high temp. in a current of *hydrogen.* Since this oxide is volatile at a high temp. as pointed out by H. Debray, and A. Rogers and F. H. Mitchell, it is better to work at a lower temp. at first so as to make the less volatile lower oxides, and reduce these at the higher temp. M. Guichard said that the reduction to the brown dioxide begins at 300°, and the dioxide begins to reduce at about 500°, and is fairly rapid at 600°. The sole product of the reduction is molybdenum—the incompletely reduced portion is a mixture of molybdenum and its dioxide. Finely-divided molybdenum is not appreciably oxidized by steam at temp. below 700°. Consequently, the steam produced by the action of hydrogen on the oxides of molybdenum at 600–700° has no tendency to reverse the action, and may be considered as an inert gas; above 700°, however, it is a reagent and the inverse change becomes possible. When molybdenum and its dioxide are heated at these temp. in a mixture of hydrogen and steam, both reactions, oxidation and reduction, occur simultaneously, and the state of equilibrium finally attained: $MoO_2+2H_2 \rightleftharpoons Mo+2H_2O$ depends on the partial press. of the constituents of the gaseous mixture. The metal or its dioxide is not affected at 800° by a current of the gaseous mixture containing its constituents in approximately molecular proportion; when the proportion of steam is larger than this, the metal is almost wholly oxidized to dioxide, whilst excess of hydrogen brings about a complete reduction of the oxide. L. Meyer and H. Haas, and L. P. Liechti and B. Kempe found that it is difficult to remove all the oxygen from the reduced metal by hydrogen and they said that the last traces of oxygen can be removed by dry hydrogen chloride at 200°, but A. Vandenberghe, and M. Guichard showed that molybdenum dioxide does not volatilize when heated in hydrogen chloride. There is a difficulty in obtaining a suitable vessel for the reduction, to avoid contaminating the molybdenum, since, as was shown by O. von der Pfordten, and by A. Vandenberghe, that metal reacts at a high temp. with platinum, and porcelain. A. Vandenberghe found that an old porcelain vessel gave the best results since it acquired a protective film of metal from previous reductions. E. W. Engle preferred the hydrogen reduction process when the metal of a high degree of purity is required. The reduction of molybdenum trioxide commences at about 300°. J. H. Müller used a quartz vessel. H. N. Warren used a tube of compressed lime as container. Some impurities can be removed by washing the molybdenum powder with hydrofluoric acid, hydrochloric acid, and water. F. Wöhler and L. von Uslar reduced molybdenum chloride at a red-heat by means of hydrogen. O. von der Pfordten reduced molybdenum sulphide or molybdenite in the same way—but A. Vandenberghe added that the method is useful only when small quantities have to be reduced. A. E. van Arkel obtained molybdenum by heating a filament of the metal in an atmosphere of an easily dissociated volatile compound.

Most of the molybdenum compounds are reduced by *carbon* at a high temp., and although there is a tendency to form a carbide, a metal of a high degree of purity can be so obtained. Thus, P. J. Hjelm, C. F. Bucholz, and J. J. Berzelius reduced molybdenum trioxide, or acid potassium molybdates by heating a white-hot admixture with carbon in a carbon crucible ; and H. Debray added that the product contains 4 to 5 per cent. of carbon which makes the metal more fusible than if it were pure. E. D. Clarke obtained molybdenum by reducing it in the oxyhydrogen blowpipe flame. A. Sternberg and A. Deutsch reduced alkaline earth molybdates by heating them with carbon at 1000° to 1400° ; carbon monoxide is evolved, and the alkaline earth oxide can be removed from the product by hydrochloric acid. According to A. Vandenberghe, with calcium molybdate, the product contained 3 per cent. of carbon. If alkali molybdates are used, the alkali metal is also formed. H. Moissan prepared molybdenum as follows : Molybdenum dioxide, prepared by strongly heating ammonium molybdate, is mixed with one-tenth of its wt. of sugar carbon, and heated for about six min. in a carbon crucible in an arc produced by a current of 800 ampères and 60 volts. With the proportions given, the molybdenum oxide is in excess, and if the action of the arc is stopped before the outer portions of the mixture in contact with the crucible have had time to fuse, molybdenum is obtained quite free from carbon, and containing only from 0·1 to 0·2 per cent. of slag as an impurity. If, however, the action of the arc is prolonged until the whole mixture fuses, the crucible is attacked, and, on cooling, a hard, brittle ingot of carboniferous molybdenum is obtained. A. Vandenberghe found 0·28 per cent. of carbon in the molybdenum obtained under the former conditions. The Ampère Gesellschaft obtained molybdenum by melting a mixture of calcium molybdate, molybdenite, and carbon. M. Guichard reduced molybdenite by H. Moissan's process ; and C. Lehmer, by electrolytically heating a mixture of molybdenite with carbon and calcium oxide : $MoS_2+2CaO+2C=Mo+2CaS+2CO$. O. W. Brown reduced molybdenite by carbon and calcium oxide in an electrically heated furnace : $MoS_2+2C+2CaO=Mo+2CaS+2CO$. J. N. Pring and W. Fielding reduced molybdenum tetra- and penta-chlorides by carbon at a temp. below 1300° ; above that temp., carbide was formed. J. E. Loughlin obtained a small yield of molybdenum by heating for 12 hrs. at a white-heat a mixture of molybdenum trioxide with $1\frac{1}{2}$ times its wt. of *potassium cyanide* in a luted porcelain crucible contained in a larger crucible with the intermediate space packed with animal charcoal.

W. Muthmann and co-workers obtained the metal by melting in an electric furnace at a high temp. a mixture of molybdenite, calcium oxide, in the molar proportions 3 : 4 along with calcium fluoride as a flux. A. B. du Jassonneix reduced molybdenum oxide with *boron* in a magnesia crucible in an electric furnace ; and B. Neumann heated electrically a bath of alumina and lime to which was added molybdenum trioxide and *silicon*. The product contained about 2 per cent. of silicon and a little carbon. L. Kahlenberg and W. J. Trautmann studied the reduction of the trioxide and of molybdates by silicon. A. Burger, H. Kuzel and E. Wedekind, and E. Wedekind and O. Jochem found that molybdenum trioxide in an iron boat in vacuo is reduced by the vapour of *calcium*—the product obtained by the reduction of the oxide with calcium, contained 2 to 3 per cent. of calcium ; with *zinc* as reducing agent, a little iron is usually present. E. Wedekind and O. Jochem found that the metal is produced in a powdered form. W. Prandtl and B. Bleyer used a mixture of calcium and aluminium ; and O. P. Watts and J. M. Breckenridge, an alloy of calcium, magnesium, and aluminium. A. Stavenhagen and co-workers, H. J. Braun, J. J. Boericke, H. Biltz and R. Gärtner, and H. Lohmann found that the *aluminium* thermite process can be used for the reduction of molybdenum oxide. The most common method for preparing molybdenum commercially is to reduce molybdenum concentrate or molybdenite with finely-divided aluminium. The metal may contain 1 to 2 per cent. of iron, and a small proportion of silicon. A. Rosenheim and H. J. Braun obtained a good yield of metal, free from air-bubbles, by moderating the reaction by the addition of a flux of 50 parts of calcium fluoride for every 100 parts of molybdenum trioxide and 38 parts of aluminium, and allowing the metal to agglomerate by keeping the mass in a liquid condition for some time after the reaction. W. Lederer said that owing to the reactivity of the molybdenum, the heating of the metal should not be prolonged more than is necessary. L. Weiss and O. Aichel used *Mischmetal* as the reducing agent in place of aluminium. The metal of a high degree of purity was prepared by C. Müller and W. Schubardt, by heating the carbonyl.

In 1803, J. G. Gahn noticed the separation of molybdenum in the electrolysis of a soln. of ammonium molybdate—*vide infra*, molybdenum trioxide; and in 1815, J. G. Children obtained some molybdenum by the electro-reduction of molybdenum trioxide; M. Junot, by the electrolysis of a soln. of molybdenum trioxide in molten potassium cyanide; the Wolfram Lampen A. G., by the electrolysis of soln. of say molybdenum hexachloride in an organic solvent like acetone using a platinum or nickel cathode; and L. Ott, by the electrolysis of molten molybdates mixed with molybdenum trioxide. H. Mennicke discussed the commercial preparation of the metal. E. W. von Siemens and J. G. Halske deposited molybdenum from a bath of fused salt as in the case of tungsten (*q.v.*). A. Chilesotti did not succeed in depositing molybdenum from a soln. of the trioxide in hydrochloric or sulphuric acid. L. Andrieux obtained the metal by the electrolysis of a soln. of the trioxide in a bath of borate and fluoride. J. L. Merrill and A. S. Russell found that mercury is the most suitable cathode for the deposition of molybdenum, and the best current densities are 0·6 to 1·0 amp. per sq. cm., and the best acidities, 1·2 to $1{\cdot}4N\text{-}H_2SO_4$; the time required for the deposition of a gram of molybdenum from a soln. of sodium molybdate is then about 50 min., and the time is not shortened by the use of a rotating cathode. J. Férée, A. S. Russell and S. W. Rowell, and R. E. Myers also used a mercury cathode. R. E. Pearson and E. N. Craig reduced molybdenum oxide or hydrated oxide by making it into a paste with sulphuric acid, and introducing the mixture into a porous pot surrounding a cathode consisting of a bundle of nickel-chromium alloy rods. The anode of the cell consists of a lead plate embedded in a mass of scrap molybdenum (or other easily oxidizable material) contained in a porous pot. On passing a direct current through the cell and agitating the paste surrounding the cathode, the oxide contained therein is reduced to a lower oxide from which, by suitable washing, impurities such as iron, calcium, and sodium salts may be more readily removed than from the original trioxide. At the same time, the waste metal surrounding the anode is oxidized to trioxide, which is used to make further quantities of the reduced oxide. The latter, after washing and drying, is reduced to a metallic powder by heating in a current of hydrogen in known manner. L. St. C. Broughall electrolyzed a soln. of a molybdenum salt in liquid ammonia at a low temp. or under press. C. Lehmer obtained ferromolybdenum, chromomolybdenum, nickelmolybdenum, manganomolybdenum, and cupromolybdenum by electrolytically heating a mixture of the respective metal oxide with molybdenum sulphide, calcium oxide, and carbon. L. Andrieux obtained molybdenum by the electrolysis of fused borates. Electrolytic processes for the preparation of molybdenum were described by R. E. Pearson and E. N. Craig. The preparation of ferro-molybdenum at the works of the Molybdenite Co. at Orillia, Ontario, Canada, was described by B. C. Lamble:

A wrought-iron jacket, fitted to a cast-iron base, is connected with one terminal of the electric supply. Inside the iron jacket a cubical crucible, with a tap-hole in the bottom, is built up with carbon blocks, the space between the crucible and the jacket being filled with magnesia bricks. The second electrode consists of a 10-inch graphite rod, held by a water-cooled head over the centre of the furnace. The power used is 4000 amperes at 50 volts. The smelting mixture consists of 70 per cent. molybdenite concentrate and 30 per cent. pyrite, while coke is the reducing agent and lime and silica are used as fluxes. The ferro-molybdenum produced has approximately the following composition: Molybdenum, 71·0; carbon, 3·66; sulphur, 0·08; phosphorus, 0·03; silica, 1·35; iron, 23·8 per cent. About 80 per cent. of the molybdenum in the charge is recovered in the alloy with a power consumption of 6 to 7 kilowatt-hours per lb. of alloy. The remainder of the molybdenum is recovered as dust or by wet dressing of the slag. Some analyses were also reported by A. W. Judge.

E. K. Jenckes discussed the preparation of oxides and salts of a high degree of purity for the purpose of preparing the metal for electric lamps. J. Férée obtained molybdenum by distilling in vacuo mercury from the amalgam obtained by the electrolysis of a hydrochloric acid soln. of molybdic acid using a mercury cathode. The Badische Anilin- und Sodafabrik obtained the metal by heating the nitride in vacuo. The nitride was obtained by heating molybdenum oxide, or a mixture of the oxide and the metal at 500° to 600°, in an atm. of a mixture of equal parts of hydrogen and nitrogen at 60 atm. press.

The heated metal is very reactive and is very susceptible to contamination from the containing vessel, the reducing agent, the furnace gases, and, in the electrolytic process, from the material of the electrodes. W. Lederer, and K. Wolf discussed the purification of small quantities of the metal containing, say, 3 per cent. of iron, aluminium, silicon, carbon, and oxygen. The metal is pressed into a pencil which is then heated electrically in hydrogen. The pencil is then used as an electrode in a vacuum furnace—cf. **8**. 31, 4, Fig. 1.

According to C. G. Fink,[6] **ductile molybdenum** can be prepared by methods analogous to those used for ductile tungsten, and discussed by O. Ruff, N. L. Müller, and W. D. Coolidge. P. Schwarzkopf and S. Burgstaller pressed rods from the powdered oxide, and heated them to 1100°–1150° in a current of hydrogen, and then heated them electrically to 2600°–2700° in a current of hydrogen. The resulting rods of molybdenum are ductile and can be bent into rings at a red-heat. According to O. Ruff, the ductile metal is prepared as follows:

> Molybdenum trioxide is purified by reduction at 1000° in a current of hydrogen and steam to the dioxide, which is then heated in chlorine, the oxychloride being sublimed and transferred to hydrochloric acid, when pure molybdenum trioxide is precipitated. The precipitate is washed, dried, and ignited at 1200°, when considerable shrinkage takes place. The finely-powdered product is then reduced in hydrogen at 1250°, nickel boats being used in a porcelain tube. The crystalline metal is compressed into the form of rods under about 5000 atm. press., and the brittle rods are rendered stronger by heating in hydrogen at 1300°. The presence of 0·05 per cent. of carbon is favourable. The final sintering takes place by electrical heating at a temp. of 2620°–2650°. The molybdenum contracts by about 14 per cent. The sintered rods are still quite brittle, and have to be rendered malleable and ductile by hammering at 1250° in an atm. of hydrogen. A special apparatus for the hammering is described. The hammered rods are then drawn at 400°–600° to the required size through diamond dies. The thin wires finally obtained are perfectly flexible, and may be drawn cold. The worked metal is silver-white, and does not oxidize appreciably below a red-heat.

J. Férée [7] found that the metal prepared by distilling the amalgam in vacuo is pyrophoric. A suitable reducing agent for the preparation of **colloidal molybdenum** from its salts has not been obtained. T. Svedberg obtained it by the electrical dispersion process—*vide* gold—as an *isobutylalcosol* which is brownish-black by transmitted light, and black by reflected light. H. Küzel obtained the colloidal metal by grinding or by cathodic disintegration—*vide* chromium. E. Wedekind and co-workers found that if powdered molybdenum, obtained by reducing the di- or tri-oxide by heating it with zinc, be washed in the absence of air successively with warm alcohol and warm water, then treated with dil. hydrochloric acid, and successive quantities of water added to it on a filter, an acid soln. first passes through, but later, a neutral colloidal soln. of the metal is obtained. When the precipitated metal no longer yields a colloid on washing, this property can be re-imparted to it by renewed treatment with acid. The particles of the resulting hydrosol, which keeps well if air is excluded, are negatively charged. They are immediately coagulated by alkaline electrolytes and more slowly by neutral electrolytes, but are comparatively resistant to hydrogen ions. L. Hamburger studied the properties of thin films.

§ 4. The Physical Properties of Molybdenum

The early preparations of molybdenum were very impure, and the description of the physical properties of these samples do not always accord with later observations. J. J. Berzelius[1] described it as a greyish-white metal; C. F. Bucholz said that it is silvery white; and L. Weiss and O. Aichel, that it is silvery white with a crystalline fracture. The hammered and drawn metal is fibrous. A. W. Hull found that the **X-radiogram** of molybdenum corresponds with a body-centred cubic lattice with sides 3·143 A. T. Fujiwara, E. C. Bain, E. Schmid, A. E. van Arkel, P. Stoll, W. P. Davey, W. Hume-Rothery, and K. Weissenberg made observations on this subject. J. Hengstenberg and H. Mark studied the effect of mechanical work on the X-radiogram; and S. T. Konobejevsky, and M. Ettisch and co-workers, the structure of hard-drawn wires. They found that the crystallites are regularly arranged, whereas in soft wires the crystallites are irregularly arranged. Z. Jeffries and R. S. Archer gave 900° for the lowest temp. of recrystallization. T. Fujiwara found that the arrangement of the fibrous structure of a hard-drawn molybdenum wire with respect to the axis of the wire is retained after bending.

For the powdered metal the older workers found values approximating 8·6 for

the **specific gravity**—P. J. Hjelm gave 7·75 for the sp. gr.; H. Debray, 8·6; C. F. Bucholz, 8·62; and J. E. Loughlin, 8·56. Later observers found for the massive metal values approximating 10; thus, H. Moissan, and A. B. du Jassonneix observed 9·01; K. Wolf, 8·95 at 17°/4° (impure); T. Barratt and R. M. Winter, 9·933; W. Lederer, 10·2 at 17·5/4°; and C. G. Fink gave 10·02 for the hammered but not drawn metal; 10·04 for the metal drawn to a diameter of 3·75 mm.; 10·29, when drawn to a diameter of 0·25 mm.; and 10·32, when drawn to a diameter of 0·038 mm. E. Donath and J. Mayrhofer gave 11·5 for the at. vol.; and W. Lederer, 9·4. M. L. Huggins gave 1·54 A. for the **ionic radius;** L. Vegard, 1·03 A.; and H. G. Grimm, 0·72 A. The subject was studied by J. C. Slater, A. M. Berkenheim, V. M. Goldschmidt, L. Pauling, and E. T. Wherry. The results show that for sexivalent molybdenum atoms, the effective at. radius is 0·62 A., for quadrivalent atoms, 0·66 to 0·83 A., and for typical molybdenum atoms, 1·36 A. I. Traube investigated the at. soln. vol.; and P. Vinassa, the mol. number.

J. J. Berzelius said that the metal is harder than topaz; H. Moissan, and A. B. du Jassonneix, that it does not scratch glass or quartz; and J. R. Rydberg gave 8·5 for the **hardness** on Mohs' scale. E. W. Engle gave 147 for the hardness of molybdenum on Brinell's scale. According to H. Moissan, A. B. du Jassonneix, and F. Wohler, molybdenum can be filed, and, when hot, it can be forged—hammered and rolled. C. G. Fink found the **tensile strength** of wires 0·125 mm. diameter to be 140 to 180 kgrms. per sq. mm.; wires 0·07 mm. diameter, 161 to 189 kgrms. per sq. mm.; and wires 0·038 mm., 189 to 217 kgrms. per sq. mm. W. P. Sykes measured the tensile strength of molybdenum wires after different heat treatments. No. 1 was swaged and drawn hot (1000°–1300°) from a diameter of 0·125 to 0·025 in.; No. 2 was similarly treated at 800°; No. 3 was swaged and drawn hot (1000°–1300°) from 0·045 to 0·025 in.; No. 4 was similarly treated at 800°; No. 5 was annealed to give medium grain size; No. 6 was annealed to give small grain size; and No. 7, annealed to give large grain size. The tensile strengths in lbs. per sq. in. are shown in Fig. 2; the percentage elongation per 2 in., in Fig. 3; and the percentage reduction in area, in Fig. 4. These observations were discussed by Z. Jeffries and R. S. Archer. P. Ludwik studied the effect of temp. T. Fujiwara found that the tensile strength of molybdenum is 20 per cent. greater when the tension is applied in a direction parallel to that of rolling than it is when the tension is applied at an angle of 45° or 90° to the direction of rolling:

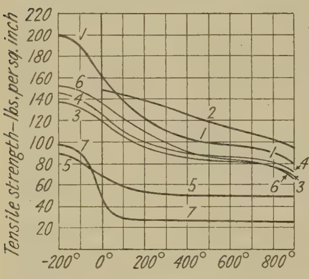

Fig. 2.—Tensile Strength of Molybdenum.

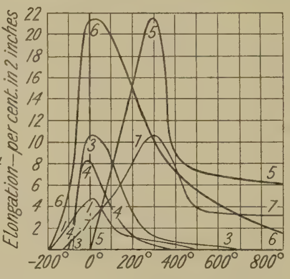

Fig. 3.—Elongation of Molybdenum.

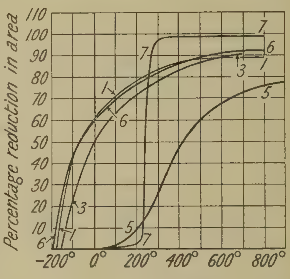

Fig. 4.—Reduction of Area of Molybdenum.

Direction of rolling	0°	22·5°	45°	67·5°	90°
Tensile strength	113·9	101·2	94·8	97·0	92·8 kgrms. per sq. mm.

J. Königsberger gave 250 to 270 kgrms. per sq. mm. for the tensile strength of molybdenum wires, and 125 kgrms. per sq. mm. for single crystal wires. The **torsion modulus** was found to be $13{\cdot}5\times10^{11}$ to 15×10^{11} C.G.S. units; and for single crystal wires, 18×10^{11} C.G.S. units. A. L. Kimball and D. E. Lovell found the **elastic modulus,** E, of swaged molybdenum to be $34{\cdot}6\times10^{11}$ dynes per sq. cm.

They also measured the internal friction. W. Widder gave $E=E_{20}\{1-0\cdot0004032(\theta-20)\}$. E. Edwards and co-workers examined the increase in torsional stiffness produced by increasing the tension of molybdenum wires. G. Grube and F. Lieberwirth, and J. Laissus studied the **diffusion** of molybdenum into iron. According to T. W. Richards and E. P. Bartlett, the **compressibility** is $0\cdot47\times10^{-6}$ at 20° for one megabar at 20°, at press. between 100 and 500 megabars. P. W. Bridgman found the compressibility, β, of swaged rod at 30° to be $\delta v/v=-10^{-7}(3\cdot47-1\cdot2p)p$, and at 75°, $-10^{-7}(3\cdot48-1\cdot2p)p$; and for drawn wire at 30°, $\delta v/v=-10^{-7}(3\cdot61-1\cdot0p)p$, and at 75°, $-10^{-7}(3\cdot62-1\cdot0p)p$, for p kgrms. per sq. cm. with p between 1 and 12,000. For drawn wire and swaged rod respectively at 30°, $\beta=0\cdot0_6361$ and $0\cdot0_6347$; $\delta\beta/\beta\delta p=0\cdot0_558$ and $0\cdot0_572$; $-\delta\alpha/\alpha\delta p=0\cdot0_52$ and $0\cdot0_52$; and $\beta_0-1(\delta\alpha/\alpha\delta p)=5\cdot54$ and $5\cdot76$, where α denotes the coeff. of thermal expansion. L. H. Adams gave $\delta\beta=-0\cdot02$. P. W. Bridgman studied the effect of pressure on the rigidity.

C. G. Fink found $\alpha=0\cdot0_536$ for the coeff. of **thermal expansion** between 20° and 100°, and B. Beckman, $\alpha=0\cdot0_556$. The thermal expansion of an exceptionally pure sample of molybdenum was found by L. W. Schad and P. Hidnert to be represented by the expression : Length at $\theta°$, $l=l_0(1+5\cdot15\theta\times10^{-6}+0\cdot00570\theta^2\times10^{-6})$ for $\theta°$ between $-142°$ and 19° ; and between 19° and 305°, length at $\theta°$ is $l=l_0(1+5\cdot01\theta\times10^{-6}+0\cdot00138\theta^2\times10^{-6})$ with a probable error less than 3×10^{-6} per unit length. P. Hidnert and W. B. Cero gave for the mean coeff. of linear expansion, $\alpha=0\cdot0_549$ between 25° and 100° ; and $0\cdot0_555$ between 25° and 500°. If l_0 denotes the length at 300° K., and l, the length at $T°$ K., W. Widder gave $0\cdot0_5549$ at 20° and $0\cdot0_5416$ at 190° for the coeff. of thermal expansion. A. G. Worthing represented the measurements by $l/l_2=0\cdot0_2500(T-300)+0\cdot0_8105(T-300)^2$. C. Zwikker found for the linear expansion l/l_0, 1·00623 at 1440° ; 1·00760 at 1648° ; 1·00920 at 1855° ; and 1·0111 at 2059°. According to E. Podszus, wires of molybdenum or of molybdenum-tungsten alloy may be sealed gas-tight into vitreous quartz by the aid of the flux : silica 10, alumina 1, boric oxide 1, and orthoclase 2. J. Disch gave for the expansion of molybdenum wires in mm. per litre between 0° and $\theta°$:

	−190°	−78°	0·00°	100°	200°	300°	400°
Expansion .	−0·79	−0·375	0·00	0·52	1·07	1·64	2·24 mm.

T. Barratt and R. M. Winter gave for the **thermal conductivity** of molybdenum 0·346 cal. per sec. per degree at 17°, and 0·333 cal. at 100°. C. Zwikker gave for the thermal conductivity k in watts per cm. per degree :

	1234°	1440°	1648°	1855°	2059°	2259°	2460°
k . .	0·98	1·00	1·02	1·05	1·11	1·17	1·24

J. Dewar gave 0·0141 for the **specific heat** between $-253°$ and $-196°$, and 1·35 for the **atomic heat ;** P. Nordmeyer obtained too high a value 0·062 between $-188°$ and 20°, for T. W. Richards and F. G. Jackson obtained 0·0555 for the sp. ht. and 5·33 for the at. ht. ; A. de la Rive and F. Marcet obtained respectively 0·0659, and 6·33 between 5° and 15° ; H. V. Regnault, respectively 0·0722 and 6·93 between 0° and 100° ; W. Lederer obtained the unlikely value 0·0461 between 17° and 100° ; whilst for a metal with only 0·22 per cent. impurity, E. Defacqz and M. Guichard obtained respectively 0·0723 and 6·94 between 15° and 91° ; 0·0735 and 7·06 between 15° and 264° ; and 0·0740 and 7·10 between 15° and 440° ; N. Stücker, 0·0647 and 6·21 between 20° and 100°, and 0·0722 and 6·93 between 20° and 550° ; and P. Nordmeyer and A. L. Bernoulli, 0·063 between 0° and $-185°$; N. Stücker gave for the true sp. ht.

	60°	125°	225°	325°	425°	525°
c . .	0·06468	0·07076	0·06912	0·06967	0·08206	0·08121

$c=0\cdot0708-0\cdot000052(\theta-125)+0\cdot0_64(\theta-125)^2$, between 125° and 225° ; $c=0\cdot0707-0\cdot000027(\theta-125)+0\cdot0_61(\theta-125)^2$, between 125° and 325° ; $c=0\cdot0697-0\cdot000113(\theta-325)+0\cdot0_61(\theta-325)^2$, between 325° and 425° ; $c=0\cdot0697+0\cdot000190(\theta-325)-0\cdot0_67(\theta-325)^2$, between 325° and 525 ; $c=0\cdot0708$

$-0·000037(\theta-125)^{\circ}-0·0_{6}3(\theta-125)$, between 125° and 525°; and $c=0·0647+0·000094(\theta-60)$, between 60° and 125°. T. E. Stern gave $c=0·06054$ between 0° and 108°; 0·06333 between 0° and 441·5°; and $C_p=0·05973+0·00001619\theta$, at temp. θ between 0° and 441·5°. D. Cooper and G. O. Langstroth gave:

	—40°	0°	25°	50°	100°	150°	200°	250°
Sp. ht. .	0·0564	0·0589	0·0597	0·0609	0·0612	0·0616	0·0624	0·0632

and the results are plotted in Fig. 5; the at. ht. was represented by $C_v=0·0593+0·0_{4}13(\theta+40)-0·0265(\theta+40)^{-1·06}$. F. Wüst and co-workers found $C_p=6·11$ at 100°, and 7·80 at 900°. H. A. Jones gave $c=0·0578+0·0000257T$; and C. C. van Voorhis, $c=0·0606+0·000028T$. F. Simon and W. Zeidler gave $C_p=D(379T-1)+0·0_{4}263T^{\frac{3}{2}}$; and for C_v between 16° K. and 24° K., $C_v=0·0785T^3$; they also gave the following values for at. ht. of molybdenum:

T° K. .	15·97°	20·66°	31·52°	56·0°	105·6°	144·6°	200·2°	274·7°
C_p .	0·040	0·073	0·264	1·230	3·380	4·38	5·09	5·53
C_v .	0·040	0·073	0·264	1·230	3·374	4·37	5·06	5·49

H. A. Jones and co-workers gave $C_p=4·88+0·00248T$. J. Maydel discussed some relations of the sp. ht.; and E. D. Eastman and co-workers, the thermal energy of the electrons in molybdenum, and computed $C_p-C_v=0·047$ Cal. per degree per mol.

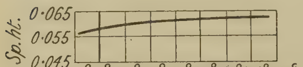

FIG. 5.—The Effect of Temperature on the Specific Heat of Molybdenum.

R. C. Smith gave 800° for the sintering temp. of molybdenum filings. According to H. von Wartenberg, the **melting point** of pure molybdenum is 2550° when that of platinum is 1745°. C. W. Waidner and G. K. Burgess, and W. R. Mott gave 2500°; M. Pirani, 2450°; M. von Pirani and A. R. Meyer, 2450°; A. G. Worthing, 2622°±10°; E. Siedschlag, 2530°; and M. von Pirani and H. Alterthum, 2840°±40°. For a commercial sample, O. Ruff and O. Goecke gave 2110°. H. Moissan distilled the metal in an electric arc furnace; and W. R. Mott estimated the **boiling point** of the metal to be 4700°; I. Langmuir calculated 3617°. C. Zwikker gave 4780° K. for the sublimation temp. at 1 atm. press. I. Langmuir measured the **rate of evaporation** from hot filaments, and W. H. Rodebush observed the value of A in the equation for the number of electrons evaporating from a metal filament, $n=AT^{-\frac{1}{2}}e^{-b/T}$ per sq. cm. per second, to be $1·32\times10^{26}$; the calculated result at 2000° K. is $5·50\times10^{26}$. I. Langmuir represented the rate of evaporation m grms. per sq. cm. per sec. to be $\log m=17·11-38600T^{-1}-1·76\log T$, or

T° K. . .	1994°	2040°	2121°	2287°	2326°	2373°
$m\times10^6$ . .	0·00766	0·0305	0·124	1·74	3·65	8·47

and C. Zwikker, $\log m=-33800T^{-1}+8·24$ grms. per sq. cm. per sec. The subject was discussed by F. J. Wilkins, and H. A. Jones and co-workers. For the **vapour pressure,** p mm., I. Langmuir gave $\log p=17·354-38600T^{-1}-1·26\log T$, or

T° K. . .	1800°	2000°	2500°	2800°	3890°
p	$6·43\times10^{-9}$	789×10^{-9}	$43·0\times10^{-9}$	1679×10^{-9}	760

C. Zwikker gave $\log p=33800T^{-1}+10·16$ mm.; and J. A. M. van Liempt, $\log p=-37710T^{-1}+9·90$, and 43·53 to 44·96 for **Trouton's constant.** W. Herz estimated that the **heat of fusion** lies between 1000 and 5000 cals. I. Langmuir gave for the latent **heat of vaporization** $177,000-2·5T$; and for the **chemical constant,** 4·4. W. Zeidler gave 170,400 cals. for the heat of vaporization, and 4·07 for the chemical constant. G. N. Lewis and co-workers, and E. D. Eastman gave 7·5 for the at. **entropy** of molybdenum at 25°; W. Herz, 12·66; R. C. Tolman, 56·4 at 25°; and B. Bruzs, 23·0 at the m.p. R. D. Kleeman discussed the internal energy of molybdenum; and W. Herz, the entropy. M. Delépine gave for the **heat**

of oxidation, $\mathrm{Mo+3O=MoO_3}$+166·14 Cals. at constant vol., and 167 Cals. at constant press. W. Lederer gave 168·576 Cals.; J. E. Moose and S. W. Parr, 1829 Cals. per gram; and W. G. Mixter, 181·5 Cals. for the oxidation of the metal by sodium dioxide.

W. W. Coblentz [2] observed the percentage **reflecting power,** R, for light of wave-length λ to be:

λ .	0·40	0·7	1·0	1·4	2·0	4·0	6·0	1·0	1·2
μ .	44·0	49·8	58·2	69·0	81·6	90·5	93·0	94·5	95·2

G. Jaffé calculated theoretical values for these constants. W. W. Coblentz said that the reflectivity curves of molybdenum and tungsten are so nearly alike that from a consideration of their emissivities and luminous efficiencies there seems to be no great choice in the use of these two metals in incandescent lamps. On the other hand, from a consideration of their physical properties, the molybdenum filament would be preferable because of its toughness and its ductibility, in contrast with tungsten which is very brittle. Their m.p. are high, and it is principally a question of overcoming certain physical weaknesses in the molybdenum in order to make it practical. A. G. Worthing gave for the spectral emissivity, e, of molybdenum for wave-lengths 0·665μ and 0·475μ, from 273° K. to the m.p., 2895° K.; for the average visible emissivity, e_v; the colour emissivity, e_c; and the total emissivity, e_t,

T° K. .	273°	400°	800°	1200°	1600°	2000°	2400°	2895°
e { 0·665μ.	0·420	0·415	0·398	0·390	0·367	0·353	0·341	0·328
e { 0·475μ.	0·425	0·421	0·409	0·403	0·388	0·279	0·371	0·363
e_v . .	—	—	—	0·393	0·373	0·362	0·352	0·342
e_c . .	—	—	—	0·361	0·321	0·297	0·277	0·255
e_t . .	—	—	—	0·096	0·168	0·210	0·248	0·290

The values for the spectral emissivity at room temp. for 0·665μ and 0·475μ, are respectively 0·580 and 0·576. The subject was studied by C. Zwikker, C. Davisson and L. H. Germer, R. L. Petry, E. Patai, and S. Dushman and co-workers—*vide* tungsten. A. G. Worthing found for the brightness temp., T_b for wave-lengths 0·665μ; the colour temp., T_c; and the radiation temp., T_v:

T° K. . .	1000°	1400°	1800°	2200°	2600°	2895°
T_b . .	958°	1316°	1658°	1986°	2297°	2519°
T_c . .	1004°	1411°	1823°	2244°	2672°	2997°
T_v . .	557°	864°	1187°	1523°	1866°	2122°

The normal brightness, B candles per sq. cm.; the radiation intensity, η watts per sq. cm.; and the luminous efficiency in lumens per watt, are:

T° K. . .	1000°	1400°	1800°	2200°	2600°	2895°
B . .	0·00010	0·089	4·13	48·5	270	730

Efficiency .	—	0·093	1·22	5·28	13·0	—

E. S. Lamar and W. E. Deming studied the distribution of temp. in a heated filament. S. C. Roy, M. J. Martin, and A. T. Watermann studied the variation of the thermionic emission with temp.; A. W. Hull and J. M. Hyatt, J. M. Hyatt and H. A. Smith, E. Meyer, and H. B. Wahlin, the secondary emission of electrons; W. J. Jackson, the emission of electrons by bombardment with positive ions; R. L. Petry, the critical potential for the emission of secondary electrons; E. Meyer and L. P. Smith, the emission of positive ions; T. Soller, and L. J. Haworth, the velocity of the secondary electrons; H. R. Kiehl and co-workers, W. R. Ham and M. W. White, the emission of electrons from a molybdenum target; and the radiation, by A. L. Helfgott; the reflection of electrons from molybdenum was studied by W. R. Ham; the diffraction of electrons, by E. Rupp; the liberation of electrons by positive ions, by M. L. E. Oliphant; and the heat of condensation of electrons and positive ions on molybdenum, by C. C. van Voorhis and K. T. Compton. The cold electronic discharge from molybdenum was investigated by R. J. Piersol; the heats of condensation of electrons and positive ions, by C. C. van Voorhis; the photoelectric effect, by H. Klumb; the electron theory of thermionic emission, by R. H. Fowler; electronic collisions, by M. Pirani and H. Schönborn.

R. Bunsen,[3] G. Merz, and C. F. Plattner discussed the flame reactions of molybdenum compounds. The colourless blowpipe flame is coloured greenish-yellow. R. T. Simmler found that molybdic oxide, in the colourless gas flame, gives a continuous **flame spectrum.** W. N. Hartley and H. Ramage studied the banded spectrum in the oxy-hydrogen flame. The **spark spectrum** was investigated by W. A. Miller, R. Thalén, J. N. Lockyer, E. Demarçay, F. Exner and E. Haschek, M. Eppley, C. Weigand, M. A. Catalan, E. O. Hulburt, R. J. Lang, H. Nagaoka and co-workers, O. Lohse, A. Hagenbach and H. Konen, A. G. G. Leonard, and J. Formanek. The principal lines are 6030, 5888, and 5857 in the orange-yellow; 5792 and 5751 in the yellow; 5688 in the yellowish-green; 5570, 5532, and 5506 in the green; and 4278 in the indigo-blue. E. O. Hulburt studied the spectrum of the condensed spark in soln. of the salts; and E. J. Allin and H. J. C. Ireton, the under-water spark-spectrum. The **arc spectrum** was studied by B. Hasselberg, F. Croze, M. Eppley, M. Puhlmann, C. Weigand, M. A. Catalan, C. C. Kiess and W. F. Meggers, and F. Exner and E. Haschek; the **ultra-violet spectrum,** by W. A. Miller, J. C. McLennan and A. C. Lewis, R. J. Lang, T. Aden, and F. Exner and E. Haschek. According to W. H. Fulweiler and J. Barnes, the light of the molybdenum arc, under water, gives a continuous spectrum in the ultra-violet. The **ultra-red spectrum** was studied by J. M. Eder and E. Valenta. The effect of *pressure* was examined by W. J. Humphreys; and of a *magnetic field*, or the **Zeeman effect,** by R. Jack, E. Wilhelmy, and M. A. Catalan. J. N. Lockyer studied the *enhanced lines*; H. Geisler, the *anomalous dispersion* of light in the vapour of molybdenum; and M. Kimura and G. Nakamura, *enhanced lines*. No **series spectrum** has been observed, but E. Paulson noted some pairs of constant difference lines; P. G. Nutting, O. Laporte, and M. A. Catalan have studied the *structure of the line spectrum.* Unlike J. E. Paulson, M. Puhlmann observed no lines in the arc spectrum which exhibit constant frequency differences. The subject was discussed by M. A. Catalan. C. C. Kiess, W. F. Meggers and C. C. Kiess, R. C. Gibbs and H. E. White, and C. C. Kiess and O. Laporte studied the series spectrum. F. Croze studied the ultimate rays and resonance rays of molybdenum.

H. B. Dorgels studied the **absorption spectrum** of the vapour. According to J. Formanek, although colourless aq. soln. of molybdenum salts give no characteristic absorption spectrum, a soln. of the chloride in absolute alcohol gives a green soln. which if concentrated shows absorption bands in the red, blue, and violet, but no lines. If about two drops of tincture of alkanna be added to the soln. of molybdenum chloride, in absolute alcohol, the brownish-red soln. has narrow bands at 6002, 5560, and 5185, and a band in the violet. The soln. however, gradually becomes violet, then blue with a reddish fluorescence; and the narrow bands are displaced to the right until finally in about 10 hrs., when equilibrium is attained, the narrow bands occur at 5845, 6415, and 5040. The spectrum is not changed by the addition of a little ammonia, but an excess makes the liquid turbid and the spectral bands move to the left. C. Horner studied the spectra of beads of boric or phosphoric acid containing molybdenum oxide in soln. S. Kato studied the absorption spectrum of aq. soln.

The K-series in the **X-ray spectrum** was measured by F. C. Blake and W. Duane,[4] S. Tanaka and J. Tsutsumi, L. H. Martin, J. W. M. du Mond, F. L. Nutting, J. Valasek, H. Mark and G. von Susich, F. Wisshak, D. Mitchell and B. Davis, N. S. Gingrich, B. Davis and co-workers, L. R. G. Treloar, A. P. R. Wadlund, J. Schrör, H. Purks, B. Davis and H. Purks, Y. H. Woo, B. Walter, A. Dauvillier, S. Björek, D. Nasledoff and P. Scharawsky, M. Siegbahn, H. R. Robinson and co-workers, A. Larsson, A. Jönsson, A. Liede, D. Coster and co-workers, P. A. Ross, E. O. Wollan, F. K. Richtmyer, F. K. Richtmyer and L. S. Taylor, M. Balderston,

F. K. Richtmyer and R. C. Spencer, H. A. Erickson, A. Bouwers, G. E. M. Jauncey and A. H. Compton, A. H. Compton, G. Kettmann, P. Anger, A. H. Compton and Y. H. Woo, S. K. Allison and co-workers, G. E. M. Jauncey, M. Siegbahn and E. Friman, M. de Broglie, A. P. R. Wadlund, S. Tanaka and J. Tsutsumi, H. G. J. Moseley, and J. Malmer. The lines include $\alpha_2\alpha'=0{\cdot}71196$; $\alpha_1\alpha=0{\cdot}759$; $\beta_1\beta=0{\cdot}63065$; and $\beta_2\gamma=0{\cdot}61398$. The L-series was measured by D. Coster, E. Hjalmar, M. Siegbahn and A. Larsson, H. G. J. Moseley, J. Malmer, F. K. and R. D. Richtmyer, M. Siegbahn and E. Friman, W. Bothe and H. Franz, S. Björek, W. Bothe, M. J. Druyvesteyn, W. Duane and R. A. Paterson, H. Hirata, B. B. Ray, A. Jönsson, A. H. Compton and R. L. Doan, J. Zahradnicek, J. M. Cork, H. R. Robinson and C. L. Young, and M. Siegbahn. The lines include $\alpha_2\alpha^1=5{\cdot}400$; $\alpha_1\alpha=5{\cdot}3943$; $\alpha_3\alpha^{11}=5{\cdot}3721$; $\beta_1\beta=5{\cdot}1658$; and $\gamma_1\delta=4{\cdot}7111$. A. Dauvillier observed no $M\alpha$-ray ; but J. Thibaud found the $M\alpha$-line=65·0 A. O. W. Richardson and C. B. Bozzani, and C. B. Bozzani and C. T. Chu found that the critical potential of the X-ray radiation from a tungsten wire is 356 volts corresponding with a wave-length of 34·8 A. The calculated $M\alpha$-line of molybdenum is 35·2 A., indicating that the observed radiation is the M-series. The M-series was also studied by S. Björek, H. R. Robinson and C. L. Young, and J. M. Cork ; and the N-series by S. Björek, and H. R. Robinson and C. L. Young. E. O. Wollan found that the $K\alpha$-lines are not polarized more than one per cent. W. Ehrenberg and co-workers studied the widths of the X-ray emission lines.

J. E. P. Wagstaff gave $6{\cdot}7\times10^{12}$ for the **vibration frequency.** F. Wagner discussed the linear relation between the at. numbers and the frequency. According to T. E. Auren, the at. absorption coefficient for X-rays is 244 when that of hydrogen is unity. R. A. Houstoun, P. Günther, L. M. Alexander, K. A. Wingärdh, and F. W. Warburton and F. K. Richtmyer also studied this subject. S. K. Allison and W. Duane, G. Hagen, F. Kirchner, E. N. Coade, R. W. G. Wyckoff, and G. L. Clark and co-workers studied the scattering of the X-rays from molybdenum, and the Compton effect ; J. Hengstenberg, the reflection of X-rays ; H. R. Robinson and co-workers, and R. Whiddington, the emission from molybdenum bombarded by X-rays ; G. L. Clark and co-workers, the action of primary X-rays from a molybdenum target on the secondary and tertiary rays from various substances. M. A. Rewutzka, and O. W. Richardson and F. S. Robertson investigated the soft X-rays from molybdenum ; L. P. Davis, the effect of oxidation on the emission of soft X-rays ; and G. B. Bandopadhyaya, and O. W. Richardson and F. S. Robertson, the photoelectric effect of these rays. R. Whiddington, studied the velocity of the electrons liberated by X-rays from molybdenum ; D. Nasledoff and P. Sharawsky, D. L. Webster and A. E. Hennings, A. Jönsson, and A. Bouwers, the velocity of the X-rays ; and C. C. van Voorhis and K. T. Compton, the heat of condensation of electrons. M. A. Catalan gave for the **ionization potential,** 7·1 volts ; and the first **resonance potential,** 3·19 volts. L. Rolla and G. Piccardi studied the electronic equilibrium and ionizing potentials of molybdenum, etc. D. L. Webster and A. E. Hennings studied the penetration by cathode rays ; H. R. Robinson, the secondary corpuscular X-rays ; W. Herz gave $7{\cdot}27\times10^{6}$ for the **vibration frequency.**

M. J. Martin [5] found that photoelectric currents are produced by the action of the light from a quartz mercury lamp on molybdenum heated in vacuo to 1325°. The sensitiveness of the **photoelectric effect** increases to a final limiting value, and the wave-length limit shifts from about 2600 A. to 3800 A. The work function is 3·22 volts. The subject was studied by T. Pavolini. N. Piltschikoff observed that molybdenum emits practically no **Moser rays.** J. Lifschitz, and R. T. Dufford investigated the **volta-luminescence** which occurs with an electrolytic cell under certain conditions when molybdenum electrodes are used.

K. F. Herzfeld [6] discussed the metallic conductivity of molybdenum. According to C. G. Fink, the **electrical resistance** of hard-drawn molybdenum wire is $5{\cdot}6\times10^{-6}$ ohm per cm. cube, and of annealed wire, $4{\cdot}8\times10^{-6}$ ohm at 25°. The temp. coeff. is

0·5 per cent. per degree between 0° and 170°. C. E. Blom gave $R \times 10^{-4} = 22{\cdot}4$ ohms for the resistance of molybdenum at 0°, and at θ°, $R \times 10^{7} = 44 \times 0{\cdot}117\theta + 0{\cdot}00053\theta^2$ ohms per cm. cube. A. Schulze gave $R = R_0(1 + 0{\cdot}004020\theta + 0{\cdot}0512\theta^2)$. C. Zwikker found for the sp. resistance in microhms per cm.:

	1234°	1440°	1648°	1855°	2059°	2259°	2460°
R . .	29·2	35·2	41·2	47·3	53·5	59·7	66·0

A. A. Sommerville found that the effect of temp. is very sensitive to the degree of purity of the metal, and he gave 0·0034 for the temp. coeff. of the resistance, whilst P. W. Bridgman gave 0·004336 between 0° and 100°. A. A. Somerville represented his results for the effect of temp. on the resistance, and on the temp. coeff. of the resistance by the curves, Fig. 6. W. Geiss and J. A. M. van Liempt gave for the resistance of single crystals 0·0502 ohm per metre for wire 1 mm. cross-section, and the temp. coeff. was 473×10^{-5}. A. G. Worthing gave for the resistance, R milliohms, and for the temp. coeff.,

T° K. .	273°	400°	1000°	1400°	1600°	2000°	2400°	2600°	2895°
R .	5·14	8·15	23·9	35·2	41·1	53·1	65·5	71·8	81·4
a .	1·265	1·170	1·145	1·145	1·145	1·145	1·145	1·145	1·145

L. Holborn gave for wire annealed at 500° the ratio of the resistance, R, at θ° to that, R_0, at 0°:

	−192°	−78°	100°	200°	300°	400°
R/R_0 . .	0·193	0·667	1·435	1·885	2·349	2·825

and for the temp. coeff., a, of the resistance:

	−135°	−39°	50°	150°	250°	350°
a .	0·00415	0·00427	0·00435	0·00450	0·00464	0·00478

W. Geiss and J. A. M. van Liempt studied the effect of temp. on the resistance; and J. C. McLennan and co-workers, the effect of temp. in the vicinity of 2·2° K.; L. Holborn gave 0·00435 for the temp. coeff.; P. Kapitza, the influence of a magnetic field on the conductivity. Z. A. Epstein compared the conductivities of the elements and their position in the periodic table. A. T. Waterman discussed the electronic theory of conduction. W. Geiss and J. A. M. van Liempt found that the product of the sp. resistance and the temp. coeff. is constant in agreement with Matthiessen's rule. H. Rolnick found that the resistance decreases with tension. U. Fischer, and B. Beckman measured the influence of pressure, p kgrms. per sq. cm., on the resistance; and P. W. Bridgman found the relative resistance and the press. coeff. to be:

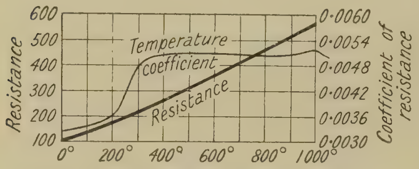

FIG. 6.—The Effect of Temperature on the Resistance of Molybdenum.

		0°	25°	50°	75°	100°
R		1·0000	1·1071	1·2150	1·3238	1·4336
Press. coeff.	0 kgrm. .	$-0{\cdot}0_5133$	$-0{\cdot}0_5132$	$-0{\cdot}0_5131$	$-0{\cdot}0_51305$	$-0{\cdot}0_5130$
	12,000 kgrms .	$-0{\cdot}0_51245$	$-0{\cdot}0_5124$	$-0{\cdot}0_5124$	$-0{\cdot}0_51235$	$-0{\cdot}0_5123$

U. Fischer gave

	13·2°	0·1°	−75°	−192°	−252·7°
Coeff. . . .	$0{\cdot}0_5134$	$0{\cdot}0_5135$	$0{\cdot}0_5150$	$0{\cdot}0_5269$	$0{\cdot}0_5414$ to $0{\cdot}0_549$

S. Morugina found that the molybdenum-tungsten thermocouple had an e.m.f. which changes sign at about 1900°. The e.m.f. are small being about −3 millivolts at 1000°; and +1·5 at 2000°, so that the couple is of little practical value. W. Rohn studied the thermoelectric force of molybdenum against nickel.

P. W. Bridgman found the **thermolectric force,** in volts ×106, of the metal uncompressed and compressed to p kgrms. per sq. cm. to be:

p	10°	20°	40°	60°	80°	100°
2,000 . .	0·012	0·025	0·065	0·109	0·129	0·140
6,000 . .	0·037	0·078	0·209	0·328	0·383	0·415
10,000 . .	0·057	0·125	0·357	0·543	0·634	0·693
12,000 . .	0·066	0·146	0·430	0·649	0·761	0·833

for **Peltier's effect** in joules per coulomb $\times 10^6$ between the uncompressed and compressed metal:

p	0°	20°	40°	60°	80°	100°
2,000 . .	0·30	0·38	0·53	0·47	0·25	0·15
6,000 . .	0·95	1·35	2·41	1·23	0·74	0·48
10,000 . .	1·45	2·28	4·23	2·00	1·23	0·93
12,000 . .	1·69	2·93	4·83	2·44	1·52	1·16

and for **Thomson's effect** in joules per coulomb per °C. $\times 10^6$ expressed as the excess with the compressed over the uncompressed metal:

p	0°	20°	40°	60°	80°	100°
2,000 . .	0	0·6	0·3	−1·3	−1·1	0·0
6,000 . .	0·8	4·4	−2·5	−7·0	−1·8	−1·1
10,000 . .	1·2	13·2	−9·4	−9·3	−2·5	−1·9
12,000 . .	1·6	15·2	−11·6	−9·7	−3·2	−2·2

The thermoelectric force against lead is given by $(5{\cdot}892\theta+0{\cdot}02167\theta^2-0{\cdot}000025\theta^3)\times10^{-6}$ volts; the Peltier's effect, by $(5{\cdot}892+0{\cdot}04334\theta-0{\cdot}000075\theta^2)(\theta+273)\times10^{-6}$ volts; and the Thomson's effect by $(0{\cdot}04334-0{\cdot}0001500\theta)(\theta+273)\times10^{-6}$ volts per °C. C. Zwikker found that the Thomson's effect of molybdenum is negligibly small at about 2000° K., being less than —2 millivolts per degree. E. Blumenthal measured the thermoelectric force of molybdenum against tungsten, and also against tantalum.

R. D. Kleeman and W. Frederickson found that molybdenum wire through which an electric current is passing, acquires a negative charge. M. Forro and E. Patai found the contact potential of sodium against molybdenum to be 2·0 volts; and they measured the contact potential of molybdenum and mercury. E. Dubois studied the Volta effect in water vapour. A. S. Russell and S. W. Rowell said that the position of molybdenum in the electrochemical series is approximately the same as that of mercury. This was determined by finding the most noble metal that can displace them from soln., and the order, relative to metals of known potential, in which it is removed from mercury by oxidation with permanganate. According to L. Marino, although molybdenum can act as a bi-, ter-, or sexivalent element, electrochemically, it acts only as a hexad. It can occur under widely varying conditions in the active and **passive states,** each of which corresponds with its own specific e.m.f. Between these two states, there is an indefinitely large number of other states corresponding with the varying conditions of the surface of the metal. W. Muthmann and F. Fraunberger found that the highest numerical values of the e.m.f. in the two states in N-KCl were —0·74 volt (active) and +0·66 volt (passive). Two fresh pieces had the air potentials 0·26 and —0·02 volt. H. Kuessner observed that two different pieces of metal—containing traces of carbon, and of oxide, and a little iron—behaved differently. One became passive when the current density was about 0·05 amp. per sq. cm., whilst the other showed no signs of passivity even with larger current densities. L. Marino showed that the metal is active when in contact with strongly oxidizing soln., such as those of chlorine, bromine, nitric acid, or chloric acid, at the ordinary temp.; further, it is active in soln. of highly oxygenated salts, but only at temp. rising with the dilution, and also in conc. soln. of certain other acids only capable of dissolving it at their b.p., the e.m.f. being here identical with that exhibited in soln. able to dissolve it readily. W. Muthmann and F. Fraunberger found that the initial and end potentials with 40 per cent. nitric acid were respectively —0·22 and 0·38 volt; with conc. chromic acid, —0·72 and 0·66 volt; with

20 per cent. hydrochloric acid, —0·06 and 0·29 volt; with 16 per cent. sulphuric acid, 0·02 and 0·26 volt; with ammonium persulphate, —0·48 and 0·45; and with 10 per cent. ferric chloride, —0·27 and 0·48 volt. According to L. Marino, the inactive condition of the metal is only possible for certain values of the current density, a fact which indicates the great influence of the latter magnitude on the surface of the metal. This influence is shown most distinctly in soln. of substances rich in oxygen, such as nitric acid and nitrates. Neglecting the slight influences exerted by different electrolytes, the highest value of the e.m.f. after the metal has acted for some seconds as a cathode is 1·50 volts for the active condition and 0·20 volt for the passive condition. The inactive state of the metal is unstable, and, as soon as its cause is removed, reverts to the active condition, the change proceeding more rapidly than with chromium. W. Muthmann and F. Fraunberger observed that bases and reducing agents activate the passive metal. Thus, the initial and end potentials with a conc. soln. of potassium hydroxide were respectively 0·13 and —0·72 volt; with aq. ammonia, 0·29 and —0·31; and with alkaline formaldehyde, 0·33 and —0·31 volt. Active molybdenum reduces soln. of mercuric, cupric, and ferric salts as well as salts of silver, gold, and platinum. L. C. Bannister and U. R. Evans measured the time-potential curves. G. C. Schmidt made observations on this subject. R. Lorenz reported the **electrode potential** of powdered molybdenum in 0·1N-molybdatosulphuric acid to be 0·41 volt; and K. Wolf, from measurements of the potential in alcoholic soln. of molybdenum dichloride calculated 0·53 to 0·55 for the normal electrode potential—but the numbers have little practical value owing to the quick changes which occur in the e.m.f. of cells. Thus L. Marino measured the e.m.f. of the cell, Mo | MX | KCl,HgCl | Hg, where MX represents a neutral salt, acid, or base, and of the cell, Mo | MX | H_2CrO_4 | Pt. The highest value with active molybdenum was 1·5 volt, and with passive molybdenum 0·2 volt—the difference 1·3 volt, and W. Muthmann and F. Fraunberger observed the difference to be 1·4 volt. All cells with a molybdenum electrode showed great difference in their e.m.f. owing to the passivation of the metal. O. Bauer gave —0·200 volt in one per cent. sodium chloride at the start, and —0·164 after 120 hrs. A. Thiel and W. Hammerschmidt found the **overvoltage** with 2N-H_2SO_4 is 0·168 volt at 25°. S. J. French and L. Kahlenberg, and A. C. Krüger and L. Kahlenberg studied the gas-metal electrodes of molybdenum and oxygen, nitrogen, or hydrogen. A. S. Russell and S. W. Rowell found that molybdenum and tungsten are in some respects more reactive than copper but in other respects they resemble mercury, and silver. The values for the electrode potentials are not concordant. O. Collenberg studied the oxidation potential of potassium molybdenum octocyanide, K_3MoCy_8; A. Coehn and O. Schafmeister, the electrokinetic potential of molybdenum; R. J. Piersol, the electronic discharge in vacuum tubes; E. S. Davenport, the surface pitting of tungsten filaments; and H. Nagaoka and T. Fatagami, the spluttering of molybdenum by the disruptive discharge in a magnetic field. W. Ogawa noted that molybdenum-activated galena is a radio detector.

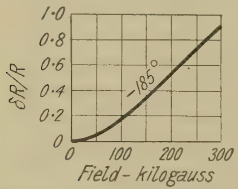

FIG. 7.—The Effect of Magnetic Fields on the Electrical Conductivity.

According to L. Weiss and O. Aichel,[7] molybdenum is para-magnetic. S. Meyer gave for the **magnetic susceptibility,** $0·25 \times 10^{-6}$ mass unit; K. Honda, $0·04 \times 10^{-6}$ to $0·039 \times 10^{-6}$; and M. Owen, $0·60 \times 10^{-6}$ to $0·93 \times 10^{-6}$. The temp., and strength of the magnetic field had only a slight influence on the result. P. Pascal found that the molybdates, unlike the molybdenum salts, are diamagnetic. The subject was studied by D. M. Bose and H. G. Dhar; in its salts, tervalent molybdenum is diamagnetic. P. Kapitza's observations on the effect of strong magnetic fields on the electrical conductivity are summarized in Fig. 7. P. R. Ray studied the magnetic susceptibility of complexes of quinquevalent molybdenum compounds.

§ 5. The Chemical Properties of Molybdenum

F. Fischer and F. Schrötter[1] observed no reaction when molybdenum was sparked beneath liquid **argon.** No *molybdenum hydride* has been prepared. According to A. Vandenberghe, J. H. Müller, and W. Lederer, molybdenum does not in general absorb **hydrogen,** but if the metal is in a fine state of subdivision, L. Hamburger found that it can occlude some hydrogen which is again given off at 300°. E. Martin made observations on this subject. J. A. Kendall made a hot molybdenum film through which hydrogen was passing serve as one element of a galvanic cell. According to J. J. Berzelius, molybdenum loses its metallic lustre by exposure to **air** for some days at ordinary temp. J. Férée found that pyrophoric molybdenum which has been heated to 400° is no longer spontaneously inflammable in air. Under ordinary conditions, molybdenum is stable in air at ordinary temp. W. Lederer, however, said that the surface of the metal exposed to air gradually acquires a brass-yellow film. According to C. Matignon and G. Desplantes, finely-divided molybdenum oxidizes at ordinary temp. in air in the presence of aq. ammonia. J. J. Berzelius said that when heated in air it becomes first brown, then blue, and lastly, nearly white ; and, if the temp. is high enough, it emits light, gives off fumes, and forms crystalline molybdenum trioxide. H. Moissan added that if the metal be free from carbon and silicon, it oxidizes but little in air below a red-heat ; but at a dull red-heat, it oxidizes superficially in air, and at 600° oxidation becomes marked, and molybdenum trioxide slowly volatilizes. The trioxide is the product of the oxidation in air at high temp., but in the oxyhydrogen flame, it is accompanied by the blue oxide. N. B. Pilling and R. E. Bedworth studied the oxidation in air of this family of metals. The metal in **oxygen** at 500° to 600° burns to the trioxide. W. Lederer added that when the metal is warmed in oxygen, it acquires a film coloured successively yellow, brown, blue, bluish-red, and black, its surface then glows, and the black substance suddenly bursts into a pale white flame forming the trioxide. L. O. Bannister discussed the coloured oxide films on molybdenum. C. F. Bucholz, and J. J. Berzelius found that **water** does not oxidize the metal at ordinary temp., and H. Moissan added that if the metal be free from carbon and silicon, it can be kept unchanged in water for several days, even when the water is charged with carbon dioxide. W. Lederer found that after molybdenum has stood in contact with water for a week, it acquires a blue film of a lower oxide, and this then becomes yellowish-brown. With water-vapour, free from air, red-hot molybdenum becomes yellow, then brown, and blue, whilst W. Guertler and

T. Liepus observed no action with sat. chlorine-water during 8 days ; H. V. Regnault observed that molybdenum decomposes water-vapour at a red-heat, first forming a blue oxide, and then molybdenum trioxide. M. Guichard said that steam first oxidizes molybdenum at 700°. W. Guertler and T. Liepus observed that sea-water, aerated sea-water, and aerated rain-water have no action on molybdenum during 8 days' exposure. By slowly oxidizing this metal in water-vapour alone, or admixed with hydrogen, no oxides other than the di- and trioxides are formed. G. Chaudron studied the equilibrium conditions in the balanced reaction : $Mo+2H_2O \rightleftharpoons MoO_2+2H_2$ over the temp. range 700° to 1100°. W. Guertler and T. Liepus observed no action during 24 hrs.' exposure to a soln. of **hydrogen dioxide** in soda-lye ; but L. J. Thénard found that the metal is oxidized. C. G. Fink, and W. G. Mixter found the molybdenum is readily attacked by melting **sodium dioxide ;** J. A. Hedvall and N. von Zweigbergk studied the action of **barium dioxide ;** and H. Moissan that there is an intense development of heat and light when a mixture of molybdenum and **lead dioxide** is heated.

According to H. Moissan, **fluorine** has no action on molybdenum *en masse* at ordinary temp., but it acts on the coarsely-powdered metal with incandescence, and the formation of a volatile fluoride. J. J. Berzelius found that **chlorine** does not act on the metal at ordinary temp.—W. Lederer said that a bluish-black film is formed—but at a gentle heat, the surface exhibits a transient glow, and a dark red vapour is formed. H. Moissan observed that chlorine attacks the metal at a dull-red heat without incandescence ; and **bromine** combines with the metal, though not energetically at a bright red-heat. C. W. Blomstrand observed that with chlorine or bromine, several chlorides or bromides are formed, and if the halogen is mixed with air, oxyhalides are produced. J. J. Berzelius found that chlorine-water oxidizes molybdenum, and W. Lederer, that bromine-water is decolorized by shaking it with powdered molybdenum. J. J. Berzelius, and H. Moissan found that **iodine** has no action on red-hot molybdenum. O. Ruff and H. Krug found **chlorine trifluoride** attacks the metal with incandescence. J. J. Berzelius, and C. F. Bucholz observed that **hydrofluoric acid** has no action on molybdenum, and H. Moissan added that hydrofluoric acid is without action except in the presence of nitric acid when the metal is rapidly attacked. W. E. Ruder said that the metal is not attacked by this acid hot or cold. J. J. Berzelius, and C. F. Bucholz said that the metal is not attacked by **hydrochloric acid ;** W. E. Ruder said that the dil. acid slowly attacks molybdenum at 110° forming some black oxide, probably Mo_2O_3. The loss in weight was 20·3 per cent. after 18 hours. The more concentrated acid (1·15) has a much slower action. After keeping the metal for 18 hours in this acid at 110°, the total loss of metal was only 0·34 per cent. and the surface was still bright. W. Guertler and T. Liepus observed no action during 48 hrs.' exposure to 10 and 36 per cent. hydrochloric acid ; W. Rohn, that the cold 10 per cent. hydrochloric acid dissolved only 0·01 per cent. in 24 hrs. in the cold, and with the hot acid 0·0015 was dissolved in one hour, and 0·08 per cent. in 24 hrs. ; W. Lederer, that boiling dil. hydrochloric acid has no action, but the hot conc. acid very slowly attacks the metal. H. Moissan found that fused **potassium chlorate** attacks the metal violently.

H. Moissan found that **sulphur** has no action on molybdenum at 440° ; but **hydrogen sulphide** at 1200° converts the metal into a sulphide closely resembling molybdenite. J. Férée found that pyrophoric molybdenum at ordinary temp. or when gently heated does not react with hydrogen sulphide. E. W. Engle found that molybdenum is resistant to corrosion by hydrochloric acid. W. Guertler and T. Liepus observed no reaction with 10 and 50 per cent. soln. of **sodium sulphide**—with or without alkali. N. Domanicky observed that an ethereal soln. of **sulphur monochloride** readily attacks molybdenum. According to E. F. Smith and V. Oberholtzer, if molybdenum is heated in the vapour of sulphur monochloride, a complex $Mo_5S_8Cl_9$ is formed. L. Storch found that the presence of sulphomolybdates prevents the precipitation of copper, cadmium, mercury, and iron sulphides.

C. H. Ehrenfeld said that when the metal is heated in **sulphur dioxide,** molybdenum dioxide and a sublimate of sulphur are formed ; whilst J. Férée observed that with pyrophoric molybdenum and sulphur dioxide, the mass glows and a sulphide and oxide are formed. According to J. J. Berzelius, and C. F. Bucholz, dil. **sulphuric acid** does not act on molybdenum, whilst the hot, conc. acid forms sulphur dioxide and molybdenum dioxide if only a small proportion of acid be present, with more acid, blue molybdenum oxide is formed. W. Lederer said that dil. and conc. sulphuric acid do not attack molybdenum ; but A. Rosenheim and H. J. Braun added that molybdenum is attacked only slowly by dil. sulphuric acid, whilst the conc. acid quickly forms a bluish-green soln. According to W. Muthmann, an excess of conc. sulphuric acid begins to act feebly on molybdenum at 160° and sulphur dioxide is evolved ; the grass-green liquid darkens to an olive-green. If the temp. is not too high, all the metal dissolves. If the temp. is near the b.p. of the acid, the soln. becomes blue and then colourless—the dioxide first formed is oxidized to molybdenum trioxide. W. E. Ruder found that sulphuric acid of sp. gr. 1·30 does not attack molybdenum at 110° ; but that the conc. acid of sp. gr. 1·82 attacks it slowly. Only 0·29 per cent. loss in weight was found after 18 hrs. With elevated temp., however (200°–250°), the metal dissolves rapidly to a green soln., with the evolution of sulphur dioxide. W. Rohn noted that 10 per cent. cold sulphuric acid dissolved 9·006 per cent. after 24 hrs., and only 0·0015 per cent. dissolved in the hot acid in an hour, and 0·03 per cent. in 24 hrs. R. H. Adie added that the reaction with conc. sulphuric acid begins with the evolution of gas at 115° ; sulphur dioxide is given off at 135°, and no hydrogen sulphide. A green solid is formed. W. Guertler and T. Liepus found that 10 per cent. sulphuric acid does not attack chromium during 48 hrs.' exposure ; and similarly with 20 per cent. H_2SO_4 sat. with sodium sulphate. C. G. Fink found that fused **potassium hydrosulphate** readily attacks the metal.

A. Vandenberghe observed no reaction between molybdenum and **nitrogen ;** I. Zschukoff said there is a slight reaction at 1000°, and H. Moissan added that no combination occurs at 1200° ; whilst J. Ferée found no combination with gently-heated, pyrophoric molybdenum in nitrogen. E. Martin studied the occlusion of nitrogen, and the formation of nitrides, by the metal. I. Langmuir observed that when a molybdenum filament is heated to 2000° or 2400° in nitrogen at 0·3 mm. press., the nitrogen is all absorbed. N. R. Campbell made some observations on this subject. E. J. B. Willey measured the rate of decay of active nitrogen in the presence of a molybdenum filament. The phenomenon is discussed in connection with molybdenum nitride—**8**. 49, 12. E. F. Smith and V. Oberholtzer found that **ammonia** has no action on molybdenum at temp. up to a red-heat. The action at high temp. was studied by C. H. Kunsman ; E. S. Lamer and W. E. Deming, and C. H. Kunsman and co-workers discussed the catalytic effect of molybdenum on the decomposition of ammonia. W. Guertler and T. Liepus observed no reaction during 8 hrs.' exposure to 10, 50, and 70 per cent. aq. ammonia ; but C. Matignon and G. Desplantes observed that when shaken up at ordinary temp. in a flask containing 10 c.c. of aq. ammonia (1 : 4), molybdenum is oxidized ; C. H. Ehrenfeld, that **methylamine** is also inactive—the trace of hydrogen cyanide which is formed is due to the decomposition of the amine ; and F. W. Bergstrom found that a soln. of **potassamide** in liquid ammonia acts very slowly or not at all. According to C. H. Ehrenfeld, when molybdenum is heated in **nitrous oxide,** it forms molybdenum trioxide ; and likewise also with **nitric oxide.** F. Emich said that with finely-divided molybdenum in nitric oxide, at the beginning of a red-heat, there are formed successively MoO_2, Mo_2O_3, Mo_5O_{12}, and finally MoO_3. C. H. Ehrenfeld also observed that in **nitrogen peroxide,** molybdenum trioxide is formed. J. Férée found that pyrophoric molybdenum glows in nitrogen peroxide, forming oxide and nitride. J. J. Berzelius, and C. F. Buchloz observed that **nitric acid** attacks molybdenum with the development of nitrous fumes ; with a large proportion of acid molybdenum trioxide is formed ; with less acid, the dioxide. W. Lederer said that dil. nitric acid does not attack the metal immediately in the cold, but with the hot acid, the liquid is coloured yellow, brown, and blue, and a protective layer of molybdenum trioxide forms on the metal; with conc. nitric acid this layer is formed at once—*vide supra,* passive molybdenum. C. Montemartini observed that molybdenum is attacked by 3 to 70 per cent. acid without the formation of ammonia. Conc. acid (70 per cent.) attacks the metal but slowly; a much more vigorous action occurs with a less conc. acid (50 per cent.), and a reddish soln. and residue are obtained. The soln. reduces permanganate, so that the metal is not immediately converted into molybdenum trioxide by 50 per cent. acid, but a nitrate is first formed; 70 per cent. acid at once gives molybdenum trioxide. The quantity of nitric oxide produced in the reaction between nitric acid and molybdenum decreases as the conc. of the acid increases; nitric peroxide is the main gaseous product with 50 per cent. acid. Neither nitrogen nor nitrous oxide is formed. W. Guertler and T. Liepus found that 10 and 50 per cent. HNO_3 have no action on molybdenum in 8 hrs., and similarly with aqua regia. W. E. Ruder said that conc. nitric acid of sp. gr. 1·40 dissolves molybdenum slowly forming molybdenum trioxide, which deposits on the surface of the metal and retards the action; but a more dil. acid of sp. gr. 1·15 attacks the metal rapidly. Aqua regia dissolves the metal rapidly, particularly when hot. W. Rohn added that 10 per cent. nitric acid in the cold dissolved 5·2 per cent. in 24 hrs., and the hot acid, 1·8 per cent. in one hour. J. J. Berzelius, C. F. Bucholz, H. Moissan, and W. Lederer found that mixtures of sulphuric, hydrofluoric, or hydrochloric acid with nitric acid quickly attack molybdenum. L. Marino, and W. E. Ruder said that molybdenum is rapidly attacked by hot aqua regia. F. W. Bergstrom found that the metal is slightly attacked by a soln. of ammonium nitrate. W. Lederer, C. G. Fink, and H. Moissan found that fused **potassium nitrate** oxidizes molybdenum rapidly though less violently than the fused chlorate; and similarly with **sodium nitrate.** Purified molybdenum does not unite with **phosphorus** at the m.p. of glass. When the metal is gently heated with **phosphorus pentachloride,** a volatile chloride is formed which rapidly acquires a blue colour when exposed to moist air. Most molybdenum compounds give this reaction and therefore it may be used as a test for molybdenum. W. Rohn found that a cold 10 per cent. of **phosphoric acid** dissolved 0·03 per cent. of molybdenum in 24 hrs., and the hot acid, 0·009 per cent. in one hour. W. Guertler and H. Schack found that if a rod of molybdenum be placed in a mass of fused **antimony trisulphide,** it dissolves to the disulphide liberating an eq. quantity of antimony.

H. Moissan observed that when a mixture of molybdenum and **boron** is heated in the electric furnace, a crystalline boride is formed; and **silicon,** under similar conditions, furnishes a crystalline silicide. When the metal is heated with **carbon** at about 1500°, it undergoes cementation, and becomes hard enough to scratch glass, and if heated at 300° and suddenly cooled in water, it becomes brittle and will still scratch glass. If carboniferous molybdenum is heated with the dioxide, at a temp. much below its m.p., the carbon is removed. The phenomenon is said to be connected with the volatility of the oxide. The reaction with carbon was also studied by G. Tammann and K. Schönert, A. Westgren and G. Phragmen, T. Takei, and K. Nischk—*vide* carbides. W. Lederer also observed that molybdenum becomes harder when heated with carbon, and that gaseous **hydrocarbons** are decomposed with the separation of carbon. S. Hilpert and M. Ornstein found that the carbide is formed when the powdered metal is heated at 600°–1000° in a mixture of hydrogen and **methane** (1 : 1); E. F. Smith and V. Oberholtzer found that **carbon monoxide** has no action on molybdenum at a red-heat; but S. Hilpert and M. Ornstein obtained the carbide Mo_2C by heating the powdered metal in an atm. of carbon monoxide, and J. Férée found that carbon monoxide acts on pyrophoric molybdenum with a slight rise of temp., and a sudden glowing of the metal with the absorption of oxygen and the separation of carbon. A. Vandenberghe observed that molybdenum (and its lower oxides) reduces **carbon dioxide,** forming carbon monoxide; the reaction is reversible: $Mo+3CO_2 \rightleftharpoons 3CO+MoO_3$, since, under suitable conditions, the trioxide is reduced to the metal by carbon monoxide. J. Férée found that pyrophoric molybdenum at ordinary temp. acts on carbon dioxide with a slight rise of temp. W. Guertler and T. Liepus observed no action on molybdenum by water sat. with carbon dioxide during 8 hrs.' exposure. S. Medsforth studied the action of molybdenum on the nickel catalyst in the hydrogenation of carbon monoxide or dioxide; and A. Korczynsky, in reactions with organic compounds. E. F. Smith and V. Oberholtzer observed that at 150° to 200°, **carbonyl chloride** forms a liquid sublimate which yields a gelatinous mass on cooling —it is a mixture of $MoOCl_4$ and $Mo(CO)Cl_4$. C. Beindl used molybdenum as catalyst in the synthesis of hydrocyanic acid from nitrogen, hydrogen, and carbon monoxide; and O. Schmidt, and R. Hocart, as a hydrogenation catalyst. W. Guertler and T. Liepus observed no reaction during 48 hrs.' exposure of the metal to soln. of **citric acid** and **tartaric acid.** E. W. Engle said that molybdenum is markedly attacked by the weaker organic acids. W. Rohn added that after 24 hrs.' action by cold 10 per cent. **acetic acid,** 0·02 per cent. of metal was dissolved; whilst 0·003 per cent. dissolved in the hot acid in an hour.

The alloys of molybdenum with the **metals** are discussed below. J. J. Berzelius, and C. F. Bucholz found that a boiling soln. of **potassium hydroxide** does not oxidize molybdenum; whilst the fused hydroxide slowly attacks the metal, and, according to J. von Liebig, converts it into the trioxide. W. Guertler and T. Liepus observed no reaction with less than 8 hrs.' exposure to 10 and 50 per cent. NaOH. H. Kuessner found that molybdenum goes into soln. anodically in N-KOH as sexivalent molybdenum, and at low temp. some oxygen is evolved. W. E. Ruder observed no action by soln. of potassium hydroxide, but the metal is soluble in the fused alkali. M. Leblanc and O. Weyl observed that between 550° and 660° fused potassium hydroxide has a slight action on fused potassium hydroxide, forming traces of potassium and hydrogen.

E. F. Smith and co-workers observed that molybdenum precipitates copper incompletely from soln. of **copper salts.** According to H. Moissan, **silver fluoride** reacts with molybdenum without forming volatile products. J. S. de Benneville observed that molybdenum dissolves in a soln. of **silver nitrate** with the separation of silver, and, added E. F. Smith and co-workers, the soln. becomes turbid owing to the separation of molybdic acid. The turbidity is not produced with an ammoniacal soln. of silver oxide or chloride. The reaction is quantitative, one gram-atom of molybdenum precipitates six gram-atoms of silver. Hence, in the case of chloride, the dark brown soln. must contain molybdenum hexachloride. This is also formed with a soln. of **gold chloride,** for a gram-atom of molybdenum precipitates two gram-atoms of gold. H. Moissan found that solid **zinc fluoride** reacts with molybdenum without forming a volatile product. According to E. F. Smith and co-workers, soln. of **cadmium salts** are not affected by molybdenum. Molybdenum reduces a neutral soln. of **mercuric chloride** to mercurous chloride and eventually to mercury. W. Guertler and T. Liepus observed that a 1 : 500 mercuric chloride soln. at 90° is stable with molybdenum; whilst a **magnesium chloride** soln. does not attack the metal in 8 hrs. H. Moissan observed that the reaction with **lead fluoride** resembles that with silver fluoride. E. F. Smith and co-workers observed no reaction with acidic, neutral, or alkaline soln. of **lead salts;** nor is there any reaction with **bismuth salts.** E. F. Smith and H. C. Burr, and C. H. Ehrenfeld found that molybdenum reduces **ferric chloride** to the ferrous salt, and from the amount of iron reduced it follows that the molybdenum forms the hexachloride. E. F. Smith observed a partial reduction to metal with soln. of **platinum, palladium,** and **rhodium salts.**

Some reactions of analytical interest.—General observations on the analysis of mixtures containing molybdenum were made by A. A. Noyes and W. C. Bray,[2] and E. Knoevenagel and E. Ebler. A conc. soln. of an alkali molybdate gives a white precipitate when treated with **dilute acids.** The precipitate is soluble in excess. According to F. von Kobell,[3] O. Maschke, and L. Schönn, if a trace of a molybdenum salt mixed with conc. **sulphuric acid** is evaporated nearly to dryness the mass is coloured intensely blue. If antimony or tin be present, the mixture should be first evaporated to dryness with phosphoric acid before heating it with sulphuric acid. P. Truchot added that if vanadic acid be present, a green colour may be produced. If the molybdenum soln. be treated with **hydrogen sulphide,** the liquid becomes blue, and molybdenum trisulphide is gradually precipitated as a brownish-black solid which forms a brown soln. with alkali or ammonium sulphide. The trisulphide is reprecipitated by acids. The molybdenum sulphide is oxidized by hot sulphuric or nitric acid, or by roasting in air, to white molybdenum trioxide. Molybdenum sulphide is not attacked by a soln. of oxalic acid whereas tin sulphide is dissolved. Hydrogen and ammonium sulphides act similarly on salts of the lower oxides; and, it might be added, the salts of the lower oxides furnish precipitates with **alkali hydroxides and carbonates** which are soluble in an excess of the carbonate soln. As shown by E. Dohler,[4] E. H. Miller, etc., the precipitation of molybdenum as sulphide from acidic soln. by hydrogen sulphide atm. press. is imperfect. If the soln. be sat. with hydrogen sulphide and heated in a sealed bottle on a water-bath, the precipitation is complete. If a soln. of a molybdate be treated with a **reducing agent**—*e.g.*, zinc and hydrochloric or sulphuric acid, stannous chloride, mercurous nitrate, ferrous sulphate, sodium hypophosphite, sulphur dioxide, etc.—the liquid is coloured blue, then green, and finally brown. L. A. Munro found that the reaction when used as a test for tin in stannous chloride is sensitive to 1 : 1,423,000. According to E. Kafka,[5] if to the neutral soln. of either compound is added a drop of sat. soln. of mercurous nitrate, then 1 c.c. of conc. hydrochloric acid, and further an excess of potassium iodide, a precipitate of mercurous iodide will form and redissolve, mercury will deposit, and the supernatant liquid will gradually turn blue—very dil. soln. of molybdic acid are, however, not affected. To distinguish between tungsten and molybdenum, potassium thiocyanate is added, when in the case of molybdenum the blue colour will change to blood-red. If **potassium thiocyanate** be added to an acidic soln. of a molybdenum salt, there is no perceptible change, but if the soln. be then treated with zinc, stannous chloride soln. or hydrogen sulphide,[6] a blood-red coloration appears. Unlike the case with iron, this coloration occurs in the presence of phosphoric acid. The presence of tartaric and other organic acids hinders the reaction. If the red soln. be shaken with ether, the coloured compound passes from the aq. to the ethereal layer. A few drops of a soln. of **sodium phosphate** added to a nitric acid soln. of a molybdate slowly furnishes a yellow precipitate of ammonium phosphomolybdate. The precipitation occurs more quickly with hot soln. Arsenates produce an analogous precipitation. Salts of the lower oxides also give precipitates with alkali phosphate. According to M. Siewert, molybdenum compounds give a red or plum coloured reaction with **xanthic acid.** S. L. Malowan recommended applying the test as follows: Absolute alcoholic potash is shaken with excess of carbon disulphide until no more of the latter is dissolved. To the soln. so obtained, 30 per cent. acetic acid is added until it shows a slight yellow turbidity, and the reagent is added drop by drop to the soln. to be tested. If molybdenum is present, an intense red colour develops, which is quite stable in water, and the intensity of which is proportional to the quantity of molybdenum present. The sensitiveness of the reaction is such that 0·000005 grm. of molybdenum in 0·0007 per cent. soln. can be detected with certainty in presence of other elements. The coloured product is readily soluble in ethyl or amyl alcohol, ether, or chloroform. less easily in petroleum and benzene. It is readily extracted from its reddish-violet ethereal soln. by alkalies, from which acids precipitate it. The ethereal soln. decomposes on keeping, with formation of molybdenum sulphide. The reaction is not given by vanadium, tungsten, titanium, or uranium; chromates give a dark coloration with xanthic acid, and should be reduced, if present, before the test is made. The reaction can be used for the colorimetric estimation of molybdenum, the coloured product being extracted with a mixture of 65 per cent. ether and 35 per cent. light petroleum, and a mixture of 30 per cent. ether and 70 per cent. light petroleum used for dilution for comparison with the standard soln. If pure ether is used, decomposition takes place too rapidly for accurate determinations to be made. The process was studied by J. Koppel,[7] and D. Hall. Neutral soln. of molybdates give with **mercurous nitrate** a white precipitate soluble in nitric acid ; **lead acetate** precipitates white lead molybdate soluble in nitric acid ; **potassium ferroycanide,** in a soln. acidified with hydrochloric acid, gives a reddish-brown precipitate. Salts of the lower oxides also give precipitates with potassium ferrocyanide and ferricyanide. E. Lecocq obtained an indigo-violet coloration with an alcoholic soln. of **diphenylcarbazide ;** L. Spiegel and T. A. Maass, and M. E. Pozzi-Escot, a wine-red coloration with an acetic acid soln. of **phenylhydrazine ;** L. Lévy observed a number of colour reactions with **alkaloids ;** E. Kedesdy, and M. E. Pozzi-Escot, a brown colour with **tannin ;** and many other colour reactions with organic substances have been reported. F. Steidler studied the colours produced by molybdenum salts on **silk** dipped in turmeric or α-nitroso-β-naphthol with a view to the microdetection of the element. J. H. Muller [8] found that **salicylic acid** gives a yellow coloration but no precipitate with soln. of the alkali molybdates. H. J. H. Fenton observed a red or brown colour is produced by molybdates and **dihydroxymaleic acid**; and J. H. de Boer, a violet coloration with **alizarinsulphonic acid.** Like titanic acid soln., molybdates give a yellowish colour with **hydrogen dioxide.**

Some uses of molybdenum.—Several patents have been taken for the use of molybdenum filaments in the incandescent lamp industry.[9] The Gebrüder Siemens u. Co. used molybdenum as an ingredient in the preparation of arc-light electrodes. Preparations of molybdenum have been recommended in photographic work ;[10] in dyeing [11] silks, woollens, and leather,[12] and rubber ; in the preparation of blue colours,[13] and for producing red and yellow pottery glazes and glasses [14] for colouring artificial emeralds ;[15] and as a catalytic agent in chemical operations [16] molybdic acid has been tried as a depolarizing agent in place of nitric acid ;[17] various compounds are used as chemical reagents ; and as a preservative for smokeless powder in hot climates.[18] Molybdenum trisulphide has been recommended as a solder for lamp-filaments.[19] Molybdenite is used as a rectifier in wireless telegraphy. Molybdenum wire has been recommended as resistance wire in electric furnaces.[20] It is used as a substitute for platinum and platinum-iridium alloys [21] in various make-and-break contact devices ; in dentistry ; in the manufacture of X-ray tubes ; and as a wire for supporting the filaments of incandescent lamps,[22] and as a support for refractory materials.[23] The most important application of molybdenum is in the preparation of alloys, and particularly of special steels—molybdenum steels. When compared with other alloy-steels, and tempered by heat to the same tensile strength, A. H. Hunter [24] said that molybdenum steels have a slightly higher elastic limit, and elastic ratio ; a higher elongation or greater ductility ; and a higher reduction of area or greater toughness. The molybdenum steels are used for motor-car frames, shafts, and rods for motor-cars, and aeroplanes ; high-pressure boiler-plates, linings for big-guns ; rifle barrels ; armour plate and armour-piercing projectiles ; steel-balls for grinding mills ; permanent magnets ; etc.

§ 6. The Atomic Weight and Valency of Molybdenum

The valency of molybdenum has been discussed by H. Kauffmann.[1] In many ways the valency of molybdenum is analogous with that of chromium. The element appears to be *bivalent* in the dichloride, but, according to W. Muthmann and W. Nagel, this valency is disguised by the polymerization of the salt to Mo_3Cl_6. Molybdenum is probably *tervalent* in Mo_2O_3, $Mo(OH)_3$, $MoCl_3$, etc. G. Carobbi discussed the isomorphism of tervalent iron and molybdenum salts. According to A. Rosenheim, the complex thiocyanate, $Mo(SCy)_3.3KSCy.4H_2O$, is analogous to the corresponding chromium salt. It is probable that the element is *quadrivalent* in the dioxide, MoO_2; the tetrachloride, $MoCl_4$; the complex oxalates of H. M. Spittle and W. Wardlaw; and the $MoCl_4.6PyHCl$ of J. Sand and A. K. H. Burger. When $MoCy_4.4KCy.2H_2O$ is titrated with potassium permanganate, A. Rosenheim said that it consumes as much oxygen as if the salt were quinquevalent. The element is *quinquevalent* in $MoCl_5$, in the complex salt $MoOCl_3.2RbCl$, and in the oxide Mo_2O_5 of P. Klason, and I. Nordenskjöld. In the molybdenum hexafluoride of O. Ruff and F. Eisner, the element is probably *sexivalent*, and this is possibly also the case with the compounds $MoOF_4$ and MoO_2F_2, as well as with the trioxide, MoO_3, and the molybdates. W. Muthmann and W. Nagel also consider that the element is sexivalent in the permolybdates, but, possibly, it is septivalent in these compounds—*vide infra*. L. Pauling discussed the co-ordination number.

Molybdenum compounds were analyzed by M. H. Klaproth,[2] and C. F. Bucholz, and from these results, J. J. Berzelius inferred that the sulphide has the mol. ratio Mo : S=1 : 2, and molybdic anhydride Mo : O=1 : 3, using the present-day system of at. wts. He also said that chromic and molybdic anhydrides have a similar composition. This conclusion makes the at. wt. of molybdenum approximate to 96. This is in agreement with H. Debray's observation on the density of molybdenum pentachloride, and of A. Vandenberghe on the vap. density of molybdenum trioxide. It is also in agreement with W. Muthmann and W. Nagel's observations on the mol. wt. of Mo_3Cl_6 from its effect on the b.p. of alcohol; and with A. Vandenberghe's observation on the mol. wt. of the pentachloride from its effect on the b.p. of carbon tetrachloride, and with the mol. wt. of $MoO(OH)_2Cl_2$ from its effect on the b.p. of alcohol, acetone, and ether. The at. wt. 96 also fits in with the sp. ht. rule at ordinary temp.—*vide supra;* it also fits in with the isomorphism observed by J. G. Gentele, and R. Funk with the sulphates, chromates, selenates, and molybdates, and the isomorphism observed by F. Ullik with the ammonium magnesium complex salts; with the chemical equivalent observed by E. F. Smith in the precipitation of silver or gold salts by molybdenum; and with the electrochemical equivalent observed by L. Marino, and H. Kuessner. The position assigned to molybdenum in the periodic table of at. wts. is also in harmony with the at. wt. 96; and the same remark applies to the at. number obtained by H. G. J. Moseley, and J. Malmer from the frequency of the X-ray spectral rays.

For the at. wt. of molybdenum, J. J. Berzelius calculated 95 from the ratio $Pb(NO_3)_2 : PbMoO_4$. In 1837, H. Rose made an unsatisfactory attempt to calculate the at. wt. from the ratio Mo : 5Cl; M. Delafontaine also obtained some unsatisfactory results in 1865. L. von Meyer calculated 96·2 from L. P. Liechti and B. Kempe's analyses of the molybdenum chlorides. In 1848, L. F. Svanberg and H. Struve calculated 92 from the ratio $MoO_3 : CO_2$; and 93 to 95 from the ratio $MoS_2 : MoO_3$. N. J. Berlin obtained 96·5 from the ratio $3(NH_4)_2MoO_4.4H_2MoO_4 : MoO_3$; O. F. von der Pfordten, 96·1 from the ratio $3(NH_4)_2MoO_4.4H_2MoO_4 : Mo$; E. F. Smith and P. Maas, 96·03 from the ratio $Na_2MoO_4 : 2NaCl$; and K. Seubert and W. Pollard, 95·92 from the ratio $2AgCl : MoO_3$. J. B. A. Dumas calculated from the ratio $Mo : MoO_3$, 95·9; H. Debray, 95·4; C. F. Rammelsberg, 96·2; K. Seubert and W. Pollard, 95·97; A. Vandenberghe, 96·06; and J. H. Müller, 96·02 to 96·05. F. W. Clarke computed 96·029 for the best representative value for date up to 1910; and J. Meyer, 96·04 up to 1919. The International Table for 1926 gave 96 for the best representative value.

The **atomic number** is 42. F. W. Aston[3] found that molybdenum has seven **isotopes** with mass numbers, and approximate proportions respectively 92 and 14·2; 94 and 10·0; 95 and 15·5; 96 and 17·8; 97 and 9·6; 98 and 23·0; and 100 and 9·8. The packing fractions of Mo^{98} and Mo^{100} are both approximately —5·5 giving an at. wt. of 95·97. M. Gerber considers that his neomolybdenum—*vide supra*—is an isotopic form. N. Bohr's view of the **electronic structure** is symbolized (2) for the K-shell; (4, 4) for the L-shell; (6, 6, 6) for the M-shell; (4, 4, 4) for the N-shell; and (2) for the O-shell. The subject was studied by O. Feussner, R. Ladenburg, H. Lessheim and R. Samuel, C. D. Niven, J. N. Frers, J. D. M. Smith, and E. C. Stoner. According to E. Rutherford and J. Chadwick, and H. Pettersson and G. Kirsch, the **atomic disruption** of molybdenum by α-particles has not yet been proved. The subject was discussed by G. I. Podrowsky.

§ 7. Alloys and Intermetallic Compounds of Molybdenum

Alloys of molybdenum with some of the metals have been prepared by the fusion of the mixed metals, by reducing the mixed oxides in the electric furnace (C. L. Sargent[1]), or by the alumino-thermite process (A. Stavenhagen and E. Schuchard).

L. Rolla and G. Piccardi studied the ionization produced by mixtures of molybdenum and **sodium.** L. P. Hamilton and E. F. Smith reported that a molybdenum and **copper** alloy can be formed by heating a mixture of the two metals in an electric furnace at 1600°, but their product contained 78·53 per cent. Cu; 8·53, Mo; 2·71, Fe; 2·42, C; and 8·02, gangue. W. Lederer also prepared cupromolybdenum as indicated above, but C. L. Sargent could not get copper to alloy directly with molybdenum. According to L. F. Dreibholz, if purified metals are employed no alloy is formed. The elements are immiscible. He considers that the thermal diagram of the two elements has the form shown in Fig. 8. L. Jordan and co-workers observed that **silver** does not alloy with molybdenum; but, added L. F. Dreibholz, at 1600°, it may dissolve about 5 per cent. of molybdenum—this is rejected during solidification. There is no evidence of molybdenum dissolving silver at 1600°; at this temp., globules of molybdenum float in the silver. Similarly with **gold,** L. F. Dreiholz observed that a little molybdenum may be dissolved at 1500°, but on solidification the molybdenum is rejected. No alloys with the **alkaline earths,** or with **beryllium** have been prepared. N. J. Tram found

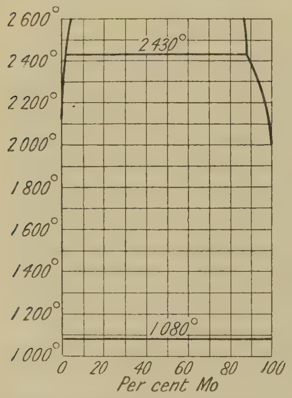

FIG. 8.—Freezing-point Curves of the System: Mo–Cu.

that **magnesium** reacts explosively when heated with molybdenum trioxide, and he added that the product develops hydrogen when treated with water. Alloys of molybdenum and **zinc,** or with **cadmium,** have not been formed. G. Tammann and J. Hinnüber found the solubility of molybdenum in mercury to be too small for measurement. A. S. Russell and co-workers found that between 10^{-5} to 5×10^{-5} grm. per gram of mercury passes into soln. at room temp. G. Tammann and J. Hinnüber, A. Chilesotti, and R. E. Myers obtained **molybdenum amalgams** by the electrolysis of acidic soln. of molybdic acid with a mercury cathode. According to J. Férée, hydrochloric acid of sp. gr. 1·18, sat. with molybdic acid, is diluted with nine times its vol. of water, and electrolyzed with a mercury cathode and a platinum anode, the current being about 5 ampères for each sq. cm. of mercury surface. After some time, the mercury is dried and filtered through chamois leather, when it yields a solid amalgam, **molybdenum enneamercuride,** $MoHg_9$, which is but slightly affected by moist air. When it is subjected to a press. of 200 grms. per sq. cm., it yields another amalgam, **molybdenum dimercuride,** $MoHg_2$, and if this is broken up and again compressed, it yields a third compound, **molybdenum hemitrimercuride,** Mo_2Hg_3, which alters rapidly in moist air. The decomposition of the amalgams under press. is the inverse of the phenomenon observed by W. Spring—**1.** 13, 17. A. S. Russell found that the order of the removal of metals from amalgams by oxidizing agents is Zn, Cu, Cr, Fe, Mo, Co, Hg, Ni, and W.

Alloys of molybdenum and **aluminium** were prepared by F. Wöhler and F. R. Michel, H. Moissan, H. Reimann, and H. Schirmeister. H. Reimann worked with molybdenum disulphide in place of the trioxide. C. Combes was not very successful in preparing alloys by the action of aluminium on molybdenum chloride and sulphides. According to L. Guillet, alloys are obtained by the aluminothermite process, and from the elements. Mixtures of 5 gram-atoms of molybdenum, as MoO_3, and one gram-atom of aluminium furnish **molybdenum icositaluminide,** $AlMo_{20}$, in well-formed crystals which develop no gas with hydrochloric acid; **molybdenum tetritaluminide,** Mo_4Al, from 2 gram-atoms of molybdenum and one gram-atom of aluminium, the crystals are not attacked by hydrochloric acid. With the atomic proportions Mo : Al =1 : 3 fibrous crystals of **molybdenum aluminide,** AlMo, are formed; whilst 1 : 1-mixtures furnish crystals of **molybdenum dialuminide,** Al_2Mo. L. Guillet obtained **molybdenum tetraluminide,** Al_4Mo, in lamellar crystals from the 1 : 1 mixture; and F. Wöhler and F. R. Michel, from a mixture of dry molybdenum fluoride, cryolite, potassium sodium chloride, and aluminium in the proportions 1 : 2 : 2 : 1. The microscopic prisms are black, or iron-grey. They are soluble in hot hydrochloric or nitric acid. L. Guillet prepared crystal aggregates of **molybdenum heptaluminide,** Al_7Mo, by reducing molybdenum trioxide with a large excess of aluminium. There is here nothing to show that any of these products is a chemical individual. H. Reimann said that it is highly probable that **molybdenum tritaluminide,** Al_3Mo, exists as a chemical compound; and he gave Fig. 9 as a probable equilibrium diagram for mixtures with up to 50 per cent. of molybdenum.

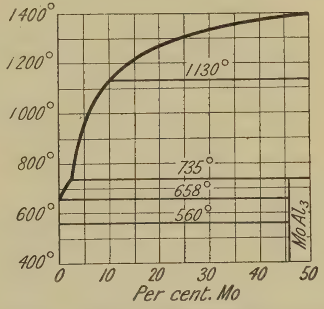

Fig. 9.—Supposed Freezing-point Curve of Mo–Al Alloys.

Alloys of molybdenum with **thallium** or with **tin** have not been reported. L. Rolla and C. Piccardi studied the ionization produced by mixtures of thallium and molybdenum. P. J. Hjelm said that **lead** alloyed with a little molybdenum is whiter and harder than ordinary lead, whilst with more molybdenum, the alloy becomes black and brittle. A. Stavenhagen and E. Schuchard obtained an alloy by the alumino-thermite process; but L. Ott did not obtain it by the electrolysis of a molten mixture of sodium carbonate and molybdate by means of a molten lead cathode.

J. J. Boericke prepared alloys of molybdenum and **vanadium** made by reducing a mixture of a molybdenum or vanadium compound with aluminium in the presence of the alloying metal and a large quantity of an indifferent flux. W. von Bolton obtained alloys with **tantalum.** W. Lederer, C. L. Sargent, and E. Haynes found that alloys of **chromium** and molybdenum can be readily prepared. The alloys were discussed by W. Guertler. E. Siedschlag found that molybdenum dissolves readily in molten chromium until the mass contains 25 per cent. of the former ; in investigating alloys richer in molybdenum, the finely-powdered metals were mixed and compressed into briquettes, which were then heated, but for proportions of molybdenum above 50 per cent., the initial solidification temp. could not be measured. The curve, Fig. 10, shows a eutectic at 1460°, 22·7 per cent. Mo. The liquid is homogeneous, but no mixed crystals are formed below 22·7 per cent. Mo, the solid consisting of chromium crystals and the eutectic mixture ; above this proportion, the solid consists of Mo crystals containing 2·5 per cent. Cr, and the eutectic. The alloys are not likely to be mechanically useful ; those rich in Cr cut glass with remarkable ease. The system copper-molybdenum is heterogeneous in both the liquid and solid states, whilst chromium and copper form no mixed crystals, and are only partly miscible in the liquid state. In the ternary system, Cu–Cr–Mo, the three metals remain separate in the solid state. When electrolytic copper is melted with powdered chromium and molybdenum, no mixed crystals can be detected ; the solids consist of the three metals with the Cr–Cu, and the Cr–Mo eutectics. Alloys of copper with up to ·38 per cent. of Cr should dissolve up to 8 per cent. of Mo, whilst chromium-molybdenum mixtures should dissolve up to 7 per cent. of copper.

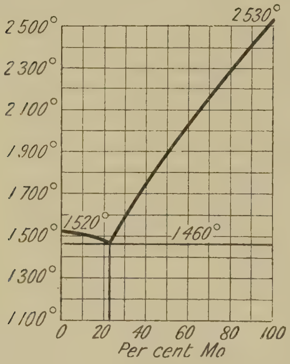

Fig. 10.—Freezing-point Curve of the Mo–Cr Alloys.

§ 8. Molybdenum and Molybdic Oxides

According to J. J. Berzelius,[1] **molybdenum monoxide,** or **molybdous oxide,** MoO, is formed as a purple or violet powder when zinc and hydrochloric acid are allowed to act for a long time on fused or sublimed molybdenum trioxide; but the product is probably molybdic oxide. W. Muthmann and W. Nagel could not prepare this oxide. C. W. Blomstrand thought that **molybdous hydroxide,** $Mo(OH)_2$, is formed as a black solid by the action of conc. potash-lye on molybdenum dibromide, but he later represented it as $Mo_3(OH)_6$. W. Muthmann and W. Nagel found that the hydrogen is given off while the black precipitate is being formed, and they find that it is molybdic hydroxide, $Mo(OH)_3$. The same product is obtained by the action of potash-lye on molybdenum dihydroxytetrabromide, $Mo_3(OH)_2Br_4+4KOH+3H_2O=3Mo(OH)_3+4KBr+3H$. This makes it doubtful if a bivalent molybdenum compound has yet been prepared.

What J. J. Berzelius [2] called molybdous oxide was shown by C. W. Blomstrand, and C. F. Rammelsberg to be hydrated **molybdic oxide,** or **molybdenum sesquioxide,** or **molybdenum hemitrioxide,** Mo_2O_3. J. J. Berzelius obtained the hydrated oxide by the action of reducing agents on a soln. of a molybdenum salt or of molybdic acid. Thus, by treating a hydrochloric acid soln. of molybdenum chloride, standing over mercury, with liquid potassium amalgam, added drop by drop, the soln. becomes greenish, and then black and opaque. As soon as the oxide begins to separate, the soln. is decanted, and the hydroxide is precipitated by ammonia, washed, dried over sulphuric acid in vacuo, and heated out of contact with air. If an excess of hydrochloric acid be not present, a higher dark brown oxide is precipitated instead of the black molybdic oxide. As indicated above, this oxide was also obtained by the prolonged action of hydrochloric acid and zinc on fused or sublimed molybdenum trioxide; and also by the action of zinc on a conc. soln. of ammonium or alkali molybdate in an excess of hydrochloric acid so that the molybdic acid first precipitated is redissolved. The soln. becomes blue, then reddish-brown, and finally black. It is then poured off the zinc and mixed with enough aq. ammonia to precipitate the molybdic oxide alone. The precipitate is washed with dil. aq. ammonia to remove the zinc oxide, and afterwards with cold water. It is then pressed, dried over sulphuric acid in vacuo, and heated out of contact with air. M. Guichard found that the hydrated form alone exists because, when the black product $Mo(OH)_3$ is dehydrated, internal oxidation occurs, and the composition is not Mo_2O_3. Modifications of this process were used by J. Sopp, A. Atterberg, C. F. Rammelsberg, A. C. Chapman and H. D. Law, D. L. Randall, M. Guichard, A. Chilesotti, A. Wernecke, F. Pisani, and I. Macagno. C. W. Blomstrand used magnesium, zinc, or zinc coated with cadmium, and sulphuric or hydrochloric acid, washing out the zinc salts by very dilute hydrochloric acid. F. von Kobell boiled lead molybdate with hydrochloric acid and copper; C. F. Rammelsberg, and H. Hirzel used ammonium molybdate or molybdic acid. C. Paal and H. Büttner found that the reduction of ammonium molybdate by colloidal palladium at ordinary temp. yields hydrated molybdenum dioxide, but at 50° to 60°, under a slight press., hydrated molybdic oxide is formed. If the reduction occurs in the presence of a protective colloid—sodium protalbinate—**colloidal molybdenum trihydroxide** is formed. L. F. Svanberg and H. Struve obtained this oxide by heating molybdenum trioxide in dry hydrogen—*vide supra*, the preparation of molybdenum—and E. F. Smith and W. S. Hoskinson, E. T. Wherry and E. F. Smith, and E. F. Smith obtained *molybdic hydroxide*, $Mo_2O_3.3H_2O$, or $Mo(OH)_3$, by the electrolysis of a neutral soln. of ammonium molybdate, or a soln. acidified with sulphuric acid. J. J. Berzelius, and C. W. Blomstrand also obtained the hydrated oxide by adding potash-lye to a soln. of molybdenum dichloride or dibromide, and W. Muthmann and W. Nagel found that hydrogen is simultaneously evolved.

Molybdic oxide is pitch-black, and is slowly oxidized by exposure to air. In some cases J. J. Berzelius observed that when heated in vacuo, it may show a feeble calorescence—*vide* **5**. 33, 10. P. Sabatier and J. B. Senderens found that when heated to about 500° in nitrous oxide, it yields a mixture of molybdenum dioxide, and trioxide; and in nitric oxide, molybdenum dioxide. J. J. Berzelius observed that it is insoluble in soln. of potassium hydroxide, ammonia, or ammonium carbonate. Acids do not dissolve the anhydrous oxide; and the hydroxide is dissolved with difficulty to form molybdic salts. F. Isambert said that soln. of the oxide in acids are black. The salts of tervalent molybdenum were studied by F. A. Gooch and O. S. Pulman, F. Pisani, C. F. Rammelsberg, and W. Wardlaw and W. H. Parker. G. Unger, G. Reissaus, and E. Müller studied the electrometric oxidation of soln. of tervalent molybdenum with permanganate. R. Montequi, and J. Koppel prepared compounds with the xanthates—*e.g.* $(C_2H_5OCS_2)_4Mo_2O_3$.

§ 9. Intermediate Oxides—MoO_2 to MoO_3

C. F. Bucholz[1] prepared **molybdenum dioxide**, MoO_2, by gently heating the metal for a short time in air; and J. J. Berzelius found that the lower oxide, free from zinc oxide, burns with a feeble glow when it is heated in air. L. F. Svanberg and H. Struve obtained this oxide by heating molybdenum trioxide; and H. Rose, and L. F. Svanberg and H. Struve, by heating ammonium molybdates. C. F. Rammelsberg said that the product is not homogeneous. C. F. Bucholz also heated ammonium molybdate in a covered crucible, and J. J. Berzelius added that the dioxide so produced is contaminated with molybdenum trioxide which can be removed by potash-lye, or by hydrofluoric acid. According to E. Uhrlaub, this product, as well as that obtained by J. J. Berzelius—by igniting in a covered crucible a mixture of sodium molybdate and ammonium chloride, and washing the products with water—contains nitrides (*q.v.*). The dioxide was also obtained by L. F. Svanberg and H. Struve, D. K. Tuttle, N. J. Berlin, W. Muthmann, and M. Guichard by heating a mixture of ammonium molybdate and molybdenum trioxide, or a mixture of sodium molybdate and ammonium chloride, and washing the residue with aq. ammonia, and then with hydrochloric acid. F. Mauro and R. R. Panebianco obtained crystals of the dioxide by heating a mixture of 14·4 grms. MoO_3, 14 grms. K_2CO_3, and 7 grms. B_2O_3 for 3 or 4 hrs. at a high temp., and washing the cold mass successively with aq. ammonia, water, hydrochloric acid, and water. W. Muthmann obtained the dioxide by fusing a mixture of anhydrous ammonium molybdate, molybdenum trioxide, potassium carbonate, and boric acid in the proportions 8 : 7 : 14 : 7 by weight. H. Debray obtained an oxide, possibly the dioxide, by heating molybdenum trioxide in a mixture of steam and hydrogen. L. P. Liechti and B. Kempe reduced the trioxide to dioxide by heating it in a current of hydrogen. M. Guichard studied the equilibrium conditions in the balanced reaction: $Mo+2H_2O \rightleftharpoons MoO_2+2H_2$—*vide supra.* C. Friedheim and M. K. Hoffmann also reduced molybdenum trioxide with hydrogen at 450°, and removed the unchanged trioxide as volatile oxychloride by heating the product in a current of hydrogen chloride. H. Debray also used a mixture of carbon monoxide and dioxide as the reducing agent. L. F. Svanberg and H. Struve obtained the dioxide by heating to redness for several hours an alkali molybdate in hydrogen and washing the product; F. Ullik heated a mixture of sodium trimolybdate and zinc, and washed product with a soln. of potassium hydroxide and then with hydrochloric acid. C. Paal and H. Büttner reduced ammonium molybdate with colloidal palladium at ordinary temp. and obtained molybdenum dioxide. W. Püttbach obtained the dioxide by heating molybdenum dioxydichloride in carbon dioxide or in hydrogen; and E. Friederich and L. Sittig by heating to about 1200° a mixture of 4·8 grms. of molybdenum powder and 14·4 grms. of molybdenum trioxide. H. Buff, and M. Guichard obtained the dioxide by the electrolysis of fused molybdenum trioxide, or potassium molybdate; and L. Ott, by the electrolysis of molten sodium or barium molybdate using a high current density.

Analyses in agreement with the formula MoO_2 were made by J. J. Berzelius, C. F. Bucholz, F. Ullik, and M. Guichard. Molybdenum dioxide is described by L. F. Svanberg and H. Struve as a brownish-black powder; L. Ott, as a violet crystalline powder; and F. Ullik, as forming dark bluish-violet prisms which appear pale violet-red in transmitted light. F. Mauro and R. R. Panebianco said that the bipyramidal crystals are tetragonal with the axial ratio $a : c=1 : 0·5774$; but S. Stevanovic showed that the pseudotetragonal crystals are monoclinic prisms with the axial ratios $a : b : c=0·9869 : 1 : 0·5765$, and $\beta=91° 34'$. V. M. Goldschmidt and co-workers, M. L. Huggins, and L. Pauling discussed the lattice-structure. The X-radiogram shows that the space-lattice is of the rutile-type with $a=4·86$ A., and $c=2·79$ A., so that $a : c=1 : 0·573$. S. Stevanovic gave for the sp. gr. 6·34; and F. Mauro and R. R. Panebianco, 6·44. W. Biltz studied the mol. vol. N. Parravano and G. Malquori gave for the dissociation press., $\log p=-27·843$ at 600°. W. G. Mixter gave 142·8 Cals. for the heat of formation from its elements. B. A. Dima studied the photoelectric effect of the oxide. J. Vrede observed that the dioxide has no value as a radio-detector. F. Ullik, and M. Guichard observed that it is a good electrical conductor; E. Friederich and L. Sittig gave $40·0\times10^{-4}$ ohm for the resistance of a metre wire 1 sq. mm. cross-section at 1000°; and the temp. coeff. is negative; and E. Wedekind and C. Horst found that its magnetic susceptibility is greater than that of the metal, being $0·33\times10^{-6}$ mass unit at 19·5°. S. Berkman and H. Zocher gave $0·09\times10^{-6}$ mass unit.

M. Guichard found that the oxide is reduced by hydrogen to the metal without the formation of intermediate oxides—a subject discussed by G. Martin. The equilibrium conditions were studied by M. Guichard—*vide supra.* G. Chaudron studied the equilibrium conditions in the reaction: $2H_2O+Mo \rightleftharpoons MoO_2+2H_2$ over the temp. range 700° to 1100°. H. Debray found that water vapour at a red-heat oxidizes the dioxide to the trioxide; H. Rose found that chlorine converts the dioxide into the dioxydichloride; and A. Vandenberghe, and C. Friedheim and M. K. Hoffmann, that it does not volatilize when heated in hydrogen chloride. J. J. Berzelius found that the dioxide is not soluble in hydrofluoric, hydrochloric or sulphuric acid. W. R. E. Hodgkinson and F. K. S. Lowndes found that if a little dioxide be added to molten potassium chlorate, oxygen and chlorine are evolved. J. J. Berzelius said that a little dioxide dissolves in boiling, conc. sulphuric acid; and it dissolves slowly in fused alkali hydrosulphate. It is converted by nitric acid into the trioxide. C. Friedheim and M. K. Hoffmann observed that the dioxide is decomposed when heated in carbon dioxide; and A. Michael and A. Murphy, that carbon tetrachloride converts it into molybdenum tetrachloride. W. Skey, and E. Péchard observed that thiocyanates produce a red coloration with the dioxide. J. J. Berzelius found that the dioxide does not dissolve in a boiling soln. of potassium hydrotartrate. G. Rauter found that silicon tetrachloride has no action on the dioxide. J. J. Berzelius found that the dioxide is insoluble in soln. of alkali hydroxide or carbonate. F. Ullik observed that a crystal of molybdenum dioxide in a soln. of copper sulphate, and in contact with zinc, quickly becomes covered with a film of copper. E. F. Smith and O. L. Shinn found that a mol of the dioxide liberates two gram-atoms of silver from an ammoniacal soln. of silver nitrate: $MoO_2+2Ag^{\cdot}\rightarrow MoO_3+2Ag$, etc.; salts of copper and mercury are not so reduced. C. Friedheim and M. K. Hoffmann found that ferric sulphate oxidizes the dioxide to trioxide. The electrometric oxidation of soln. of quadrivalent molybdenum by permanganate was studied by G. Unger, E. Fricke, G. Reissaus, and E. Müller. C. Engler and L. Wöhler discussed molybdenum dioxide as a catalytic agent. M. Guichard was at first inclined to believe that the dioxide does not form salts, although J. J. Berzelius, H. Rose, and others have described a series of salts.

J. J. Berzelius, H. Rose, and C. F. Rammelsberg described what they considered to be hydrated molybdenum dioxide, obtained by adding alkali-lye to soln. of more or less reduced molybdic acid. P. Klason showed that in all probability these products are impure molybdenum pentahydroxide, and that the tetrahydroxide does not exist.

This remark applies to the so-called *monohydrate*, $MoO_2.H_2O$, of E. Péchard, produced by the electrolysis of a hydrochloric or oxalic acid soln. of ammonium molybdate; or by adding alkali-lye to a hydrochloric acid soln. of alkali molybdate mixed with potassium iodide; and to the *dihydrate*, $MoO_2.2H_2O$, reported to be formed by adding ammonia to a hot hydrochloric acid soln. of acid ammonium molybdate and potassium iodide. O. W. Gibbs obtained some complexes with tungstic acid—*e.g.* $5K_2O.12WO_3.MoO_2.16H_2O$. The *trihydrate*, $MoO_2.3H_2O$, was said by F. J. Faktor to be produced by the action of sodium thiosulphate on a soln. of ammonium molybdate; and G. Krüss obtained the *hemiheptadecahydrate*, $2MoO_2.15H_2O$, by the action of conc. alkali-lye on the oxysulphide, $(NH_4)H.Mo_2O_4S_4$.

C. Paal and co-workers, however, found that a soln. of ammonium paramolybdate in the presence of a little colloidal palladium is reduced at room temp. by hydrogen at normal press. to form a greenish-black precipitate approximating the monohydrate, $MoO_2.H_2O$, or $MoO(OH)_2$, when dried at ordinary temp., and it yields the dioxide, MoO_2, if dried at a higher temp. If the reduction occurs in the presence of a protective colloid—sodium protalbinate—**colloidal molybdenum tetrahydroxide** is formed at ordinary temp. H. Freundlich and W. Leonhardt found that the monohydrate obtained by E. Péchard—by precipitation with alkali hydroxide from the soln. produced by the action of potassium iodide on hydrochloric acid soln. of alkali molybdate or by the electrolysis of hydrochloric or oxalic acid soln. of molybdic acid—behaves towards water like a colloid. The coagulated dioxide shows differences in the readiness with which it undergoes peptization, in that the sol form is more readily produced from coagulates which have been precipitated by the less active electrolytes. Low temp. is also favourable to the re-formation of the sol. The coagulation by electrolytes depends on the cation.

According to W. Muthmann, the compound **magnesium hypomolybdate,** $2MgO.3MoO_2$, is formed by fusing sodium trimolybdate with magnesium oxide; and zinc oxide similarly furnishes **zinc hypomolybdate,** $2ZnO.3MoO_2$.

J. J. Berzelius digested in a stoppered flask, at 40°–60°, a mixture of powdered molybdenum and a soln. of molybdic acid ; the soln. became dark blue, and finally green. The addition of ammonium chloride to the green soln. precipitates an olive-green oxide which redissolves in water—presumably as a peptized colloid. A soln. of the brown and blue molybdenum oxides in hydrochloric acid precipitates a green oxide on the addition of ammonia. C. F. Bucholz obtained a pale blue oxide which J. J. Berzelius supposed to be the same as the green oxide. W. Muthmann could not prepare an olive-green oxide of constant composition. J. Reich obtained the blue soln. by the action of lead on a soln. of molybdic acid ; and the green soln. by the electrolysis of a soln. of 2 grms. of molybdenum trioxide in aq. ammonia mixed with sulphuric acid and diluted with water, by means of platinized platinum electrodes and a current density of 0·5 amp. per sq. dm. Many blue oxides have been reported, and the differences in the analysis probably turn on the presence of variable proportions of molybdenum trioxide. M. Guichard added that if the trioxide be removed by successive washing with soda and hydrochloric acid, molybdenum dioxide is the sole oxide formed by the action of heat on a mixture of molybdenum trioxide and ammonium molybdate, or by the electrolysis of fused molybdenum trioxide.

According to W. Muthmann, the blue oxide which is formed by the action of reducing agents on soln. of molybdic acid, or by boiling molybdenyl sulphate with powdered molybdenum, is **molybdenum tritoctoxide,** Mo_3O_8. The olive-green oxide prepared by J. J. Berzelius is probably a mixture of this oxide with the tetrahydroxide, $Mo(OH)_4$. If a soln. of molybdenum in conc. sulphuric acid be heated to a high temp., a mixture of the tritoctoxide and trioxide is formed. A. Rogers and F. H. Mitchell obtained the tritoctoxide by adding stannous chloride to a soln. of ammonium molybdate slightly acidified with nitric acid ; washing the precipitate as quickly as possible; and drying it at 100°. According to L. A. Munro, by the addition of excess of stannous chloride, a green and then brown soln. can be obtained due to further (reversible) reduction. Molybdenum-blue forms a (negative) colloidal soln. which can be bleached by animal charcoal, partly by absorption and partly by oxidation. It can also be obtained in the crystalloidal form by dialyzing the colloidal soln., precipitating the hydrogel with ammonium chloride, and evaporating the remaining soln. E. J. Millard obtained the blue oxide by adding a soln. of ammonium molybdate and a little sulphurous acid to a soln. of hypophosphite ; H. Buff, by the electrolysis of molten molybdenum trioxide with platinum electrodes ; C. F. Rammelsberg, by heating ammonium molybdenum dioxymolybdate in a closed vessel ; C. Bärwald, by melting a mixture of ammonium peroxymolybdate and molybdenum trioxide in a closed vessel ; and N. J. Berlin, by melting a mixture of ammonium 3 : 7-molybdate and molybdenum trioxide in a covered crucible, and washing the product with aq. ammonia—E. Uhrlaub said that the product is contaminated with nitride. Analyses in agreement with Mo_3O_8 were made by W. Muthmann, C. Bärwald, N. J. Berlin, and C. F. Rammelsberg. L. A. Munro found that the formula obtained by analysis of the hydrogel is approximately $Mo_3O_8.H_2O$, but since the substance is readily soluble in alcohol the water is probably not combined as hydrate; hence the true formula is Mo_3O_8. This oxide was said by H. Buff to form copper-red crystal plates ; and by C. Bärwald, a bluish-violet crystalline powder. H. Buff observed that the oxide is a good conductor of electricity, and that in air it acquires a bluish film. A. Rogers and

F. H. Mitchell said that the oxide is more easily reduced by hydrogen than is molybdenum trioxide. W. Muthmann said that the tritoctoxide is not attacked by hydrochloric and sulphuric acids, or by aq. ammonia ; it is easily oxidized by nitric acid ; and it is decomposed by alkali-lye. According to J. Duclaux and R. Titéica, molybdenum blue is an acid comparable in strength with mineral acids, the colloidal anion of which contains molybdenum in two states of oxidation and is capable of union with metallic ions to form salts. Molybdenum-blue is peculiar in its solubility in a large number of organic solvents, whilst it is insoluble in all liquids of low dielectric constant. When certain organic solvents are shaken with an aq. soln. of molybdenum-blue, the aq. soln. is almost immediately decolorized, the molybdenum compound passing into the organic liquid phase. This is the first example recorded of a colloid passing from one solvent into another ; glycerol appears to be the best solvent. The solubility in butyl alcohol provides a rapid means of purifying molybdenum-blue by extraction of the aq. soln.

H. Höfer[2] described a complex molybdenum oxide which he found embedded in the barytes and wulfenite at Bleiberg, Carinthia. It appeared to have been formed by the decomposition of the metal molybdates by acidic waters. W. T. Schaller suggested that it is formed by the alteration of molybdenite, jordisite, wulfenite, and molybdosodalite. H. Höfer called the mineral **ilsemannite**—after J. C. Ilsemann. Ilsemannite is bluish-black or black, and cryptocrystalline. It becomes blue on exposure to air, and it has been called *natural molybdenum blue*. It forms a deep blue soln. with water ; and the aq. soln. yields blue crystals on evaporation. H. Höfer considered it to have the composition of J. J. Berzelius' $MoO_2.4MoO_3$; C. F. Rammelsberg gave the formula Mo_2O_5, or $MoO_2.MoO_3$. W. Muthmann said that its composition is not Mo_5O_{14}, as supposed by H. Höfer, but is nearer to Mo_3O_8. More probably, ilsemannite is a mixture. F. Cornu represented it as **colloidal molybdenum tritoctoxide,** $Mo_3O_8.nH_2O$, and added that it is the only reversible colloid occurring in nature. The subject was discussed by A. Himmelbauer, E. Dittler, F. L. Hess, H. F. Yancey, and C. W. Greenland. W. T. Schaller obtained from Ouray, Utah, a mineral of the composition $MoO_3.SO_3.5H_2O$, which he called ilsemannite, but H. F. Yancey did not agree that this represents the composition of ilsemannite. E. Dittler supposed ilsemannite to be an oxidation product of molybdenite. When molybdenum sulphate soln. are treated with ferrous sulphate, free molybdenum trioxide separates. This when washed contains no iron or sulphate, but is reduced to $Mo_3O_8.H_2O$. Some varieties are free from iron, so that W. T. Schaller's hypothesis is based on samples in which the sulphate was an accidental constituent.

W. Biltz[3] prepared colloidal molybdenum tritoctoxide, and found that the hydrosol passes to the anode on electrolysis. A. Dumansky showed that when molybdenum trioxide suspended in water, is heated on a water-bath with a large excess of powdered metallic molybdenum, a soln. of the oxide Mo_3O_8 is obtained, which, according to cryoscopic measurements, contains unpolymerized mols. of the oxide. On addition of ammonium chloride, barium chloride, and other salts to this soln., polymerization takes place, and the oxide passes into the colloidal form. W. Biltz found that the colloid is adsorbed from its sol by fibres of cotton, wool, and especially silk. C. Winssinger observed that the absorption spectrum is similar to that produced by colloidal molybdenum sulphide.

C. F. Bucholz prepared what appears to have been the colloidal *pentahydrate* of molybdenum tritoctoxide by exposing moist molybdenum, or the hydrated trioxide to air for a long time, or boiling these substances with water in an open vessel. He also made it by boiling in water a mixture of molybdenum with twice its weight of molybdenum trioxide, and evaporating the blue soln. out of contact with air, or in contact with molybdenum. J. J. Berzelius prepared this hydrate by mixing a soln. of molybdenum dioxide in hydrochloric acid with a soln. of ammonium 3 : 7-molybdate, and collecting the precipitated oxide which is washed, first with water containing ammonium chloride, and then with alcohol or cold water.

It is dried in air. O. Maschke dissolved calcium molybdate in warm, dil. hydrochloric acid and added sucrose or glucose, boiled the mixture for a few minutes, added a soln. of sodium or calcium chloride, and washed the precipitate first with the precipitant and then with a little water. G. Marchetti dissolved molybdenum in conc. aqua regia, and after all the nitric acid had been expelled by evaporating the soln. on a water-bath, with the addition of hydrochloric acid, diluted the filtered soln., and reduced it by an electric current. The dark blue liquid yields crystals of the pentahydrate. C. F. Bucholz described his product as a dark indigo-blue powder; and G. Marchetti obtained dark blue, almost black, triclinic crystals. J. J. Berzelius said that all the water can be driven off by heating the crystals in vacuo. C. F. Bucholz said that the salt is fairly soluble in water forming a blue soln. which, according to G. Marchetti, does not give a precipitate on adding ammonium chloride. Cryoscopic determinations show that in aq. soln. the pentahydrate is neither ionized nor polymerized. J. J. Berzelius said that the aq. soln. becomes paler in air owing to oxidation. Alcohol dissolves a little of the hydrated oxide. O. Maschke found that the aq. soln. is easily decolorized by alkalies, chlorine, nitrous acid, hydrogen dioxide, permanganic acid, etc. L. Schönn said that the blue soln. is first decolorized by hydrogen dioxide, and then forms a yellow liquid. According to G. Marchetti, aq. ammonia, and alkali-lye extract molybdenum trioxide and leave the dioxide; whilst very dilute alkali-lye dissolves all the oxide, and when the soln. is boiled, it deposits molybdenum dioxide. Acids do not appear to form salts. C. F. Rammelsberg obtained **ammonium dimolybditetramolybdate,** $(NH_4)_2O.2MoO_2.4MoO_3.9H_2O$, or $(NH_4)_2O.(Mo_3O_8)_2.9H_2O$, as brown crystals under the blue precipitate by allowing a mixed soln. of molybdenum dioxide and ammonium molybdate in hydrochloric acid to stand for some time. The brown crystals form a brown soln. with water, and the addition of silver nitrate to the soln. gives a yellow precipitate soluble in nitric acid. The salt gives off water and ammonia when heated.

According to C. F. Rammelsberg,[4] the precipitate formed on mixing a hydrochloric acid soln. of molybdenum dioxide and molybdic acid, when washed with an alcoholic soln. of ammonium chloride, and dried over sulphuric acid, is the *trihydrate* of **molybdenum hemipentoxide,** $Mo_2O_5.3H_2O$, or $MoO(OH)_3$. J. Reich said that the electro-reduction of a soln. of 2 grms. of molybdenum trioxide in 11 grms. of sulphuric acid, and 100 c.c. of water with a current density of 0·005 amp. per sq. dm., and 0·49 volt gives a blue deposit of the hemipentoxide. P. Klason made it by adding exactly three mols of ammonia to an aq. soln. of a mol of ammonium molybdenyl chloride. The precipitate resembles freshly-precipitated ferric hydroxide, only it is brighter in colour; sodium acetate can also be used as a precipitant. It is soluble in water to the extent of 2 parts in 1000, but insoluble in the presence of ammonium chloride; it has no acid properties, since it does not dissolve in aq. alkali hydroxides, and is only slightly soluble in ammonia and alkali carbonates. If in its preparation an excess of ammonia be used, the hydroxide is partially decomposed, and the filtered soln. contains much molybdic acid, as stated by H. Debray. P. Klason added that molybdenum blue does not contain molybdenum dioxide as assumed by M. Guichard, but rather the hemipentoxide. The anhydrous oxide, Mo_2O_5, was obtained by C. F. Rammelsberg, by dehyrating the hydrate in vacuo; or, in a current of carbon dioxide. E. Péchard obtained it by heating a mixture of ammonium molybdate, potassium iodide, and hydrochloric acid. E. Friederich and L. Sittig obtained the hemipentoxide by heating to about 1200° a mixture of 2·4 grms. of molybdenum powder and 18 grms. of molybdenum trioxide. E. Friederich gave 9·5 ohms for the resistance of a metre wire 1 sq. mm. cross-section. E. F. Smith and V. Oberholtzner treated the trioxide at 105°–120° with dry hydrogen iodide, and obtained a blue *hemitrihydrate*, $Mo_2O_5.1·5H_2O$, which was stable in air, and at a red-heat furnished brown hemipentoxide. W. Wardlaw and F. H. Nicholls obtained molybdenum hemipentoxide, Mo_2O_5, by heating the oxysulphate, $Mo_2O(SO_4)_2 \rightarrow Mo_2O_5 + 2SO_2$, or the oxyoxalate, $Mo_2O(C_2O_4)_2 \rightarrow Mo_2O_5$

+4CO. In opposition to the statement of M. Guichard, the pentoxide is almost unchanged when boiled five successive times in aq. ammonia, washed with distilled water, and dried at 100°. A little molybdenum passes into soln., but there is no evidence that the product is impure dioxide. J. Vrede found the oxide has no value as a radio-detector; and W. Meissner, that it is not a super-conductor. E. Friederich and L. Sittig, found the sp. resistance of the dark violet hemipentoxide to be $9{\cdot}5\times10^{-4}$ ohm at 1000°, and the temp. coeff. is negative. A. Schulze discussed the super-conducting qualities of the oxide. E. Newbery and J. N. Pring found that the pentoxide is reduced to the monoxide by hydrogen at 2000° and 150 atm. press. The violet-black powder, said E. Péchard, is easily soluble in water, and when hydrogen dioxide is added to the dark blue aq. soln., the colour becomes green, and then yellow. P. Klason, and W. Wardlaw and F. H. Nicholls, said that the hemipentoxide dissolves with difficulty in hydrochloric and sulphuric acids, and this the more slowly, the higher the temp. of preparation. G. Reissaus, E. Fricke, G. Unger, and E. Müller studied the electrometric oxidation of soln. of quinquevalent molybdenum with permanganate. S. Ghosh and N. R. Dhar studied the sensitization of the negative colloid, by other colloids. G. A. Barbieri studied the action of molybdenum hemipentoxide on formic and oxalic acids. P. Sabatier and A. Mailhe, and J. N. Pearce and A. M. Alvarado studied the dehydrating action on ethyl alcohol. P. Sabatier and A. Mailhe, and J. N. Pearce and A. M. Alvarado observed that this oxide acts catalytically in decomposing formic acid into carbon dioxide, carbon monoxide, water, and hydrogen; and formaldehyde, into carbon dioxide and water. The hemipentoxide was also prepared by F. Mawroff and M. Nikoloff, who also observed that when the violet molybdenum oxyhypophosphite is rubbed with aqua ammonia, the yellowish-brown precipitate can be washed and dried. It dissolves sparingly in water, and the aq. soln. has a neutral reaction. If dissolved in acids, and precipitated by ammonia, and washed with dil. aq. ammonia and then with absolute alcohol, the residue has the composition of **ammonium molybdenum hemipentoxide,** $NH_4Mo_2O_5.3H_2O$, which, when ignited in a current of carbon dioxide, yields molybdenum pentoxide. If sodium hydroxide soln. be used in place of ammonia, **sodium molybdenum hemipentoxide,** $NaMo_2O_5.3H_2O$, is formed, and this, on ignition, yields the anhydrous form $NaMo_2O_5$. Similarly also with the hydrate **barium molybdenum hemipentoxide,** $BaMo_2O_5.3H_2O$, and the anhydrous $BaMo_2O_5$.

J. J. Berzelius[5] obtained what he regarded as **molybdenum pentitatetradecaoxide,** Mo_5O_{14}, or $MoO_2.4MoO_3$, by heating molybdenum or one of the lower oxides in air for a short time. C. F. Rammelsberg obtained the *hexahydrate* by allowing an aq. soln. of molybdic acid to stand in contact with reduced molybdenum for some days, and then shaking up the filtered, blue liquid with an excess of molybdenum for some days. M. Guichard said that this compound is best obtained by mixing cold, dil. hydrochloric acid soln. of molybdenum dioxide and ammonium molybdate; the hydrochloric acid should be that of sp. gr. 1·18 diluted with 9 parts of water, this bringing about complete precipitation without decomposition. A more conc. acid decomposes the oxide. The product thus obtained is nearly insoluble in cold water, although that prepared by C. F. Rammelsberg, by precipitation at 50°, is easily soluble; an aq. soln. of the oxide is readily obtained by leaving molybdenum trioxide and metallic molybdenum in contact in water. The oxide obtained by precipitation is a dark blue powder of sp. gr. 3·6 at 18°; by the evaporation of its soln., it is obtained in vitreous, faceted fragments, which yet are not truly crystalline. It dissolves in water at 50°, but is insoluble in sat. soln. of ammonium, sodium and calcium chlorides, and potassium iodide and nitrate; sodium and magnesium sulphate do not alter its solubility. It dissolves in 95 per cent. alcohol, although it is insoluble in most organic solvents. When heated in vacuo or an inert gas, it loses part of its water at 100°, and the rest near a red-heat, a non-homogeneous mixture of molybdenum dioxide and trioxide being formed. Hydrogen ultimately reduces it to the metal; chlorine yields the volatile oxychloride, MoO_2Cl_2, and molybdenum trioxide. Contrary to J. J. Berzelius' statement, it slowly oxidizes in the air, and at a red-heat oxygen rapidly converts it into the trioxide. Gaseous hydrogen chloride at a red-heat and superheated steam decompose it, giving mixed dioxide and trioxide; gaseous ammonia gives initially the same result, but at a red-heat reduces the oxides to the metal. Acetic acid does not affect it; by conc. hydrochloric acid, it is dissolved to a yellowish-red soln. of molybdenum tetrachloride, but the action is a reversible one, since, on diluting with water, the blue oxide is precipitated. With sulphuric acid, a like result is obtained. K. von der Heide and K. A. Hofmann reported **ammonium molybditetramolybdate,** $(NH_4)_2O.MoO_2.4MoO_3.6H_2O$, to be formed by heating an aq. soln. of ammonium molybdate with half its weight of hydroxylamine hydrochloride on the water-bath until the orange precipitate which is at first formed is dissolved, and a greenish-brown soln. is obtained; this soln. is then rapidly filtered, protected from access of air, and allowed to cool. The compound separates in dark red crystals belonging to the triclinic system; dissolves gradually in water with a reddish-yellow coloration; and is fairly stable. It gradually reduces Fehling's soln. in the cold and quickly when heated. With copper sulphate, it gives a beautiful, blue coloration; with mercurous and mercuric salts, a flesh-coloured precipitate; with lead nitrate, a yellowish-white precipitate; and with potassium thiocyanate, an intense red coloration. It is gradually decomposed by dil. acids, and it reduces ammoniacal silver soln. with the separation of metallic silver. Other ammonia derivatives with the lower oxides of molybdenum, analogous to the chromammine bases, could not be prepared.

P. Klason [6] obtained a soluble oxide $Mo_{20}O_{41}.21H_2O$, or $Mo_2O_5.18MoO_3.21H_2O$, by exposing an aq. soln. of ammonium molybdenyl chloride to air. The solid furnishes a blue soln. with water, and it is precipitated by adding ammonium chloride. According to W. Muthmann, the oxide Mo_5O_{12}, first described by N. J. Berlin, is obtained by heating a mixture of ammonium molybdate with twice its weight of molybdenum trioxide. The product is repeatedly extracted with ammonia, and finally with conc. hydrochloric acid to remove a compound of molybdenum and nitrogen. This oxide is not attacked by alkali-lye, but it dissolves in warm conc. sulphuric acid, forming a green soln., which easily parts with sulphur dioxide, and turns blue. Nitric acid, aqua regia, and chlorine-water convert Mo_5O_{12} into the trioxide. H. O. Schulze obtained Mo_4O_{11}, or $Mo_2O_3.2MoO_4$, by heating a mixture of potassium iodide and molybdenum trioxide; G. Bailhache, the *hexahydrate* by the action of barium molybdate on the oxysulphate, $Mo_2O_5.2SO_4$; G. Bailhache, $Mo_{20}O_{57}.18H_2O$, or $2Mo_2O_3.2Mo_7O_{24}.18H_2O$, by the action of barium 3 : 7-molybdate on $Mo_2O_5.2SO_4$; A. Junius, Mo_7O_{20}, by the electrolysis of a hydrochloric acid soln. of ordinary ammonium paramolybdate, or of sodium molybdate; and P. Klason, $Mo_{26}O_{77}.24H_2O$, or $Mo_2O_5.24MoO_3.24H_2O$, by exposing an aq. soln. of ammonium molybdenyl chloride to oxidation by air for several months. There is nothing to show that these products are not merely arbitrary intermediate stages in the reduction of molybdenum trioxide. Some suggestions have been made for the use of the blue oxides of molybdenum as pigments—*vide supra*, the uses of molybdenum. Hydrosols of *molybdenum blue* were found by P. Lal and P. B. Ganguly to be coagulated by ultra-violet light.

§ 10. Molybdenum Trioxide and its Hydrates

D. L. G. Karsten[1] recognized a yellow earth associated with the molybdenite at Nummedalen, Norway, as a mineral species which he called **molybdic ochre**—*Wasserbleiocker*, and *Molybdänocker ;* J. F. L. Hausmann said that the essential constituent is molybdenum oxide; and J. J. Berzelius, and F. von Kobell, molybdenum trioxide. R. P. Greg and W. G. Lettsom called it *molybdin*, and A. Breithaupt, **molybdite.** It appears as an oxidation product of molybdenite. W. T. Schaller represented the composition of samples from California; Westmoreland, New Hampshire; Telluride, Colorado; and Renfrew, Ontario, by $Fe_2O_3.3MoO_3.7\frac{1}{2}H_2O$—*vide infra*, ferric molybdate; and F. N. Guild, that of a sample from Santa Rita Arizona, by $Fe_2O_3.3MoO_3.7H_2O$. D. D. Owen had previously suggested that the molybdic ochre from Nevada City, California, is a ferric molybdate, but F. A. Genth regarded this sample as a molybdic ochre mixed with limonite—P. P. Pilipenko called the ferruginous mineral ferrimolybdite—*vide infra*, ferric molybdate.

Occurrences have been noted at Caldbeck Fell, Cumberland, by R. P. Greg and W. G. Lettsom ; at Mount Coryby and Tulloch, Scotland, by R. P. Greg and W. G. Lettsom, and M. F. Heddle ; at Creux and Vaubry, Saint-Léonard, Vilati, etc., France, by A. Lacroix ; near Porto, Portugal, by C. F. A. Tenne and S. Calderon ; in Novara, and Sardinia, Italy, by W. P. Jervis, and D. Lovisato ; in Glarus, Switzerland, by E. Stöhr, and G. A. Kenngott ; at Pfitsch, Tyrol, by C. C. von Leonhard, and J. F. L. Hausmann ; at Berggiesthübel, and Altenberg, Saxony, by A. Breithaupt, and A. Frenzel ; at Schlaggenwald, by V. von Zepharovich, at Nummedalen, Norway, by D. L. G. Karsten ; at Linnäs, and Bispberg, Sweden, by C. C. von Leonhard, W. Hisinger, and J. F. L. Hausmann ; Pitkäranta, Finland, by A. Breithaupt ; on the Adun-Chalon Mountains, Siberia, by J. D. Dana ; in Victoria, and Tasmania, by G. H. F. Ulrich, and W. F. Petterd ; in St. Fernando, Chile, by I. Domeyko ; in Huaylas, Peru, by A. Raimondi ; in Mexico, by C. F. de Landero ; in Nevada, Texas, Georgia, North Carolina, Pennsylvania, and New Hampshire, United States, by D. D. Owen, F. A. Genth, W. E. Hidden and J. B. Mackintosh, W. T. Schaller, F. N. Guild, T. S. Hunt, P. Groth, and J. D. Dana ; and in Quebec, and Ontario, Canada, by G. C. Hoffmann.

The end-products of the oxidation of molybdenum, and, naturally, of the lower oxides, is **molybdenum trioxide,** MoO_3. J. J. Berzelius obtained the trioxide by roasting molybdenum sulphide in air. According to H. V. Regnault,[2] it is formed when steam acts on the red-hot metal, or on a lower oxide ; and, according to J. von Liebig, when heated potassium hydroxide acts on the metal—in that case, hydrogen is evolved. J. J. Berzelius obtained the trioxide by the action of an excess of nitric acid on molybdenum or its lower oxides, and either evaporating the soln. to dryness and igniting, or allowing the soln. to evaporate spontaneously. C. W. Scheele also obtained molybdenum trioxide by the action of nitric acid on molybdenite. The extraction of molybdates from molybdenite or wulfenite has been previously described, and J. J. Berzelius, and G. C. Wittstein obtained molybdenum trioxide from the ammonium salt by heating it in an open crucible at a temp. below the fusion point. In the roasting of ammonium molybdate the residual molybdenum trioxide is more or less reduced, and L. Ott, and W. Muthmann said that it should be heated to dull redness for 4 or 5 hrs. in a current of oxygen. R. Stierlin obtained the trioxide by sublimation from ammonium phosphatomolybdate ; and F. Elias heated molybdenum phosphate with a soln. of phosphoric acid in a sealed tube at 140° and obtained microcrystalline molybdenum trioxide.

The purification of molybdic acid is described in connection with the recovery of molybdenum from laboratory residues where the trioxide is associated with more or less phosphoric acid. P. Klason found commercial molybdenum trioxide of the composition $NH_3.3MoO_3.\frac{1}{2}H_2O$. H. Debray found commercial molybdenum trioxide associated with sodium salts and sulphuric acid. He purified it by admixture with ammonium chloride; and washing with water, and oxidizing the product by roasting it in air, or by treatment with nitric acid. The purification of the trioxide by sublimation frees it from metallic impurities, tungsten trioxide, silica, and phosphates. L. Rolla and G. Piccardi, for instance, purified the trioxide by sublimation in a current of air in a quartz tube. According to L. Wöhler and W. Engels, the precipitation which occurs when soln. of molybdates are acidified is due to the presence of tungstates. The readiness with which precipitation takes place is dependent on the proportion of tungstic acid present, and when this is present in very small amount, the temp. may be raised to nearly 100° before a precipitate is obtained. The precipitation is primarily due to the tungstic acid in the soln., and when this separates out, molybdic acid is simultaneously removed from the soln. A. Arnfeld observed that commercial molybdenum trioxide contains some of the lower oxides which are converted into the trioxide by roasting at a red-heat. In order to prepare the trioxide free from ammonia, M. Liebert boiled 50 grms. of ammonium molybdate in 100 c.c. of aqua regia until the liquid no longer gave a sign of the presence of ammonia when tested with Nessler's reagent. The product was then evaporated a number of times with nitric acid, and finally dried at 180°. W. D. Collins and co-workers discussed the impurities in commercial molybdic acid. The so-called " molybdic acid, 85 per cent." consists largely of ammonium molybdate.

The analyses of J. J. Berzelius,[3] J. B. A. Dumas, H. Debray, C. F. Bucholz, L. Ott, K. Seubert and W. Pollard, C. F. Rammelsberg, J. H. Müller, and A. Vandenberghe, are in agreement with the formula MoO_3. From the effect of molybdenum trioxide on the b.p. of sulphuric acid, E. Beckmann calculated the mol. wt. to be in accord with the formula $(MoO_3)_2$, or Mo_2O_6. Molybdenum trioxide has a platy or talcose structure, and it is colourless and non-pleochroic. The mass which has been fused is greyish- or yellowish-white with a radiating fibrous structure, whilst the sublimed trioxide furnishes colourless, transparent, thin plates, or needles which, according to A. E. Nordenskjöld, belong to the rhombic system; the **crystals** have the axial ratios $a:b:c=0.3872:1:0.4792$. P. Groth said that the crystals are probably isomorphous with those of tungsten trioxide. The (100)-, (010)-, and (001)-**cleavages** are distinct. The **optical character** is positive. A. des Cloizeaux gave for the **optic axial angles** at 13°, $2H_0=117°\,15'$ for red-light, 119° 33′ for yellow-light, and 127° for blue-light. A. Lacroix found the natural crystals from Corsica to be pleochroic—*a* and *b* are pale yellow, whilst *c* is nearly black. P. Niggli discussed the electronic structure; and H. E. Buckley, the effect of molybdates on the growth of crystals of sodium chlorate.

A. Breithaupt gave 4·49 to 4·50 for the **specific gravity** of molybdic ochre; T. Bergman, 3·46 for molybdenum trioxide; V. Eggertz, 4·5 for the sublimed oxide; E. Wedekind and C. Horst, 4·50 at 19·5°; and A. Safarik, 4·39 at 21° for the trioxide which had been fused. W. Biltz, D. Balareff, and C. del Fresno studied the mol. vol. The hardness of molybdic ochre is 1 to 2. J. Maydel discussed the **specific heat.** T. Carnelley gave $759°\pm2°$ for the **melting point** of the trioxide; F. Hoermann, and F. M. Jäger and H. C. Germs, 795°. E. Groschuff said that it melts without decomposition at 791°. When molybdenum trioxide is heated, it becomes lemon-yellow, and the original colour is restored on cooling. W. D. Bancroft and H. B. Weiser observed that when the trioxide is introduced in the oxyhydrogen flame, the flame gives a bright, lustrous, metallic mirror on a cold surface. It fuses at a red-heat to a brownish-yellow liquid. C. Zenghelis obtained evidence of a slight volatilization at ordinary temp. In covered vessels, it volatilizes at a high temp. only, but when exposed to air, even at its m.p., it volatilizes forming white fumes which condense above the fused mass to form a crystalline sublimate. E. Groschuff said that sublimation begins in the vicinity of the m.p. P. H. M. P. Brinton and A. E. Stoppel found that the trioxide is non-volatile below 500°, and volatilizes only slightly between 500° and 600°. G. Merz, and C. F. Plattner noticed that the trioxide volatilizes before the blowpipe flame which is coloured a greenish-yellow; W. R. Mott made some observations on the volatilization of the trioxide in the electric arc. A. A. Read said that the trioxide gives off oxygen at 1750°; and K. W. G. Kastner, that it is reduced to metal in the oxyhydrogen blowpipe flame. W. G. Mixter gave for the **heat of formation** when the metal is oxidized by sodium dioxide, $(Mo,3O)=181{\cdot}5$ Cals. at constant vol., or $(MoO_2,O)=38{\cdot}7$ Cals. S. M. Delépine gave $(Mo,3O)=166{\cdot}14$ Cals. at constant vol., and 167·00 Cals. at constant press.; W. Lederer gave 168·675 Cals. at constant vol.; J. E. Moose and S. W. Parr, 1829 cals. per gram. The subject was discussed by A. Berkenheim.

R. Stierlin referred to *das wunderbare Farbenspiel* which occurs when the crystals are examined by polarized light. E. L. Nichols and B. W. Snow found the fractional **reflecting power,** R, for light of wave-length, λ, to be:

λ	7530	6685	6080	5570	4920	4685	4500	4340
R 25°	—	0·695	0·613	0·517	0·309	0·139	0·068	0·045
R 275°	0·720	0·596	0·465	0·335	0·101	—	0·040	—

The reflected light is partly made up of mainly white light reflected from the surface, and partly, of light reflected from the interior, and this determines the colour of the reflected light. D. Gernez showed that molybdic acid, and the alkali molybdates, though optically inactive, can augment the optical activity of other substances—*e.g.* tartaric acid. L. W. Andrews examined the action with malic acid; and C. N. Riiber and J. Minsaas, with galactose. G. A. Dima studied the **photoelectric effect.** T. W. Case said that no electrical conductivity is to be observed when molybdenum trioxide is exposed to light. J. M. Eder, unlike T. L. Phipson, observed that a sulphuric acid soln. of molybdic acid is not reduced by exposure to light provided organic matter be absent. M. Jungck observed that the soln. of ammonium molybdate used in analytical chemistry suffers photolysis. R. Robl observed but a faint luminescence in ultra-violet light; E. Tiede and A. Schleede, the phosphorescence of molybdenum trioxide in active nitrogen; J. Ewles, the cathode luminescence, but no ultra-violet fluorescence with X-rays was observed by J. O. Perrine; H. T. Meyer, the K-series of the X-ray spectrum; and H. Nisi, the **Raman effect.**

F. Beijerinck found that molybdic ochre is a non-conductor of electricity; and T. W. Case observed that the trioxide is also a non-conductor, whilst L. Bleekrode said that it is a good conductor. A. Miolati studied the **electric conductivity** of mixtures containing molybdic acid. E. Friederich calculated $7{\cdot}8\times10^{10}$ ohms for the resistance of a metre wire 1 sq. mm. cross-section. H. Buff, and M. Guichard found that molten molybdenum trioxide is a good conductor, and on **electrolysis** furnishes crystals of the tritoctoxide at the cathode; K. W. G. Kastner obtained the metal. T. de Grotthus observed that when a soln. of molybdic acid in sulphuric acid is electrolyzed, the liquid about the cathode is coloured blue. G. Gore made a similar observation with respect to soln. in hydrofluoric acid; and J. Terwelp found that water with molybdenum trioxide in suspension becomes blue about the cathode when it is electrolyzed. L. Schicht also noticed the blue soln. formed when a soln. of ammonium molybdate is electrolyzed, and J. G. Gahn observed the separation of what he thought to be molybdenum at the cathode. G. Gore obtained a black deposit on electrolyzing fused molybdic acid. E. Péchard found that the electrolysis of a soln. of ammonium molybdate in hydrochloric or oxalic acid gives a soln. of molybdenum dioxide, which, with strongly ammoniacal soln., gives a deposit of $MoO_2.H_2O$ on the cathode. A. Chilesotti found that the electrolysis of a feebly acid soln. of molybdic acid in sulphuric acid gives a quantitative separation of molybdenum at the mercury cathode, but not so with a $3N$-H_2SO_4 soln. The electrolysis of a hydrochloric acid soln. of molybdenum trioxide or of a soln. of ammonium molybdate in dil. sulphuric acid using a mercury cathode gives a soln. of tervalent molybdic chloride or sulphate. J. Férée also obtained molybdenum amalgam at the mercury cathode when a soln. of molybdic acid in hydrofluoric acid was electrolyzed—current density 5 amp. per sq. cm. The electrolysis of these soln. was also studied by R. E. Myers, E. F. Smith and co-workers, and A. Chilesotti and A. Rozzi. According to A. Chilesotti, when a soln. of molybdic acid is electrolyzed, part of the hydrogen at the cathode reduces the molybdic acid, and part escapes as a gas, so that the current efficiency for any period can be calculated by comparing the amounts of hydrogen produced in the cell, and in a voltameter in the same circuit. When the reduction is completed, the current efficiency is zero. With a soln. containing 3·5 per cent. of molybdenum trioxide in $9N$-HCl, and a mercury cathode, and high current densities, a large fraction of the current is employed in liberating hydrogen, but the time required for complete reduction is short. Increasing the conc. of the molybdic acid increases the current efficiency; with the $9N$-HCl, the current efficiency is at first 100, it afterwards falls regularly to zero. With $4N$-acid, the curve again begins at 100, but soon falls very rapidly to about 10 and then rises slowly to a maximum at 29, thereafter falling to zero. With more dil. acid, the curve follows a similar course, but the maximum occurs sooner and at a much higher value of the current efficiency. The probable explanation is that a film of oxide is first formed on the cathode, which acts as a diaphragm and prevents reduction; later this film is dissolved or reduced to metal and metallic molybdenum amalgam is formed on the surface of the cathode, the reducing action of the amalgam being much greater than that of the mercury alone. It is known that molybdenum amalgam is formed in presence of dil. acid, but not in conc. acid. Rise of temp. increases the current efficiency considerably. The material of the cathode has a greater effect on the current efficiency. Using a soln. of 3·5 per cent. of molybdenum trioxide in $4N$-HCl, a current density of 0·042 amp. per sq. cm. at 10°–20°, the average current efficiencies were, with platinized platinum, 10·6 per cent., mercury, 18·9 per cent., smooth platinum, 51·7 per cent., tin, 66·9 per cent., and lead, 74·5 per cent. In $9N$-HCl, tin gave the best result, lead and platinum slightly worse results, and mercury was worst of all. The behaviour of these metals has obviously no connection with the overvoltage required to liberate hydrogen in their surfaces; rather would it appear to be connected with their solubility, both lead and tin being found in soln. after the electrolysis, which was not the case with platinum and mercury. The molybdic acid is always reduced to tervalent molybdenum compounds except when a platinized platinum cathode is used; in this case, the reduction stops at the quinquevalent stage. Soln. in sulphuric and oxalic acids gave similar results, the tin cathode being insoluble in the oxalic acid soln., and the lead cathode insoluble in the sulphuric acid soln. gave results similar to those obtained with platinum.

A. Chilesotti also measured the **potential difference** between platinum and the soln. at different stages of the reduction. It was found that in all cases the same general result was obtained. The potential difference increases slowly as the reduction proceeds, until the whole of the molybdenum is in the quinquevalent condition; it then rises very suddenly to a higher value, after which it again increases slowly until the molybdenum is almost reduced to the tervalent state, when a further rather sudden increase occurs. During the first stage of the reduction, the potential is doubtless conditioned by the process $MoO_4''+8H^{\cdot}+\oplus =Mo^{\cdot\cdot\cdot\cdot\cdot}+4H_2O$; during the second stage, the main change is probably the reduction of quinquevalent to tervalent molybdenum. The final increase is due possibly to the formation of bivalent molybdenum ions. With regard to colour, the soln. in $7N$- to $9N$-HCl first becomes emerald-green owing to the formation of the complex compound of the oxychloride, $MoOCl_3$; they then become brown and finally orange-red, and contain complex compounds of the formula ($MoCl_3,nHCl$). The soln. in more dil. hydrochloric acid change, when the reduction is almost complete, from a brownish-red colour to a deep olive-green colour. The green soln. are unstable; they decompose water, taking up oxygen and becoming brownish-red again. Both the red and the green soln. contain molybdenum trichloride, and it is supposed that they are related in the same way as the green and violet soln. of chromic chloride. The soln. in sulphuric acid behave similarly. The change from one modification to the other is due possibly to the presence of traces of molybdenum dichloride. J. Terwelp found that the electrolysis of 10 per cent. soln. of $(NH_4)_6Mo_7O_{24}.4H_2O$, and of 2 to 10 per cent. soln. of normal sodium molybdate without diaphragms gives only a small cathodic deposit of indefinite composition; with a diaphragm, the former salt gives with a small anode current density a deposit of $(NH_4)_2Mo_7O_{22}.8H_2O$, and a yellow anode liquid of molybdic acid. L. Ott found that the electrolysis of fused sodium or barium polymolybdate gives molybdenum dioxide, whilst with fused normal sodium molybdate oxygen is given off at the anode and a pulverulent mixture of the lower oxides is deposited. L. Ott also studied the electrolysis of soln. of molybdenum trioxide, and of the sodium molybdate. According to F. Förster and co-workers, the fact that soln. of molybdic acid in dil. hydrochloric acid can only be reduced to the quinquevalent stage, whilst soln. in more conc. hydrochloric acid can be reduced electrolytically to the tervalent stage, is explained by assuming that the next stage to quinquevalent molybdenum is $Mo^{\cdot\cdot\cdot}$-ions, which in the presence of a high conc. of Cl'-ions immediately form complex ions and the static potential of the soln. is reduced below that necessary for the generation of hydrogen from platinized platinum electrodes. If the conc. of chloride-ions is low, however, comparatively few complex ions are formed, and the static potential of the soln. remains higher than that necessary for the evolution of hydrogen. If polished platinum electrodes are used, however, owing to the much higher potential necessary for the evolution of hydrogen, the tervalent stage can be reached even in dil. hydrochloric acid soln. The electrolytic reduction of molybdenum shows changes of potential parallel with those occurring in vanadium and titanium soln. under similar conditions. L. Rolla and G. Piccardi found that molybdenum trioxide, completely freed from bases by sublimation, has an **electro-affinity** of 2·73 volts, calculated on the assumption that no dissociation occurs at 1970° K.

According to H. T. S. Britton and W. L. German, the **electrometric titration** curve of soln. of sodium molybdate with hydrochloric acid shows an inflexion at $p_H=4{\cdot}8$, corresponding with the formation of $3Na_2O.7MoO_3$ (or $5Na_2O.12MoO_3$). By boiling the soln. or ageing it prior to measuring the p_H-curve furnishes a sharper inflexion corresponding with $Na_2O.4MoO_3$. In acidified soln. the sodium polymolybdate, which is first formed, gradually decomposes and yields a highly ionized polymolybdic acid, which causes the p_H of the soln. to assume slightly lower values than would be produced by the hydrochloric acid. A further addition of acid causes the ionization of the poly-acid to be thrown back until only non-ionized molybdenum trioxide remains in soln.; only from relatively conc. soln. is the trioxide precipitated on boiling. The changes of conductivity during the titration in general confirm the results obtained by the electrometric method. The addition of a weak acid, such as acetic or phenylacetic, to a sodium molybdate soln. causes the formation of a stable polymolybdate, $Na_2O.3MoO_3$, which is not further decomposed by the weak acid; in soln. containing monochloroacetic acid, the salt formed has a composition between $Na_2O.3MoO_3$ and $Na_2O.5MoO_3$. In soln. of molybdic acid there probably exists an equilibrium of the type $H_2[O(MoO_3)_n] \rightleftharpoons 2H^{\cdot}+[O(MoO_3)_n]''$, where n is about 4. Observations were also made by A. Travers and L. Malaprade, by A. Dumansky and co-workers, W. F. Jakob and W. Trzebiatowsky, and D. D. Peirce and L. F. Yntema.

J. Reich found that the olive-green liquid obtained by the electrolysis of a soln. of molybdenum trioxide in sulphuric acid—*vide supra*—has a potential of

—0·76 volt with smooth platinum, and —0·91 volt with platinized platinum against a mercurous sulphate electrode. A. Iléeff studied the thermoelectric force of powdered molybdenum trioxide compressed into pastilles. E. Wedekind and C. Horst found the **magnetic susceptibility** to be $0·876 \times 10^{-6}$ mass unit at 19·5°. S. Berkman and H. Zocher gave $0·12 \times 10^{-6}$ mass unit.

G. C. Gmelin[4] discussed the physiological action of salts of molybdic acid. T. G. y Arnal studied the reactions of molybdic acid with various salts of the metals. The ready reduction of molybdenum trioxide was discussed by W. Muthmann,[5] and O. F. von der Pfordten, and the formation of complex anions, by R. Abegg and G. Bodländer. Complex salts with the oxides of phosphorus, arsenic, antimony, bismuth, and other oxides have been prepared by O. W. Gibbs, etc. K. W. G. Kastner observed that when molybdenum trioxide is heated in **hydrogen,** it is reduced to the metal. E. W. Engle noticed that the reduction commences at about 300°; and M. Guichard added that it is reduced to MoO_2 between 300° and 470°, without forming intermediate oxides, and over 500°, it is reduced to the metal: $MoO_2 + 2H_2 \rightleftharpoons 2H_2O + Mo$—*vide supra.* F. R. M. Hitchcock noticed that in the reduction of molybdenum trioxide by hydrogen, a gas, probably impure nitrogen, is formed. The tendency to form a little nitride when one of the lower oxides molybdenum is heated in air has been observed by E. Uhrlaub. G. Canneri studied the reduction of molybdates with hydrogen. K. W. G. Kastner found that in the presence of hydrochloric acid and potassium amalgam, or zinc, or copper—or several other metals—molybdenum trioxide is reduced to a blue soln. of a salt of a lower oxide. C. Reichard also observed that in the presence of zinc and dil. hydrochloric or sulphuric acid, molybdenum trioxide gives a brown coloration which soon becomes pale green; and that molybdates give a transient reddish-brown coloration and then a greyish-brown precipitate. E. Wrede found molybdenum trioxide not so good as tungsten trioxide as a target for indicating the magnetic separation in a stream of unimolecular hydrogen. From the conductivity of flames charged with molybdenum trioxide, L. Rolla and G. Piccardi calculated the electronic affinity potential to be 2·73 volts. W. H. Rodebush and W. A. Nichols found that atomic **oxygen,** like atomic hydrogen, reduces the trioxide. For the action of **water,** *vide infra.* The aq. soln. has a sharp metallic taste, and reddens litmus, and, according to G. C. Wittstein, and A. Müller, it turns turmeric brown, especially in hydrochloric or nitric acid soln. For the action of **hydrogen dioxide,** *vide infra,* permolybdic acid. E. Spitalsky and A. Funck discussed the homogeneous catalytic decomposition of hydrogen dioxide by sodium molybdate. J. A. Hedvall and N. von Zweigbergh found that barium dioxide begins to react at about 200°—*vide* the molybdates.

H. Rose found that dry **chlorine** converts molybdenum trioxide into the dioxychloride less readily than is the case with the dioxide; H. E. Quantin, that at a dull red-heat, a mixture of chlorine and carbon monoxide forms molybdenum pentachloride. The attack by chlorine was studied by R. Wasmuth; and the attack by **chlorine trifluoride,** observed by O. Ruff, and H. Krug, proceeds with incandescence. H. Debray observed that **hydrogen chloride** at 150°–200°, forms the white dihydrochloride, $MoO_3.2HCl$; and K. W. G. Kastner, that boiling **hydrochloric acid** forms a blue soln. with the evolution of oxygen, and with boiling **hydriodic acid,** iodine separates and a green and then a blue soln. is formed. B. Kalischer found that when molybdenum trioxide is digested with alcoholic hydrochloric acid, a green soln. is obtained which does not yield a crystalline substance, but on evaporation, it furnishes a gelatinous, dark green mass which dissolves partially in water to form a brown soln. The original green soln. gives a double salt with pyridine hydrochloride. With alcoholic **hydrobromic acid,** no smell of aldehyde can be observed, and a yellowish soln. is obtained which behaves something like that obtained with the hydrochloric acid soln. Aqueous hydrobromic acid forms with molybdenum trioxide a deep brown soln. which becomes blue when water is added. No definite salt can be isolated from the soln., but if it be sat. with hydrogen bromide, it gives a brown, granular mass with pyridine hydrobromide. H. O. Schulze found that molybdenum trioxide decomposes **potassium iodide** especially in the presence of air, similarly also with the **alkali bromides and chlorides.** The reaction was also studied by C. F. Schönbein. W. R. E. Hodgkinson and F. K. S. Lowndes found that if a little molybdenum trioxide be added to molten **potassium chlorate,** oxygen and chlorine are evolved.

According to K. W. G. Kastner, a little **hydrogen sulphide** in the presence of water, or by the aid of heat, forms sulphur dioxide and sulphur, and sulphuric acid and a blue oxide. E. Uhrlaub observed that with an excess of hydrogen sulphide under similar conditions, molybdenum sulphide is formed. E. Abel studied the catalytic effect of the trioxide on the reaction between hydrogen dioxide and sodium thiosulphate. R. D. Hall observed that when heated with **sulphur monochloride,** the molybdenum oxide dissolves in the liquid and a volatile oxychloride is formed.

E. Uhrlaub found that when the trioxide is heated with **ammonia,** it is decomposed—*vide* nitrides, **8.** 49, 12 and 21. T. Curtius and F. Schrader said that **hydrazine hydrate** is vigorously decomposed forming molybdenum dioxide; and W. F. Jakob and W. Kozlowsky studied the reaction whereby quinquevalent molybdenum and nitrogen are formed. C. H. Ehrenfeld, and P. Sabatier and J. B. Senderens observed no reaction with **nitric oxide** at 500°. K. W. G. Kastner found that in the presence of water, and **nitrous acid,** the blue oxide is formed. R. Hac and V. Netuka studied the reduction of nitric acid to nitric oxide by ferrous chloride in an acidic soln. with molybdic acid as catalyst. P. Kulisch found that molybdenum trioxide is slowly attacked by **phosphine** in the cold and more rapidly when heated, a blue oxide being formed; C. H. Ehrenfeld said that purple Mo_2O_4 is formed. A. Michaelis observed that it is coloured blue by **phosphorus trichloride,** and in a sealed tube at 160°, it reacts: $MoO_3+PCl_3=MoO_2+POCl_3$; and with **phosphoryl chloride:** $2POCl_3+3MoO_3=3MoO_2Cl_2+P_2O_5$. H. Schiff found that with **phosphorus pentachloride,** molybdenum trioxide is coloured blue and then violet, heat is developed, and white and red vapours are given off—molybdenum oxychloride is formed. C. H. Ehrenfeld added that molybdenum pentachloride, mixed with some lower chlorides, is produced. According to J. J. Berzelius, with **phosphoric acid,** a lemon-yellow complex salt is formed—*vide infra*, the phosphomolybdic acids. When fused with **microcosmic salt,** molybdenum trioxide forms a colourless mass in the oxidizing flame, and in the inner flame a blue or grey mass. C. H. Ehrenfeld found that **arsine** acts like phosphine.

J. J. Berzelius observed that an aq. soln. of **boric acid** dissolves molybdenum trioxide; and fused **borax** dissolves molybdenum trioxide forming a clear glass in the oxidizing flame, but in a reducing flame, brown flecks of molybdenum dioxide are formed. K. W. G. Kastner observed that when the trioxide is heated with **carbon,** it is reduced to the metal. When the reduction is performed under definite conditions a factor can be obtained which represents the result with a known amount of molybdate, and, keeping rigorously to the same conditions, it can be assumed that the reduction proceeds to the same extent, and the factor can be employed to determine the amount of molybdenum in a given soln. H. Moissan, and H. N. Warren observed that with **calcium carbide,** a molybdenum-calcium alloy is formed. F. Göbel reduced molybdenum trioxide to a brown or violet-brown oxide by heating it in **carbon monoxide,** and W. Muthmann observed that the trioxide is successively reduced to $Mo_5O_{12}\rightarrow MoO_2\rightarrow$ and finally the metal. K. Chakravarty and J. C. Ghosh studied the catalytic action on the reaction between carbon monoxide and hydrogen. J. J. Berzelius observed that **carbon dioxide** does not unite with molybdenum trioxide. C. H. Ehrenfeld found that **ethylene** reduces the heated trioxide to bronze-coloured Mo_2O_5; similarly also with **acetylene,** but in addition a molybdenum carbide is formed; **methane** reduces the heated trioxide to the dioxide and the metal; **ethane** has no action.

J. Milbauer found that when the trioxide is fused with **potassium thiocyanate,** molybdenum disulphide, potassium thiomolybdate, and potassium cyanide are formed. A. Rosenheim and M. Koss obtained a deep red soln. by boiling an excess of molybdenum trioxide with a 10 per cent. aq. soln. of **thiocyanic acid.** On adding pyridine or quinoline, complex salts are deposited. G. A. Barbieri found that if an excess of **ammonium or potassium ferrocyanide,** followed by a large excess of an ammonium salt, is added to the soln. of a molybdate acidified with acetic acid, a lemon-yellow *precipitate*, $(NH_4)_4Fe(CN)_6.2MoO_3.3H_2O$, is obtained which is so sparingly soluble in conc. soln. of ammonium salts that the separation of molybdic acid is almost quantitative. H. E. Quantin passed the vapour of **carbon tetrachloride** over heated molybdenum trioxide, and obtained molybdenum oxychloride ; at a red-heat, molybdenum pentachloride is formed ; P. Camboulives added that this reaction occurs at 510°, but A. Michael and A. Murphy said at about 280°, and added that with a mixture of chlorine and carbon tetrachloride vapour at 200°, a yellowish-green oxychloride is formed, mixed with unchanged molybdenum trioxide ; at 225°, a mixture of MoO_2Cl_2 and $MoOCl_4$ is produced ; and at 240°, molybdenum pentachloride. According to A. Benrath, an aq. soln. of ammonium molybdate when diluted with an equal vol. of either ethyl **alcohol** or methyl alcohol and exposed to sunlight changes to blue after a short exposure, and a reddish-brown substance is deposited on the side of the flask on which the light falls. This compound has the formula $(NH_4)_2MoO_4.2MoO_3.2MoO_2.6H_2O$. In this formation only the complex acid group, MoO_3, and not the neutral ammonium molybdate, is reduced. Colloidal molybdic acid is rapidly reduced by alcohol to the blue oxide, Mo_3O_4 ; and S. Ghosh and A. K. Bhattacharya studied the photochemical reduction of molybdic acid by ethyl alcohol. L. Fernandes studied compounds of molybdenum trioxide with gallic acid, pyrocatechol, and pyrogallol ; E. Darmois, and T. S. Patterson and C. Buchanan, the effect of the sodium salt on the optical activity of **malic acid,** and tartaric acid. C. E. Guignet found molybdic acid to be a solvent for prussian blue. M. D. de Plaza studied the action of ammonium molybdate on potassium isobutylxanthate. H. N. Warren said that molybdenum trioxide is easily reduced when heated with **silicon.** L. Kahlenberg and W. J. Trautmann observed that a good reaction occurs when a mixture of molybdenum trioxide and silicon is heated in the electric arc furnace. G. Rauter found that when heated with **silicon tetrachloride,** chlorine, silica, $MoCl_5$, $MoOCl_4$, and MoO_2Cl_2, are formed ; C. H. Ehrenfeld observed no reaction when the two compounds are heated together. K. Fuwa studied the colouring action of molybdenum compounds on glass.

J. L. Gay Lussac and L. J. Thénard, and K. W. G. Kastner found that **potassium** or **sodium,** when heated with molybdenum trioxide, reduce it with incandescence to the metal. H. N. Warren found that when the trioxide is heated with molten **magnesium,** a violent detonation occurs ; and C. H. Ehrenfeld found that with powdered magnesium in air, the hemitrioxide is formed, and in hydrogen, the dioxide ; with **zinc,** in air, the hemipentoxide is formed ; and in hydrogen, Mo_4O_9 ; and with **aluminium,** the blue oxide is formed in air, and in hydrogen, no action occurs, probably because the trioxide is reduced by the hydrogen before the aluminium can act—*vide supra*, the preparation of molybdenum. It is generally supposed—W. A. Noyes and E. D. Frohman, D. L. Randall, C. Reinhardt, W. Scott, and B. Glassmann—that when a soln. of say ammonium molybdate is reduced by zinc and dil. sulphuric acid, out of contact with air, a salt of the oxide, Mo_2O_3, is formed, and volumetric methods for determining molybdenum, by the titration of the reduced oxide back to MoO_3, have been based on this assumption. It is, however, very difficult to drive the reduction until all the MoO_3 is reduced to Mo_2O_3. E. H. Miller and H. Frank, and A. A. Blair and J. E. Whitfield, said that an acid soln. of the trioxide is reduced by zinc to $Mo_{24}O_{37}$; O. F. von der Pfordten said Mo_5O_7 ; and A. Werncke, O. S. Doolittle and A. Eavenson, and C. Jones, $Mo_{12}O_{19}$, whilst C. B. Dudley obtained slightly different results. E. Berger and L. Delmas found that the presence of molybdenum trioxide facilitates the combustion of carbon in air. According to A. C. Chapman and H. D. Law, molybdenum trioxide is completely reduced to the molybdic oxide by the action of zinc or magnesium in sulphuric or hydrochloric acid soln.; zinc coated with nickel, silver, cadmium, or platinum also effects complete reduction; the action is fastest with zinc coated with cadmium. C. Boulanger studied the reduction of soln. of molybdenum salts by zinc, and aluminium. A. Chilesotti found that **mercury, tin,** and **lead** reduce a hydrochloric acid soln. of molybdenum trioxide to form molybdenum trichloride. G. Cannerei studied the reduction with tin. J. J. Berzelius said that **molybdenum** has no action when heated with the trioxide, but G. E. Uhrlaub observed that molybdenum reduces molybdenum trioxide suspended in water to a blue soln. K. Someya found that bismuth and lead amalgams reduce molybdates to quinquevalent molybdenum. According to M. Guichard, when a soln. of the compound $MoO_3.SO_3$, containing not less than 560 grms. H_2SO_4 per litre, is placed in contact with a large excess of powdered molybdenum in a closed vessel for a period of several months, a brown soln. is obtained which contains a salt of the oxide Mo_2O_5 and not of the oxide MoO_2 as stated by C. F. Rammelsberg. This fact, taken in conjunction with the results obtained by G. Bailhache, and P. Klason, renders it probable that the oxide MoO_2 does not form salts. G. E. Uhrlaub found that **stannous chloride** reduces molybdenum trioxide to a blue oxide; and E. D. Campbell said that the reduction of a hydrochloric acid soln. of the trioxide forms molybdenum pentachloride, which can be titrated back by a soln. of potassium dichromate. A. Geuther observed that the vapour of **ferric chloride** is absorbed by red-hot molybdenum trioxide to form ferric oxide and molybdenum oxychloride. According to R. H. Bradbury, an aq. soln. of **potassium chromate** reacts: $2K_2CrO_4+MoO_3=K_2Cr_2O_7+K_2MoO_4$; and with molten **potassium dichromate,** potassium chromatotrimolybdate is formed. The catalytic effect of molybdenum oxide in the oxidation of ammonia, and sulphur dioxide is discussed in connection with these compounds; C. Killing discussed the effect of molybdenum oxide in thoria gas mantles (*q.v.*). H. Brintzinger and F. Oschatz studied the electrometric titration of molybdates with **chromium dichloride,** following the reaction down to the formation of trivalent molybdenum. D. Balareff and N. Lukowa examined the effect of molybdenum trioxide on the boiling temp. of **calcium carbonate.**

According to T. Graham,[6] a soln. of sodium molybdate can be decomposed by the gradual addition of an excess of hydrochloric acid without an immediate precipitation of molybdenum trioxide. The acid liquor may gelatinize in a few hours on a dialyzer, but it again passes into the sol-form as the salts diffuse away. After repeated additions of hydrochloric acid, and a dialysis of several days, about 60 per cent. of the oxide remains as a **colloid solution of molybdic acid.** During the dialysis, endosmosis is great, so that the acid soln. in the dialyzer increases 2 or 3 times its original volume. The consequent dilution makes the purification slow. The colloidal soln. is yellow; it has an astringent taste, and is acidic to test-paper. It is fairly stable, and the acid can be dried at 100° without losing its solubility. The dry acid is more or less vitreous like gum or gelatin, and sometimes adheres so strongly to the surface of the evaporating basin as to detach portions of it. When heated short of its volatilizing temp., the powder all dissolves in a soln. of potassium carbonate or hydrocarbonate with the evolution of carbon dioxide. The colloid forms crystalline salts with the alkalies; and it becomes insoluble when heated for some time with hydrochloric acid or other strong acids. A. Sabanéeff, C. E. Linebarger, and A. Lottermoser obtained a similar product; and probably also F. Ullik—*vide infra.*

A. Sabanéeff found that when the dialyzed soln. is evaporated over sulphuric acid, in vacuo, it leaves transparent, hygroscopic, gum-like crusts, soluble in water without change, but on heating the soln. a white precipitate separates, and on evaporating to dryness an insoluble residue is left. Immediately after preparation, the salt contains 11·2 per cent. of water; after drying for several weeks over sulphuric acid, only 6·92 per cent. With the time of drying, the solubility of molybdic acid in water is found to decrease, and after some time it becomes insoluble. The depression of the f.p. for soln. containing 1·6–5·1 parts in 100 parts of water gives a mol. wt. of 608–631, the number calculated for $(MO_3)_4$ being 576. According to A. Rosenheim and I. Davidsohn, the soln. prepared by T. Graham's method probably contain no colloidal acid, since the addition of electrolytes does not cause precipitation. Colloidal molybdic acid was obtained by evaporating a soln. of the dihydrate over sulphuric acid, under reduced press., at 20°, or by warming a soln. of a mol of sodium molybdate and 4 mols of hydrochloric acid. The vitreous mass so obtained is readily soluble, forming an opalescent liquid, from which electrolytes readily precipitate the colloidal acid. A. V. Dumansky and co-workers found that the conductivity curve, and the curve for the lowering of the f.p. on adding acid to a soln. of sodium molybdate, show well-defined maxima and minima corresponding with the formation of intermediate complexes before colloidal particles of molybdic acid are formed, say $Na_2MoO_4+2HCl=2NaCl+H_2MoO_4$, and $H_2MoO_4+MoO_4''=H_2O+[MoO_4.MoO_3]''$. When small proportions of hydrochloric acid are successively added to a soln. of sodium molybdate, the free acid acts in successive stages: $Na_2MoO_4+H_2MoO_4=Na_2O(MoO_3)_2+H_2O$, etc.; this is indicated by the electrolytic and cryoscopic methods. The two salts, $Na_2O(MoO_3)_4$ and $Na_2O(MoO_3)_8$, were synthesized. The colloidal particles appear only when the octomolybdate is formed. The colloid was not coagulated either by cooling or heating or addition of electrolytes, and had an apparent mol. wt. of 1139; it thus could be classed with the semi-colloids. A second modification of the colloid—a suspension of the oxide MoO_3, which has much larger particles, exhibiting Brownian movement—also exists. G. Wegelin prepared colloidal soln. by a prolonged grinding of the powder in an agate mortar.

G. Bruni and N. Pappada observed no variation in the vap. press. of colloidal soln. They applied the term semi-colloid to colloidal molybdic acid prepared by T. Graham's process, because it readily passes through a dialyzer, and gives small depressions of the f.p. which are quite appreciable, and proportional to the concentration. True colloids do not really dissolve, but they remain suspended in the liquid in a fine state of subdivision, and they have a constant f.p. On freezing true solutions there are three co-existent phases—ice, soln., and vapour—the system is mono-variant; whilst in the case of a soln. containing a solid in suspension, there is another phase and the system is non-variant. L. Wöhler and W. Engels confirmed G. Bruni and N. Pappada's observation that with a 3 weeks' dialysis of T. Graham's soln., all the molybdic acid diffuses through the parchment. H. Picton and S. E. Linder also found that T. Graham's colloidal soln. does not show Tyndall's effect. The ultramicroscopic observations of L. Wöhler and W. Engels show that soln. of molybdic acid can be obtained in the colloidal or non-colloidal state. By acidifying a soln. of a molybdate, the molybdic acid polymerizes but the particles are so small that the soln. behaves as an electrolyte in diffusing through a parchment membrane; whether or not the particles coalesce further depends on the age of the soln., the presence of electrolytes, the temp. and other physical conditions. W. von Behren and I. Traube studied the colloid →crystal transformation. S. Ghosh and N. R. Dhar, and D. N. Chakravarti and N. R. Dhar measured the viscosity of colloidal soln. of molybdic acid. R. Wintgen found that the sp. gr. and refractive index of the colloidal soln. are linear functions of the conc.; and the sp. vol., v, and the product of the sp. vol. and the refractive index, μ, are linear functions of the percentage content, p, of the disperse phase so that $v=1{\cdot}00289-0{\cdot}0079682p$, and $v\mu=1{\cdot}33630-0{\cdot}008403p$. W. Reinders discussed the distribution of the colloid between two liquids; and E. F. Krause and A. V. Novoseloff, the adsorption of the colloid by the membrane in ultrafiltration.

C. F. Bucholz [7] found that 100 parts of cold water dissolve 0·2 part of molybdenum trioxide; and H. Debray, 0·18 part of cold water and less in hot water; and C. Hatchett said that 100 parts of hot water dissolve 0·104 part of the trioxide.

The **soluble molybdic acid** of F. Ullik is probably identical with T. Graham's **colloidal molybdic acid.** F. Ullik prepared it by treating a thin mush of barium molybdate with enough sulphuric acid to precipitate the barium as sulphate. The filtrate is treated with barium chloride and hydrochloric acid, and again with sulphuric acid. The colourless soln., when evaporated over sulphuric acid, dries to an amorphous powder. This is soluble in water when freshly prepared, but with ageing it becomes insoluble. If the soln. be evaporated on a water-bath, and dried at 100°, or if magnesium molybdate be treated with an excess of nitric acid, and the washed powder dried at 100°, the composition of the product approximates $MoO_3.nH_2O$, where n lies between 0·20 and 0·22. L. S. Bhatia and co-workers, and W. V. Bhagwat and N. R. Dhar studied the coagulation of colloidal molybdic acid. E. F. Krauze and A. V. Novoseloff considered that the adsorption of molybdic acid by porous clay tubes covered with collodion is a mechanical process in which large aggregates are held in the pores. The adsorption is preceded by a process of complex formation.

J. J. Berzelius obtained small, silky, crystalline scales by the spontaneous evaporation of a soln. of molybdenum or one of its lower oxides in an excess of nitric acid. The product lost on ignition about 2 per cent. of water. The existence of two definite hydrates has been established. G. F. Hüttig and B. Kurre measured the dissociation temp. of the hydrates, starting from the yellow precipitate from a nitric acid soln. of ammonium molybdate. The results, plotted in Fig. 12, show that these two hydrates exist as chemical individuals. The white α-monohydrate differs from the yellow dihydrate, even in aq. soln. A. Mazzucchelli and M. Borghi showed that the α-monohydrate is readily obtained by treating methyl molybdate with water. Its behaviour with tartaric acid and hydrogen dioxide is analogous to that of the yellow acid, but the rotary powers of soln. of the same composition are different, and the maximum corresponds with the existence of a compound $C_4H_4O_6.5(MoO_3.H_2O_2)$, thus affording a further proof of the difference between the two acids.

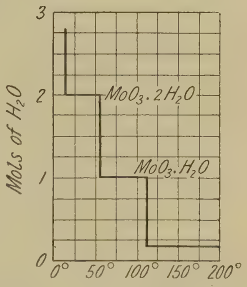

FIG. 12.—Dissociation Temperatures of the Hydrates of Molybdenum Trioxide.

The *monohydrate* of molybdic oxide, $MoO_3.H_2O$, is considered to be a kind of **metamolybdic acid,** H_2MoO_4, because the X-radiograms of H. C. Burger show that the angles of reflection are different from those of molybdenum trioxide. F. Ullik prepared this hydrate by treating a mol of magnesium molybdate with 2 mols of nitric acid, and allowing the white powder to stand for some time when prismatic crystals are formed. L. C. A. Vivier found that white crystals of this hydrate separated from a soln. of ammonium molybdate in nitric acid, and from a soln. of an ordinary molybdate on standing for several days at 50° to 60°. F. Ephraim and M. Brand obtained the monohydrate as a precipitate on mixing a soln. of a mol of normal lithium molybdate with 7 mols of nitric acid of sp. gr. 1·20, while warmed on a water-bath. A. Rosenheim and A. Bertheim obtained it by warming the dihydrate to 70°. A. Rosenheim and I. Davidsohn designate this the *β-monohydrate* to distinguish it from the *α-monohydrate* which is formed in asbestos-like, white needles when a soln. of the dihydrate is kept at 40°–50°. The β-form occurs in small white needles. The α-form differs from the β-hydrate in having a more definite crystal habit, and in the rapidity with which it settles from a suspension in water. The α-hydrate is also said to lose its water of crystallization more readily than the β-form. L. C. A. Vivier said that the monohydrate forms crystals which are probably hexagonal. A. Rosenheim and I. Davidsohn found the solubility of the α-monohydrate, S grms. MoO_3 per 100 grms. of water:

	14·8°	24·6°	36·8°	45·0°	52·0°	60·0°	70·0°	80·0°
S . .	0·2117	0·2619	0·3085	0·3661	0·4184	0·4685	0·4231	0·5212

At about 60°, there is a break in the curve, indicating that the α-monohydrate is transformed into the β-variety. The mol. conductivity, μ mhos, of the soln. of the α-monohydrate closely resembles that of methyl molybdate. For soln. with a mol of the α-monohydrate in v litres, at 25°,

v . .	31·3	62·6	125·2	250·4	500·8	1001·7
μ . .	71·4	89·4	95·2	96·9	100·3	104·1

Cryoscopic determinations show that the molybdic acid in the α-monohydrate has a smaller mol. wt. than is the case with the dihydrate. The rate of hydrolysis of methyl molybdate shows that the α-monohydrate is a weaker acid than the dihydrate.

According to A. Travers and L. Malaprade, cold, aq. soln. of the mono- or di-hydrate of molybdenum trioxide differ from soln. made at 100° and cooled, both in colour, and in their reactions with potassium ferrocyanide. It is assumed that both molybdic acid, $H_2[MoO_4]$, and tetramolybdic acid, $H_2[4MoO_3.O]$, are present in the soln., and that the latter ionizes: $H_2O.4MoO_3 \rightleftharpoons 2H^{\cdot}+[4MoO_3.O]$. This is confirmed by the neutralization curve which shows inflexions at $4MoO_3.K_2O$ and $MoO_3.K_2O$, the first resulting from the complete neutralization of the acid $4MoO_3.H_2O$, and the second from the decomposition of the salt formed first by the alkali. In support of this, the reactions of the tetramolybdate are found to be quite different from those of the neutral salt. From the analogy with the tungstic acids, $4MoO_3.H_2O$ is called metamolybdic acid. S. I. Diatschkovsky and A. V. Dumansky showed that with soln. of 10 eq. of sodium molybdate and 10 eq. of hydrochloric acid, the complex tetramolybdate, $Na_2O(MoO_3)_4$, was formed; with 12 eq. of acid, $Na_2O(MoO_3)_8$ was produced. This soln. does not coagulate at 100° nor when electrolytes are added.

M. Jungck, and S. Kern made some observations on the yellowish crystalline substance which separates when a soln. of an alkali molybdate in nitric acid is allowed to stand for a time. F. Parmentier showed that the deposit is the *dihydrate* of molybdic acid, $MoO_3.2H_2O$, or, if H_6MoO_6 be orthomolybdic acid, it can be regarded as **paramolybdic acid,** H_4MoO_5, although the term para-molybdate is usually applied to a salt of another molybdic acid. The dihydrate is not formed in hydrochloric acid soln. of the alkali molybdates. J. H. Graham, and A. A. Blair and J. E. Whitfield also found that the yellow deposit from the nitric acid soln. of alkali molybdate is dihydrated molybdenum trioxide. J. Terwelp obtained the dihydrate in the anode chamber during the electrolysis of soln. of molybdates. A. Rosenheim obtained it by pouring a soln. of 15 grms. of commercial (3 : 7)-ammonium molybdate in a litre of water with constant stirring to 29–30 per cent. nitric acid (300 c.c. of nitric acid of sp. gr. 1·42 diluted to a litre), and allowing the soln. to stand at 20°-25° for 8 to 10 days after inoculation with a crystal of the dihydrate. F. Parmentier, and L. C. A. Vivier observed that the lemon-yellow, prismatic crystals are monoclinic; and A. de Schulten added that the axial ratios are $a : b : c : =1·0950 : 1 : 1·0664$, and $\beta=90° 41'$. The angle between the basal plane and the orthopinacoid, *i.e.* (001) : (100), is 89° 19′, making the crystals appear at first glance as though they were cubes. The sp. gr. is 3·124 at 15°. F. Parmentier said that the crystals are efflorescent and lose half their water over sulphuric acid, in vacuo; and at 200°, they lose all their water. A. Rosenheim and A. Bertheim found that the dihydrate cannot be regenerated after it has been converted at 70° into the monohydrate.

E. Bruchhaus examined the reduction of ammonium molybdate by hydrogen. The solubility, S grms. of MoO_3 in 100 grms. of water, is,

	18°	23°	40°	50·2°	60°	70°	75°	79°
S .	0·1066	0·1856	0·4761	0·6873	1·2057	2·0550	2·0920	2·1064

There is a marked break in the solubility curve at 70° corresponding with the transformation of the dihydrate into the monohydrate. A. Rosenheim and

I. Davidsohn found that the solubility curves of the dihydrate and the α-monohydrate intersect at 32°; and A. Rosenheim and A. Bertheim showed that there is a change in the direction of the solubility curve of the dihydrate at 50°, and possibly below 18° another change of direction occurs. The solubility determined by saturating at a particular temp. is lower than that obtained by saturating at a higher temp. and then cooling in contact with solid. This anomalous behaviour seems not to be due to the formation of a colloidal soln., because the apparently supersaturated soln. diffuses quite readily. The cryoscopic observations of A. Rosenheim and A. Bertheim showed that the mol. wt. approximates $(MoO_3)_4$; and those of A. Mazzucchelli and G. Zangrilli, $(MoO_3)_6$. The solubility of the dihydrate is greatly increased by the addition of ammonium salts; *e.g.* with a 10 per cent. soln. of ammonium hydrosulphate, the solubility, S grms. of MoO_3 per 100 grms. of solvent, is 1·927 at 29·6°; 2·753 at 31·5°; 3·436 at 41·8°; and 3·769 at 49·7°. This is taken to mean that the dihydrate is not a colloid. The mol. conductivity, μ mhos, of soln. with a mol of the dihydrate in v litres of water, at 25°, is,

v	16·56	33·12	66·24	132·48	264·96	529·92	1059·84
μ	98·28	130·10	150·0	159·7	163·5	168·7	180·3

Acetic acid and boric acid exert scarcely any influence on the conductivity of molybdic acid soln. Tartaric acid, malic acid, and mannitol greatly increase the conductivity, and this is attributed to the formation of a complex molecule. On account of hydrolysis of the complex molecule at high dilution, the increase of the conductivity diminishes somewhat with the dilution. Oxalic acid and iodic acid, which form complex molecules with molybdic acid, which can be isolated, diminish the conductivity, but this may be due to the complex ion having a smaller speed of migration. Phosphoric acid also increases the conductivity, the maximum being reached when phosphodecamolybdic acid is present. The ionization constant of the acid in soln. of the dihydrate was found by A. Rosenheim and A. Bertheim to be $k=0{\cdot}052$ at 25° when calculated from the velocity of hydrolysis of methyl acetate which is 0·88. These results all show that the acid is greatly ionized in aq. soln. Cryoscopic measurements indicate that in the soln., an octomolybdic acid, $H_2Mo_8O_{25}$, is present, and these are supported by the fact that on adding ammonium salts, ammonium octomolybdate, $(NH_4)_2Mo_8O_{25}.13H_2O$, separates. E. Darmois and A. Honnelaitre, and A. Honnelaitre made a study of complexes of molybdic and malic acids; and E. Rimbach and P. Ley, mixtures of molybdic and hydroxy-organic compounds which were found to augment the acidity of molybdic and boric acids. R. F. Weinland and co-workers also studied this subject. F. Parmentier observed that the dihydrate is sparingly soluble in water and acids at different temp.; it dissolves completely in soln. of alkali hydroxides and carbonates, and, on evaporation, these soln. furnish ordinary molybdates. K. von der Heide studied the action of hydroxylamine, and of potassium cyanide. The soln. in aq. ammonia remains clear when magnesia mixture is added, and precipitates molybdenum trioxide when nitric acid is added to the aq. soln. E. Müller, H. H. Willard and F. Fenwick, and O. Tomicek studied the electrometric reduction of soln. of sexivalent molybdenum by titanous salt soln. R. Hac and V. Netuka studied its catalytic action on the reduction of nitric acid by ferrous chloride.

According to F. Mylius, no solid **orthomolybdic acid,** H_6MoO_6, exists corresponding with orthotelluric acid, H_6TeO_6. The colourless molybdic acid obtained in aq. soln. corresponds with *allo*telluric acid, with which it agrees in having an indefinitely large solubility in cold water, complex composition, in being soluble in alcohol, in being precipitated in the form of acid salts, and in precipitating solutions of proteids. Of the solid forms of molybdic acid, the yellow acid, H_3MoO_5, has the greatest solubility in water, and is slowly formed when soln. of molybdates or molybdic acid are treated with nitric or hydrochloric acid. As indicated above, the dihydrate, H_4MoO_5, is considered by A. Rosenheim and A. Bertheim to be an

octomolybdic acid, $H_2Mo_8O_{25}$, and it is assumed that in passing from one hydrated form to another, various complex intermediate polymerides of molybdic acid are formed—*vide infra.*

G. Jander and co-workers studied the complex acids, and some of the results have been summarized in connection with the electrometric titration of the acid. He gives for the condensation products :

$3[MoO_4{}'']+2H^{\cdot}=[Mo_3O_{11}{}'''']+H_2O$ stable in the region $p_H=6{\cdot}1$; $[Mo_3O_{11}{}'''']+H^{\cdot}=[H(Mo_3O_{11})''']$, called, by F. Ullik, the " dimolybdate " ; $2[H(Mo_3O_{11})''']+H^{\cdot}=[H(Mo_6O_{21})''''']+H_2O$, stable in the region $p_H=4{\cdot}5$, and called, by F. Ullik, " paramolybdates " ; $[H(Mo_6O_{21})''''']+H^{\cdot}=[H_2(Mo_6O_{21})'''']$, called, by F. Ullik, the " trimolybdates " ; $[H_2(Mo_6O_{21})'''']+H^{\cdot}=[H_3(Mo_6O_{21})''']$, stable with p_H approximately $2{\cdot}9$, and called, by F. Ullik, " tetramolybdates " or " metamolybdates " ; $2[H_3(Mo_6O_{21})''']+3H^{\cdot}=2[H_7(Mo_{12}O_{41})''']+H_2O$, called, by F. Ullik, " octomolybdates " ; $2[H_7(Mo_{12}O_{41})''']+H^{\cdot}=[H_7(Mo_{24}O_{78})''''']+4H_2O$, called, by F. Ullik, " decamolybdates " ; $[H_7(Mo_{24}O_{78})''''']+2H^{\cdot}=[H_9(Mo_{24}O_{78})''']$, called, by F. Ullik, " hexadecamolybdates " ; and $[H_9(Mo_{24}O_{78})'''+3H^{\cdot}=H_{12}(Mo_{24}O_{78})$, where p_H approximates $0{\cdot}9$.

§ 11. The Monomolybdates—Normal Molybdates

The action of liquid ammonia on molybdenum trioxide furnishes amides and imidies as indicated **8**. 49, 21. Normal **ammonium molybdate,** $(NH_4)_2MoO_4$, crystallizes from conc. soln. of molybdenum trioxide in warm, conc., aq. ammonia during cooling, or on the addition of alcohol. The salt was obtained in this way by L. F. Svanberg and H. Struve,[1] J. C. G. de Marignac, F. A. Flückiger, and A. Rosenheim. A. Werncke obtained it from the mother-liquor in the preparation of ammonium phosphomolybdate ; and A. S. Garnak described a method of preparing the salt from ferromolybdenum. Analyses in accord with the formula were made by L. F. Svanberg and H. Struve, F. A. Flückiger, A. Werncke, and G. Wempe. L. F. Svanberg and H. Struve described the crystals as four-sided prisms. J. C. G. de Marignac found that the monoclinic prisms have the axial ratios $a : b : c = 1{\cdot}9542 : 1 : 1{\cdot}2066$, and $\beta = 117° \ 45'$. Observations were also made by W. Keferstein ; and G. N. Wyrouboff said that the crystals are isomorphous with those of ammonium chromate, and J. W. Retgers, with those of ammonium selenate and chromate. J. W. Retgers added that ammonium chromate, selenate, and molybdate are isodimorphous with potassium sulphate. H. Schröder gave 2·270 for the sp. gr. According to J. C. G. de Marignac, the crystals effloresce rapidly in air owing to the loss of ammonia ; F. A. Flückiger said that if the crystals are freed from the mother-liquor they are stable in air. L. F. Svanberg and H. Struve found that the crystals are unstable in contact with water and rapidly form an acid salt. T. L. Phipson found that the aq. soln. is decomposed in sunlight and R. E. Liesegang observed that in light, the salt is decomposed with the separation of a blue oxide. The change can be followed titrimetrically so that the soln. can be used as a kind of actinometer. The presence of organic substances, like lactic acid, makes the liquid more sensitive to light ; some salts favour and others retard the action. In darkness the original colour is restored by the oxidizing action of the air—*vide supra*, molybdic acid and alcohol. P. Krishnamurti studied the Raman effect. W. V. Bhagwat and N. R. Dhar found the eq. electrical conductivity of ammonium molybdate to be for an eq. of the salt in v litres, at 21°,

v . .	16	32	64	128	256	512	1024
λ . .	84·5	96·45	108·8	120·3	128·6	136·9	143·5

so that $\mu_{1024} - \mu_{32} = 47{\cdot}05$.

F. Krauss and E. Bruchhaus found that ammonium molybdate in aq. soln., and exposed to rays of short wave-length, is reduced by hydrogen. For the hydrolysis of aq. soln., *vide infra*, ammonium paramolybdate. J. W. Thomas found that the salt is decomposed by hydrochloric acid; H. P. Cady and R. Taft, that ammonium molybdate is insoluble in liquid sulphur dioxide; H. Stamm measured its solubility in aq. ammonia and found that soln. with 0·170, 1·192, 1·750, and 3·382 mols of NH_3 per 100 grms. of water dissolved respectively 0·333, 0·268, 0·231, and 0·187 mol of $(NH_4)_2MoO_4$. O. Brunck observed that sodium hyposulphite precipitates molybdenum sulphide from acid soln; and F. J. Faktor, that sodium thiosulphate reduces a soln. of the molybdate to hydrated dioxide, and trioxide; and I. F. J. Kupfferschläger, that an excess of nitric acid gives a precipitate with a conc. aq. soln. A soln. of ammonium molybdate with an excess of nitric acid is used as a reagent for the detection of phosphoric acid. P. Kulisch disagreed with A. Winkler's statement that phosphine does not reduce soln. of ammonium molybdate—only in the absence of free acid is a soln. of the molybdate little affected by phosphine. O. F. von der Pfordten obtained a dark brown precipitate on adding a soln. of titanium dichloride to a soln. of the molybdate; and this is oxidized to a white mass in air. C. E. Guignet observed that the soln. of the molybdate dissolves prussian blue; and S. M. Jörgensen that it gives a precipitate with chromic chloropentamminochloride.

No normal **hydroxylamine molybdate** has yet been prepared. G. Canneri[2] observed that hydroxylamine added to a soln. of a paramolybdate forms a red soln. which deposits yellow molybdic molybdates. If hydroxylamine chloride be added to a hot, aq. soln. of alkali molybdate, and the precipitate be washed successively with water, alcohol, and ether, the following salts are formed: yellow **ammonium hydroxylamine paramolybdate,** $(NH_4)_2O.4NH_2OH.4MoO_3$; yellow **potassium hydroxylamine paramolybdate,** $K_2O.4NH_2OH.4MoO_3$; yellow **sodium hydroxylamine paramolybdate,** $Na_2O.4NH_2OH.4MoO_3$; and similarly with the guanidine salt. V. Kohlschütter and K. A. Hofmann found that **potassium hydroxylaminopentahydromolybdate,** $MoO_4H_2(NH_2OH)_3(NH_2OK)$—*vide infra*—is obtained as a salt of what they supposed to be the acid

$$\begin{matrix}(NH_2O)_2\\(ONH_4O)_2\end{matrix}\!\!>\!Mo\!<\!\begin{matrix}OH\\OH\end{matrix}$$

by mixing aq. soln. of ammonium molybdate (5 grms.), hydroxylamine hydrochloride (10 grms.), and potassium carbonate, and adding alcohol to the yellow soln. The salt reduces Fehling's soln., or ammoniacal silver nitrate; it decomposes when heated forming a black powder with the liberation of ammonia. The salt dissolves in water, and when the pale yellow, neutral, aq. soln. is treated with carbon dioxide, hydroxylaminomolybdic acid separates as a yellowish-white, flocculent precipitate. If ammonium molybdate (10 grms.) and hydroxylamine hydrochloride (7 grms.) be mixed with 50 c.c. of 7 per cent. aq. ammonia at 8°, a compound is formed which dissolves with difficulty in water; and develops a bluish-green coloration when heated with dil. sulphuric acid. The composition of the product is $MoO_5N_3H_9$, and it is regarded as **dihydroxylamine amminomolybdate,** $MoO_5N_3H_9$, or $MoO_3(NH_2OH)_2NH_3$, a salt of what they suppose to be the acid:

$$\begin{matrix}(NH_2O)_2\\O\end{matrix}\!\!>\!Mo\!<\!\begin{matrix}OH\\OH\end{matrix}$$

C. F. Rammelsberg[3] obtained **lithium molybdate,** $Li_2MoO_4.\frac{2}{5}H_2O$ (A. Rosenheim and W. Reglin find $Li_2MoO_4.\frac{3}{4}H_2O$), by boiling a mol each of lithium carbonate and molybdenum trioxide, and allowing the filtrate to crystallize. G. Wempe obtained the salt in a similar way; and M. Delafontaine, by fusing equimolar proportions of lithium carbonate and molybdenum trioxide, and allowing the syrupy aq. soln. to stand some days. F. Hoermann measured the f.p. curves of

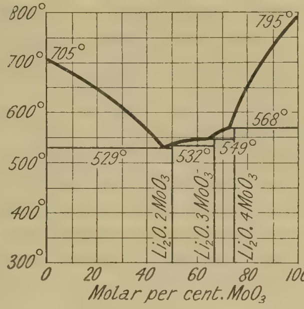

FIG. 13.—Equilibrium Curves of the System : Li_2MoO_4–MoO_3.

the system : Li_2MoO_4–MoO_3, and the results are summarized in Fig. 13. The existence of three unstable acid salts is indicated, namely, lithium di-, tri-, and tetramolybdate. W. Zachariassen found that the X-radiogram of Li_2MoO_4 agrees with a unit cell having 6 mols. and with the dimensions a=8·20 A., c=9·45 A., and $a : c$=1 : 1·153 ; and that the salt is isomorphous with phenacite, willemite, lithium tungstate, and lithium fluoberyllate. F. Ephraim and M. Brand suggest that the water in the *pentitadihydrate* prepared by both processes is merely hygroscopic moisture. M. Delafontaine also obtained the *tritoctohydrate*, $Li_2MoO_4.2\frac{2}{3}H_2O$, in monoclinic or triclinic crystals, from a soln. of an acid molybdate sat. with lithium carbonate. The prismatic crystals of the pentitadihydrate are fairly stable in air but they are hygroscopic. G. Wempe said that 100 c.c. of the aq. soln. sat. at 20° contains 46·13 grms. of the hydrated salt and has a sp. gr. of 1·44. F. Ephraim and M. Brand found that the salt is only a little more soluble in hot than in cold water. F. Hoermann gave 705° for the m.p. of the salt. A. Rosenheim and W. Reglin found the solubility of $Li_2MoO_4.\frac{3}{4}H_2O$, S grms. Li_2MoO_3 per 100 grms. of soln., to be :

	0°	25°	30°	40°	98°
S . .	45·24	44·81	44·26	43·84	42·50

so that the temp. coeff. is negative. A. Rosenheim and W. Reglin also found that the salt dissolves readily in a soln. of lithium hydroxide, and on evaporating the liquid, non-crystallizable syrups are formed. Solubility is less as the temp. rises. The aq. soln. has an alkaline reaction. The aq. soln. of a mol of the salt and 5 mols of ammonium chloride yields crystals of ammonium paramolybdate free from lithium. The eq. conductivity, λ mhos, of a mol of the normal salt in v litres of water, at 20°, was found by G. Wempe to be :

v . .	10	20	40	80	160	320
λ . .	422	524	604	664	736	800

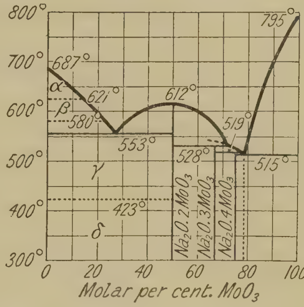

FIG. 14.—Equilibrium Curves of the System : Na_2MoO_4–MoO_3.

L. F. Svanberg and H. Struve obtained anhydrous **sodium molybdate**, Na_2MoO_4, by melting together equimolar parts of molybdenum trioxide and sodium carbonate, and cooling the mass. The salt obtained by heating the hydrate to 100° was found by J. G. Gentele, and F. E. Zenker to furnish a molten mass which cools to an opaque, white enamel of the anhydrous salt. F. Hoermann measured the f.p. curves of the system : Na_2MoO_4–MoO_3, and the results are summarized in Fig. 14. The existence of three acid salts is indicated, namely, sodium di-, tri-, and tetra-molybdate. E. Groschuff obtained a similar curve. The monomolybdate exists in four modifications. The α-form is stable above about 620° ; the β-form is stable between 620° and 580° ; the γ-form between 580° and 410° ; and the δ-form below 410°. For the $\alpha \rightleftharpoons \beta$, $\beta \rightleftharpoons \gamma$, and $\gamma \rightleftharpoons \delta$ transition temp. K. Hüttner and G. Tammann observed transformations respectively between 620° and 605°, and 410° and 380° ; H. E. Boeke gave for the three transformation temp. respectively 619°, 587°, and 431° ; E. Groschuff, 609°, 575°, and 408°—Fig. 14 ; H. S. van Klooster, 626°, 580°, and 397° ; F. Hoermann, 621°, 580°, and 423° ; and M. Amadori, 616°, 580°, and 410° when all are taken on a cooling curve. H. S. van Klooster found on a heating curve the respective values 640°, 592°, and 445°, showing that the transition temp. are overstepped. A. Hare gave 440° for the last transformation temp. The subject is still further discussed in connection with sodium tungstate. With 10 per cent. of molybdenum trioxide associated with the sodium molybdate, E. Groschuff found the transition temp. are changed respectively to 614°, 567°, and 412°. H. E. Boeke found that with 0·055, 0·40, and 3·00 molar per cent. of Na_2SO_4, the $\gamma \rightleftharpoons \delta$ transition temp. is lowered from 431° respectively to 396°, 297°, and about 180°. This depression is much greater than that calculated from the heat of the transformation, 3·33 Cals., and the anomaly is explained by H. S. van Klooster by assuming that the presence of sodium sulphate considerably augments the speed of the transformation. H. E. Boeke found that the binary system Na_2SO_4–Na_2MoO_4 forms a continuous series of solid soln. on solidification. There is a minimum in the f.p. curve, Fig. 15. For the binary system: Na_2WO_4–Na_2MoO_4, and the ternary system: Na_2SO_4–Na_2WO_4–Na_2MoO_4, *vide* sodium tungstate.

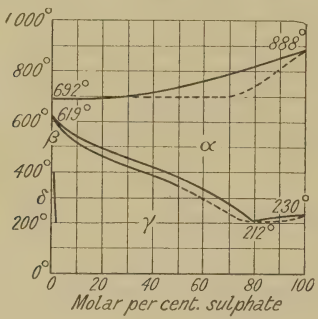

Fig. 15.—Binary System: Na_2MoO_4–Na_2SO_4.

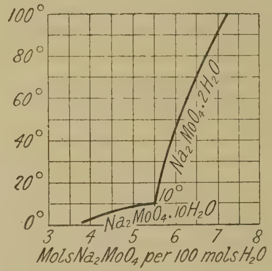

Fig. 16.—Solubility Curve of Sodium Molybdate.

The equilibrium conditions in the ternary system: Na_2O–MoO_3–H_2O have not been worked out. R. Funk's solubility curve, Fig. 16, shows that within the range of temp. 0° to 100°, there are two hydrates: $Na_2MoO_4.10H_2O \rightleftharpoons Na_2MoO_4.2H_2O + 8H_2O$ with a transition at about 10°. L. F. Svanberg and H. Struve obtained the *dihydrate* by crystallizing an aq. soln. of the anhydrous salt, and drying the crystals for 24 hrs. over lime and sulphuric acid. F. E. Zenker evaporated an aq. soln. of the paramolybdate mixed with an excess of sodium hydroxide; F. Ullik, an aq. soln. of the acid or an acid salt sat. with sodium carbonate; M. Delafontaine used a similar process; and J. G. Gentele allowed the decahydrate to effloresce in the cold. According to M. Delafontaine, the rectangular or rhombic plates or scales are probably isomorphous with the crystals of normal tungstate. They lose all their water at 100°. The molten mass does not expel carbon dioxide from sodium carbonate. R. Funk found the solubility, *S* grms. of Na_2MoO_4 per 100 grms. of solution, to be:

	0°	4°	6°	9°	10°	32°	51·5°	100°
S .	30·63	33·83	35·58	38·16	39·28	39·82	41·27	45·57
	$Na_2MoO_4.10H_2O$.					$Na_2MoO_4.2H_2O$.		

The results are plotted in Fig. 16. The transition temp. is near 10°. J. G. Gentele obtained the *decahydrate* by evaporating the aq. soln. between 0° and 6°. The columnar crystals have the appearance of Glauber's salt. The crystals effloresce at about 6°, and are stable below that temp. In a closed vessel, at room temp., the crystals become opaque and gradually form the scaly crystals of the dihydrate. M. Delafontaine could not prepare the decahydrate.

G. Beck gave 3·28 for the sp. gr. of the salt, and 62·0 for the mol. vol. F. M. Jäger measured the sp. gr. of the molten salt—D referred to water at 4°—and found:

	698·5°	751°	818·8°	903·8°	989·5°	1078·5°	1171·5°
D .	2·796	2·763	2·720	2·667	2·613	2·557	2·499
σ .	214·0	208·1	202·4	195·4	187·7	181·2	176·1
χ .	376·1	3686	3623	3544	3451	3380	3335

The results for the sp. gr. between 700° and 1171° can be represented by $D=2·795-0·000629(\theta-700)$—*vide infra*, electrical resistance. W. Herz made some observations on this subject. I. Traube found the sp. gr., D, and mol. soln. vol., v, of aq. soln. of the salt, at 15°, to be:

Na_2MoO_4	6·31	11·84	19·91	22·18 per cent.
D . .	1·0555	1·1085	1·1928	1·2194
v . .	32·9	34·4	38·1	38·3

R. Lorenz and W. Herz studied the relation between the critical densities of related salts, and they also found that the surface tension at the m.p. and b.p. are respectively 215·5 and 177·9; G. Jander and co-workers studied the diffusion; and I. Traube found 232 for the drop-weight of molten sodium molybdate when the value for water at 0° is 100. F. M. Jäger's values for the surface tension, σ dynes per cm., and the surface energy, χ ergs per sq. cm., of the molten salt, are indicated above. J. J. Coleman found that 28, 25, and 17 per cent. of normal soln. of sodium molybdate, chromate, and tungstate, respectively, diffused in water 75 mm. in 30 days at 12·5°. W. Herz gave 0·0002752 for the coeff. of thermal expansion. G. Tammann found the lowering of the vap. press. per 100 grms. of water to be 24·4, 73·2, and 166·9 mm., respectively. The m.p. of the anhydrous salt was found to be 692° by K. Küttner and G. Tammann, and H. E. Boeke; 687°, by L. I. Dana and P. D. Foote; 688°, by M. Amadori; 685°–687°, by H. S. van Klooster; and 686°, by E. Groschuff. The fusion curve with sodium sulphate mixtures is shown in Fig. 15. E. Darmois and J. Périn found that the mol. wt. is normal when calculated from its effect on the f.p. of decahydrated sodium sulphate. R. Lorenz and W. Herz studied the relation between the b.p. and the critical temp. W. G. Mixter gave for the heat of formation $(Na_2O,Mo,3O)=263·4$ Cals.; $(Na_2O,MoO_2,O)=120·6$ Cals.; and $(Na_2O,MoO_3)=81·936$ Cals. A. Hare gave 14·6 Cals. per mol for the heat of transformation at about 440°. L. Pissarjewsky found for the thermal value of the reaction: $H_2MoO_{4\text{soln.}}+2NaOH=Na_2MoO_{4\text{soln.}}+2H_2O+21·728$ Cals. A. Hare gave 14·60 Cals. per mol for the heat of the transformation at 440°.

F. M. Jäger and B. Kapma found the resistance, R ohms, of fused sodium molybdate to be:

	843°	924·5°	1026°	1122·5°	1217°	1306°	1408°
R . .	0·1256	1·1105	0·0948	0·0842	0·0752	0·0690	0·0620
Sp. gr. .	2·705	2·654	2·590	2·529	2·470	2·414	2·350

and they represented the mol. conductivity, μ, at θ° between 543° and 1408°, by $\mu=107·50+0·183(\theta-850)$. P. Walden found the eq. conductivity, λ mhos, of soln. of an eq. of sodium molybdate in v litres of water at 25°, to be:

v . . .	32	64	128	256	512	1204
λ . . .	100·5	106·1	111·0	114·6	117·8	120·8

H. Crossmann gave $\mu_{1024}-\mu_{32}=22·4$ at 25°. J. Terwelp obtained similar results, and he found the transport number of the MoO_4''-ion in $0·1N$-Na_2MoO_4 to be 0·58 at 18°. G. Jander and co-workers studied the electrometric titration of the salt. L. Ott found the decomposition voltage of the fused salt to be 1·15 volt; and the cathode deposit is MoO_2 as well as some metal. J. Terwelp, and A. Junius found that the electrolysis of neutral aq. soln. of sodium molybdate without diaphragms, does not produce very marked change since the diffusion of the anodic and cathodic products restores the original state of things. A cathodic reduction occurs only in acidic soln. In a diaphragmed cell, paramolybdate and trimolybdate appear to be formed in the anode compartment—*vide supra*, molybdenum trioxide. The aq. soln. was found by F. E. Zenker, and A. Junius to react acid; but the hydrolysis cannot be very marked because K. Seubert and W. Pollard found that a soln. of molybdic acid can be sharply titrated with a soln. of sodium hydroxide using litmus or phenolphthalein as indicator—*vide infra*, ammonium paramolybdate. F. Ullik found that the soln. of sodium molybdate is not reduced by tin.

F. Hoermann found that the f.p. curve of mixtures of lithium and sodium molybdates, Fig. 17, showed the existence of an unstable **lithium sodium molybdate,** $Li_2MoO_4.3Na_2MoO_4$.

L. F. Svanberg and H. Struve prepared **potassium molybdate,** K_2MoO_4, by evaporating for crystallization a soln. of molybdic acid or an acid molybdate in an excess of potassium hydroxide or carbonate. J. Ohly said that the product is then liable to be contaminated with potassium carbonate. The formation of the acid molybdate can be avoided only by using an excess of alkali. L. F. Svanberg and H. Struve treated an acid molybdate with soln. of potassium hydroxide in 95 per cent. alcohol. The oil which separates was washed with alcohol and allowed to crystallize first over lime and then sulphuric acid. F. Ullik fused equimolar parts of molybdenum trioxide and potassium carbonate, dissolved the product in hot water, and allowed the filtered soln. to cool. L. F. Svanberg and H. Struve supposed the crystals to be hemihydrated; and F. Ullik thought they are anhydrous. M. Delafontaine could not prepare this salt. M. Amadori found that anhydrous potassium molybdate separates from its aq. soln. at 25°; and the salt remains anhydrous in contact with water at this temp. G. Wempe reported a *tetritatrihydrate*, $K_2MoO_4.\frac{3}{4}H_2O$, to be formed by filtering a boiling soln. of molybdic acid in a conc. soln. of potassium carbonate, allowing the filtered liquid to cool on a glass plate, and separating mechanically the crystals from the amorphous, gum-like mass. The salt loses its water at 120°. F. Hoermann studied the f.p. curve of the system: K_2MoO_4–MoO_3, and the results, summarized in Fig. 18, show the existence of a dimolybdate only.

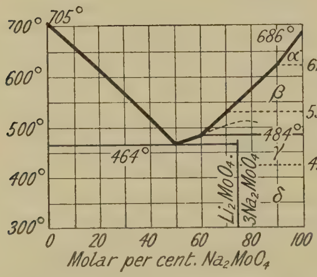

Fig. 17.—The Equilibrium Curves of the System: Li_2MoO_4–Na_2MoO_4.

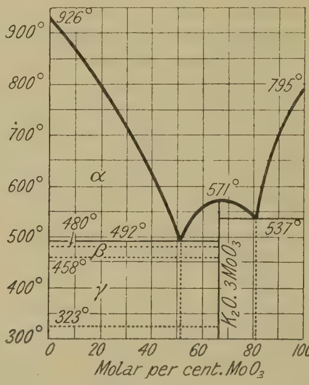

Fig. 18.—Equilibrium Curves of the System: K_2MoO_4–MoO_3.

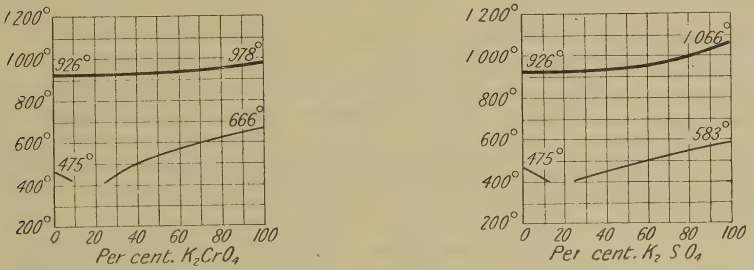
L. F. Svanberg and H. Struve said that the crystals of potassium molybdate, K_2MoO_4, are four-sided prisms. H. S. van Klooster observed that the cooling salt undergoes three transformations: there is the $\alpha \rightleftharpoons \beta$ change at 479°; the $\beta \rightleftharpoons \gamma$ change at 454°; and the $\gamma \rightleftharpoons \delta$ change at 327°; M. Amadori gave 475° for the $\alpha \rightleftharpoons \beta$ change; and K. Hüttner and G. Tammann, 200° for the $\gamma \rightleftharpoons \delta$ change. F. Hoermann gave respectively 480°, 458°, and 323°. J. W. Regters observed that during the crystallization of potassium molybdate there are formed acicular crystals supposed to be rhombic or pseudohexagonal and isomorphous with potassium permanganate; and prismatic crystals not isomorphous with the salt, and supposed to be monoclinic. M. Amadori found that mixtures of potassium sulphate and molybdate, and of potassium chromate and molybdate have the following f.p. and $\beta \rightleftharpoons \alpha$ transition points:

K_2MoO_4		100	80	70	40	20	0 per cent.
K_2SO_4	F.p.	920°	920°	934°	980°	1018°	1066°
	Tr.p.	475°	—	484°	525°	558°	583°
K_2CrO_4	F.p.	926°	926°	934°	942°	960°	976°
	Tr.p.	475°	—	502°	575°	620°	666°

The curve, Fig. 19, for the K_2MoO_4–K_2SO_4 is continuous, and it has a very flat minimum 6° below the m.p. of the molybdate, and the m.p. of the mixture with 45 per cent. of sulphate is equal to that of the molybdate alone. The curve, Fig. 20, for the K_2MoO_4–K_2CrO_4 system is continuous, and with mixtures up to 30 molar per cent. of chromate the f.p. is at the f.p. of the molybdate. M. Amadori also found the solubility isotherm of potassium sulphate and molybdate is similar to that with potassium sulphate and chromate. There is a continuous series of solid soln. in which the more soluble salt is in greater proportion in the soln. than in the crystals; similarly also with the solubility isotherm of mixtures of potassium chromate and molybdate. G. Beck gave 2·91 for the sp. gr. of the salt, and 81·8 for the mol. vol. F. M. Jäger gave the following values for the sp. gr., D, of fused potassium molybdate referred to water at 4°:



FIGS. 19 and 20.—Freezing-point Curves of the Binary System: K_2MoO_4–K_2SO_4 and K_2MoO_4–K_2CrO_4.

	930·6°	1021°	1143°	1273°	1356°	1452°·8
D	2·362	2·307	2·230	2·144	2·087	2·018
σ	150·5	145·2	138·6	130·0	123·6	116·9
χ	3261	3196	3120	3004	2908	2813

and he represented the sp. gr. at $\theta°$ between 694° and 1452° by $D=2{\cdot}342-0{\cdot}0006(\theta-964)-0{\cdot}000000128(\theta-964)^2$. W. Herz made some observations on this subject. I. Traube gave for the sp. gr., D, and mol. soln. vol., v, of aq. soln. of potassium molybdate at 15°:

K_2MoO_4	2·02	6·76	7·37	15·94 per cent.
D	1·0154	1·0548	1·0602	1·1381
v	49·7	52·4	52·2	56·4

I. Traube gave 198 for the drop-weight of the molten salt when that of water at 0° is 100. F. M. Jäger found the results indicated above for the surface tension, σ dynes per cm., and the surface energy, χ ergs per sq. cm. R. Lorenz and W. Herz gave for the surface tensions at the m.p. and b.p. respectively 161·5 and 108·3. G. Jander and A. Winkel gave for the diffusion coeff. of the anion 0·58; and they found the range of stability for $[H^{\cdot}]$ to be 10^{-14} to $10^{-6\cdot2}$. K. Hüttner and G. Tammann, and M. Amadori gave 926° for the m.p. of the salt, and H. S. van Klooster, 919°. The lowering of the vap. press. when 19·62, 56·06, and 111·13 grms. of potassium molybdate are dissolved in 100 grms. of water was found by G. Tammann to be respectively 24·6, 85·3, and 197·1 mm. R. Lorenz and W. Herz studied the relation between the b.p. and the critical temp. P. Blackman found the conductivity of soln. of an eq. of the salt in v litres at 25° to be :

v . .	32	64	128	256	512	1024
λ . .	123	129	133	138	140	144

Measurements by W. V. Bhagwat and N. R. Dhar corresponded with $\mu_{1024}-\mu_{32}=24$. E. Blanc found that there is a 0·359 per cent. hydrolysis with a 0·00975N-soln. of potassium molybdate. L. F. Svanberg and H. Struve, and F. Ullik found that the salt effloresces in moist air, and, attracting carbon dioxide from the atmosphere, forms other salts. M. Amadori observed that a sat. aq. soln. at 25° contains 64·86 per cent. K_2MoO_4. Expressing solubilities in millimols per litre, the solubility, S, of potassium sulphate in the presence of potassium molybdate is :

K_2MoO_4 .	69·88	49·04	22·65	12·21	8·60	4·13	0·00
K_2SO_4 .	0·00	19·85	73·35	192·6	417·5	742·8	774·7

and of potassium chromate in the presence of potassium molybdate :

K_2MoO_4 .	332·3	204·7	72·68	36·66	25·31	8·74	0·00
K_2CrO_4 .	0·00	162·0	414·3	578·1	694·1	767·9	774·7

L. F. Svanberg and H. Struve found potassium molybdate to be insoluble in alcohol ; and to be precipitated by alcohol from the aq. soln. as an oily liquid.

F. Hoermann studied the f.p. curve of mixtures of lithium and potassium molybdates, and found the existence of **lithium potassium molybdate,** $Li_2MoO_4.K_2MoO_4$, with a m.p. at 571°. F. Ullik prepared **potassium sodium molybdate,** $K_2O.2Na_2O_3.MoO_3.14H_2O$, or $K_{\frac{2}{3}}Na_{\frac{4}{3}}MoO_3.4\frac{2}{3}H_2O$, by treating a potassium trimolybdate with water and sodium carbonate. F. Ullik fused molybdenum trioxide with sodium and potassium carbonates, and allowed an aq. soln. of the cold mass to crystallize. J. C. G. de Marignac described the crystals as dihexagonal bipyramidal with the axial ratios $a:c=1:1·2839$. M. Delafontaine stated that all the water is expelled at 100° ; and the salt fuses at a red-heat ; fused sodium carbonate does not lose carbon dioxide when treated with the salt. F. Ullik found that the salt is soluble in cold water, but more easily soluble in hot water ; the soln. has an alkaline reaction.

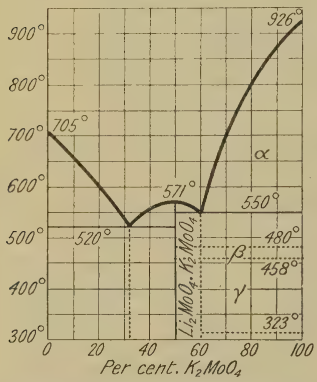


FIG. 21.—Equilibrium Curve of the System : K_2MoO_4–Li_2MoO_4.

A. Piccini [4] prepared normal **rubidium molybdate,** Rb_2MoO_4, by calcining rubidium molybdenum trioxytetrafluoride, $2RbF.MoO_3F_2.H_2O$; and F. Ephraim and H. Herschfinkel obtained the salt by evaporating a soln. of molybdenum trioxide in rubidium hydroxide, and washing the deliquescent mass with alcohol. J. W. Retgers made a few observations on the crystals of **cæsium molybdate,** Cs_2MoO_4.

No **cuprous molybdates** have yet been prepared ; and normal **copper molybdate,** $CuMoO_4$, is not known. H. Debray [5] obtained, possibly, the normal molybdate by roasting cupric sulphomolybdate at a low temp. G. Tammann noted that the reaction between cupric oxide and molybdenum trioxide begins about 615°, and the heat of formation of $CuMoO_4$ is 9·2 Cals. per mol ; J. J. Berzelius observed that a yellowish-green precipitate is produced by potassium molybdate in soln. of copper salts. The precipitate is sparingly soluble in water, and is decomposed by acids and alkali-lye. H. Struve prepared **copper oxymolybdate,** $CuO.3CuMoO_4.5H_2O$, by precipitation from a boiling soln. of copper sulphate by a conc. soln. of ammonium 2 : 5 : 3-molybdate. The green, amorphous powder loses 3 mols. of water at 100°, and the remainder at a higher temp. The dehydrated salt gradually recovers its combined water when in contact with water. According to G. Jörgensen, if sodium molybdate be treated with an excess of a soln. of copper sulphate, and the light green precipitate be dissolved in aq. ammonia, and the soln. treated with alcohol, dark blue needles of **copper tetramminomolybdate,** $[Cu(NH_3)_4]MoO_4$, are formed. The crystals readily lose ammonia, and become dark green. S. H. C. Briggs prepared **copper diamminomolybdate,** $[Cu(NH_3)_2]MoO_4.H_2O$, by mixing a soln. of 24 grms. of pentahydrated copper sulphate in 30 c.c. of water, 13 grms. of ammonium paramolybdate in 15 c.c. of water, and 40 c.c. of conc. aq. ammonia, making all up to 350 c.c., and exposing it to air. The deep blue prisms lose ammonia at ordinary temp.; and they are soluble in warm aq. ammonia. The salt may be recrystallized by allowing the warm soln. in aq. ammonia to cool, or by exposing a more dil. ammoniacal soln. to air. H. Struve obtained **ammonium copper molybdate,** $(NH_4)_2O.CuO.5MoO_3.9H_2O$, from the mother-liquor of the oxymolybdate; and by the action of a cold soln. of copper sulphate on an excess of ammonium 2 : 5 : 3 molybdate. The pale blue, microscopic, rhombic crystals lose 4 mols. of water at 100°; more at a higher temp., and finally water and ammonia are given off. The yellow mass melts at a red-heat. It is sparingly soluble in cold water, and soluble in boiling water without decomposition. Blue crystals of **ammonium copper diamminomolybdate,** $(NH_4)_2Cu(MoO_4)_2.2NH_3$, were obtained by S. H. C. Briggs by exposing to air in an open dish a mixture of 50 grms. of ammonium molybdate in 60 c.c. of water, 20 grms. of ordinary copper sulphate in 50 c.c. of water, and 70 c.c. of conc. aq. ammonia, all made up to 210 c.c.

According to F. Wöhler and F. Rautenberg,[6] if normal silver molybdate be treated with hydrogen at ordinary temp., it is partially converted into **silver submolybdate,** $Ag_4O.2MoO_3$. It was also prepared by passing hydrogen into a soln. of silver molybdate in conc., aq. ammonia. The reduction begins at ordinary temp. as the liquid turns brown; the action is complete at 90°. The black powder consists of octahedral crystals belonging to the cubic system. The salt dissolves in nitric acid giving off nitric oxide; with potash-lye, molybdenum trioxide is dissolved, and silver suboxide is left as a black powder. W. Muthmann said that the alleged silver submolybdate is nothing more than a mixture of silver and the normal molybdate. C. W. Scheele, J. B. Richter, and L. F. Svanberg and H. Struve prepared **silver molybdate,** Ag_2MoO_4, as a white or yellowish-white, amorphous precipitate, by adding a silver salt to a soln. of a molybdate. E. F. Smith and R. H. Bradbury obtained it in a similar way. H. Debray obtained the salt in cubic crystals by allowing an ammoniacal soln. of ammonium molybdate and silver nitrate to evaporate spontaneously. W. Muthmann obtained the crystals in a similar way. R. W. G. Wyckoff studied the X-radiogram of the crystals, and showed that the structure is like that of the spinels or of magnetite. The length of the side of the unit cube, containing 8 mols., is 9·26 A. P. P. Ewald studied this subject. Silver molybdate is coloured when heated, and it readily melts to a yellow liquid. It forms a colloidal soln. with water, particularly when freshly precipitated; according to H. Rose, it readily dissolves in nitric acid; and, according to E. F. Smith and R. H. Bradbury, it dissolves in a soln. of potassium cyanide, or of sodium hydroxide. J. Krutwig observed that the fused salt is not attacked by chlorine; and O. Widman, that if the ammoniacal soln. is evaporated in an atm. of ammonia, or if the solid salt is treated with ammonia, **silver diamminomolybdate,** $[Ag(NH_3)_2]_2MoO_4$, is formed, in the latter case, as a white powder, and, in the former case, crystals which are probably isomorphous with the corresponding tungstate. The salt loses all its ammonia at 65°. P. Ray and J. Dasgupta prepared a complex with hexamethylenetetramine.

According to J. B. Richter,[7] when potassium molybdate is added to a soln.

of auric chloride, orpiment-yellow **gold molybdate** is precipitated. It is soluble in hydrochloric or nitric acid, and sparingly soluble in water.

W. H. Melville[8] described a greenish mineral which he obtained from the Seven Devils mining district, Idaho. It was named **powellite**—after J. W. Powell. It approximates in composition to normal **calcium molybdate,** $CaMoO_4$, associated with some calcium tungstate. F. Ullik obtained a white precipitate of calcium molybdate by adding calcium chloride to a soln. of neutral sodium molybdate. The precipitate does not form in cold, dil. soln., nor in the presence of acetic acid. The salt was obtained by E. F. Smith and R. H. Bradbury in a similar way. A. Kissock obtained it by treating roasted molybdenite with slaked lime; and H. C. Maber, by heating roasted molybdenite with calcium carbonate at 600°. F. de Carli observed that the reaction between calcium oxide and molybdenum trioxide begins at 650°. D. Balareff, W. Jander, and G. Tammann also studied this reaction. G. Tammann found the reaction between molybdenum trioxide and calcium oxide begins at about 425°; and with calcium carbonate above 600°. W. Jander studied the dynamics of the heterogeneous reaction $CaCO_3+MoO_3=CaMoO_4+CO_2$, between 487° and 550°, and examined the influence of the grain size of the component particles. H. Schultze, and L. Michel obtained crystals by melting a mixture of sodium molybdate, calcium chloride, and sodium chloride (1 : 3 : 2), and H. Traube obtained crystals as a sublimate when the molybdate is heated with a mixture of sodium and potassium chlorides to a high temp. According to T. H. Hiortdahl, the crystals are tetragonal bipyramids with the axial ratio $a:c=1:1\cdot5457$; and the sp. gr. is 4·35. From the X-radiograms, F. Zambonini and R. G. Levi gave for the dimensions of the unit cell $a=3\cdot67$ A., and $c=5\cdot69$ A., and they discussed the isomorphism of the molybdates of lead and the alkaline earth metals. E. Herlinger studied the structure of the crystals of the alkaline earth molybdates. A. Kissock discussed the use of calcium molybdate in steel making. Crystals of powellite were found by W. H. Melville to be tetragonal with the axial ratio $a:c=1:1\cdot5445$. F. Zambonini gave 1 : 5513—*vide infra,* the rare earth molybdates. W. Jander discussed the lattice-structure. L. Vegard and A. Refsum found that the X-radiogram of powellite corresponded with a space-lattice of the rutile type with $a_0=7\cdot4$ A., $c_0=11\cdot44$ A., and $a:c=1:1\cdot546$. The radius of the oxygen atom=1·12 A., that of the calcium atom, 1·03 A., and that of the positive ion, 1·12 A. The elementary cell has 8 mols. The sp. gr. is 4·526, and the hardness 3·5. F. Zambonini and R. G. Levi gave 4·28 for the sp. gr. P. P. Pilipenko gave 4·22 for the sp. gr. of some crystals from western Altai, and 3·5 to 4·0 for the hardness. F. Westphal studied the mixed crystals of calcium and ammonium molybdates. W. Jander studied the diffusion of the molybdate and tungstate. D. Balareff and N. Lukova found that calcium molybdate lowers the dissociation press. of calcium carbonate. E. Cane gave 0·166 for the sp. ht. G. Tammann gave for the heat of formation of $CaMoO_4$, 26·5 Cals. per mol. E. S. Larsen gave for the refractive indices of powellite, $Ca(Mo,W)O_4$, $\epsilon=1\cdot978$, and $\omega=1\cdot968$, or $\epsilon-\omega=0\cdot01$ for the D-line. F. Zambonini gave for $\lambda=667$, $\epsilon=1\cdot962$, $\omega=1\cdot959$, and $\epsilon-\omega=0\cdot008$; for $\lambda=570$, $\epsilon=1\cdot984$, $\omega=1\cdot974$, and $\epsilon-\omega=0\cdot010$; and for $\lambda=583$, $\epsilon=1\cdot993$, $\omega=1\cdot982$, and $\epsilon-\omega=0\cdot011$. H. Schultze obtained crystals of **strontium molybdate,** $SrMoO_4$, by fusing a mixture of sodium molybdate, strontium chloride, and sodium chloride (1 : 2 : 2). G. Tammann said that the reaction between molybdenum trioxide and strontium carbonate begins at about 700°. The tetragonal pyramids were found by T. H. Hiortdahl to have the axial ratio $a:c=1:1\cdot5738$. F. Zambonini and R. G. Levi gave for the dimensions of the unit cell $a=3\cdot79$ A., and $c=5\cdot97$ A., and they studied the isomorphism of the molybdates of lead and the alkaline earth metals. E. K. Brock gave $a=5\cdot380$ A., $c=11\cdot97$ A., $a:c=1:2\cdot226$; and the calculated density 4·718. W. Jander discussed the lattice-structure; and the diffusion of the molybdate and tungstate. F. W. Clarke gave 4·1554 for the sp. gr. at 20·5°, and 4·1348 at 21°; F. Zambonini and R. G. Levi gave 4·73; and V. G. Aranda, 4·6624. E. F. Smith and R. H. Bradbury found that 100 parts of water dissolve 0·0104 part of salt at 17°. F. Westphal studied the mixed crystals of strontium and ammonium molybdates. F. de Carli observed that the reaction between molybdenum trioxide and barium oxide begins at 290°. D. Balareff, J. H. Hevdall, and N. von Zweigbergh also studied this reaction. W. Jander represented the temp. coeff., k, of the reaction with calcium carbonate and molybdenum trioxide by $k=ce^{-43000/T}$, and the thermal value of the reaction by 21·5 Cals. E. Cane gave 0·149 for the sp. ht. L. F. Svanberg and H. Struve obtained **barium molybdate,** $BaMoO_4$, by adding barium chloride to a soln. of ammonium molybdate or paramolybdate in an excess of ammonia, and washing the product with cold water. H. Schultze obtained crystals by melting a mixture of sodium molybdate, barium chloride, and sodium chloride (1 : 3 : 2). G. Tammann said that the reaction between molybdenum trioxide and baryta begins at about 290° ; and with barium carbonate at 660°—W. Jander studied this reaction. The acicular crystals are tetragonal pyramids which, according to T. H. Hiortdahl, have the axial ratio $a : c=1 : 1·6232$. F. Zambonini and R. G. Levi gave for the dimensions of unit cell $a=3·96$ A., and $c=6·53$ A., and they studied the isomorphism of the molybdates of lead and the alkaline earth metals. L. Vegard and A. Refsum gave for the elementary cell, $a_0=7·858$ A., $c_0=12·755$ A., and $a : c=1 : 1·623$; the radius of the oxygen atom is 1·24 A. ; of the barium atom, 1·02 A. ; and of the positive ion, 1·21 A. W. Jander discussed the lattice-structure, and the diffusion of the molybdate and tungstate. F. W. Clarke gave 4·659 for the sp. gr. at 17·5°, and 4·648 at 19·5° ; F. Zambonini and R. G. Levi gave 4·84 ; and V. G. Aranda, 4·9747. E. Cane gave 0·113 for the sp. ht. G. Tammann gave 60·1 Cals. for the heat of formation of $BaMoO_4$. According to E. F. Smith and R. H. Bradbury, 100 parts of water at 23° dissolve 0·0058 part of the salt ; the solubility is augmented by the presence of ammonium nitrate. The salt is soluble in acids, and, when ammonia is added to the soln., C. J. Heine said that a basic salt is precipitated, but L. F. Svanberg and H. Struve found that the normal salt is so formed. L. Kahlenberg and W. J. Trautmann observed no reaction occurs when a mixture of barium molybdate and silicon is heated by the bunsen burner, but a slight reaction occurs in the electric arc.

A. Atterberg[9] found that if equimolar parts of beryllium hydroxide and molybdenum trioxide are boiled with water, for a long time, a voluminous precipitate consisting of interlaced needles of a basic salt—**beryllium oxymolybdate,** $BeO.BeMoO_3.3H_2O$—is formed. It loses a mol. of water at 100°. G. Tammann found that the reaction between molybdenum trioxide and beryllium oxide begins at about 400° ; and the heat of formation of **beryllium molybdate,** $BeMoO_4$, is 4·0 Cals. per mol. According to A. Rosenheim and P. Woge, the *dihydrate*, $BeMoO_4.2H_2O$, is obtained by boiling the theoretical quantity of hydrated beryllium oxide with molybdenum trioxide suspended in water. The oily liquid forms an aggregate of slender needles if kept for some time in the acid.

A. and E. Scacchi[10] obtained from an old rock embedded in Vesuvian lava, white needles consisting of tetragonal crystals of a mineral which they named **belonosite**—from βελόνη, a needle—and which was considered to be **magnesium molybdate,** $MgMoO_4$. F. de Carli observed no reaction between molybdenum trioxide and magnesia up to 1200°, but G. Tammann said that the reaction begins at about 425°, and the heat of formation of $MgMoO_4$ is 7·3 Cals. per mol. F. Ullik, M. Delafontaine, and H. Struve prepared the anhydrous salt by calcining, at not too high a temp., the hydrated salt obtained by boiling magnesia in water holding molybdenum trioxide in suspension, and evaporating the filtered liquid. G. N. Wyrouboff found that rhombic crystals of the *heptahydrate* are formed at about 30° ; and F. Westphal also obtained rhombic crystals of the heptahydrate which are isomorphous with heptahydrated magnesium sulphate ; and which lost five mols. of water at 80°. G. N. Wyrouboff observed that soln. at a temp. exceeding 30° yield the triclinic *pentahydrate.* The transition temp. has not been determined exactly. F. Westphal prepared the salt by mixing soln. of magnesium chloride and of sodium molybdate. A. and E. Scacchi described **belonosite** as a white mineral consisting of minute, acicular crystals of $MgMoO_4$, which are tetragonal with the axial ratio $a : c=1 : 0·66054$. W. Jander discussed the lattice-structure, and the diffusion of the molybdate and tungstate. The triclinic pentahydrate furnishes prismatic crystals isomorphous with the pentahydrates of copper sulphate, and magnesium sulphate and chromate. The axial ratios were found by G. N. Wyrouboff to be $a : b : c=0·5264 : 1 : 0·5732$, and $\alpha=80° 43'$, $\beta=98° 52'$, and $\gamma=107° 28'$. The sp. gr. is 2·208. Three mols. of water are lost at 120°, and the remainder at a red-heat without decomposing the molybdate. M. Delafontaine said that the salt is readily soluble in hot and cold water. F. Rodolico prepared a complex with hexamethylenetetramine, $MgMoO_4.X.10H_2O$.

F. Ullik prepared **ammonium magnesium molybdate,** $(NH_4)_2MoO_4.MgMoO_4.2H_2O$, by evaporating an equimolar soln. of the two salts spontaneously, or on a water-bath; and also by adding ammonia to a soln. of magnesium molybdate, and crystallizing the filtrate. V. von Zepharovich gave $a : b : c=0·851 : 1 : 0·436$ for the axial ratios of the probably rhombic, bipyramidal crystals. The (010)-cleavage is well defined; and the (100)-cleavage less so. When the salt is heated F. Ullik observed that water and ammonia are evolved; the salt is freely soluble in water. F. Ullik studied the isomorphism of the molybdates, sulphates, and chromates. If mixed soln. of magnesium molybdate and ammonium sulphate, or of magnesium sulphate and ammonium molybdate, are allowed to crystallize, isomorphous mixtures of the molybdato- and sulphato-complex salts are formed in which the ratio $MoO_3 : SO_3$ depends on the proportions of the radicles in the soln. With dil. soln. evaporated spontaneously, the salt which separates has a small proportion of molybdate, while a large proportion of molybdate is present if hot, sat. soln. are mixed. The crystals have the composition $(NH_4)_2Mg(MoO_4)_{2-n}(SO_4)_n.6H_2O$, and are monoclinic like the complex sulphates $(NH_4)_2Mg(SO_4)_2.6H_2O$. The mixed crystals were also studied by F. Westphal. F. Ullik also found that mixed soln. of magnesium molybdate and ammonium chromate also furnish isomorphous mixtures of the two salts. F. Ullik prepared crystals of **potassium magnesium molybdate,** $K_2Mg(MoO_4)_2.2H_2O$, by the method employed for the ammonium salt. The salt loses water and melts at a dull red-heat; and it is slowly dissolved by cold water, and quickly by hot water. F. Ullik found that mixed soln. of magnesium molybdate and potassium sulphate furnish crystals of the separate components, but with mixed soln. of molybdates and chromates, isomorphous mixtures of $K_2Mg(MoO_4)_{n-2}(CrO_4)_n.2H_2O$ are formed.

F. de Carli[11] observed that a reaction between molybdenum trioxide and zinc oxide begins at 270°. R. Brandes obtained a precipitate by adding ammonium molybdate to a soln. of a zinc salt, and the yellowish-white powder approximated in composition to **zinc molybdate,** $ZnMoO_4$. W. Jander discussed the lattice-structure; and the diffusion of the molybdate and tungstate. There is an interchange of acid radicle in the reactions $CdO+ZnMoO_4=CdMoO_4+ZnO$; $MgO+ZnMoO_4=MgMoO_4+ZnO$; $MgO+CdMoO_4=CdO+MgMoO_4$; and $MgO+MnMoO_4=MgMoO_4+MnO$. R. Brandes said that zinc molybdate is sparingly soluble in water; and readily soluble in acids. A. Coloriano, and E. Manassewitsch showed that the product obtained by precipitation is really the *monohydrate,* which does not lose all its water at 100°. H. Schultze obtained minute needles of the anhydrous salt by fusing together a mixture of sodium molybdate, zinc chloride, and sodium chloride (2 : 3 : 6), and washing the cold mass with water. The salt is fusible. F. L. Sonnenschein prepared crystals of **zinc diamminomolybdate,** $Zn(NH_3)_2MoO_4.H_2O$, by evaporating the filtered liquid obtained by digesting zinc oxide with an ammoniacal soln. of ammonium molybdate.

F. de Carli observed that a reaction between cadmium oxide and molybdenum trioxide begins at about 500°. R. Brandes obtained what appears to have been **cadmium molybdate,** $CdMoO_4$, by precipitation as in the case of the analogous zinc salt; and H. Schultze obtained yellow plates of the anhydrous salt by melting together sodium molybdate, cadmium chloride, and sodium chloride (2 : 7 : 6).

The salt was also obtained by the precipitation process by E. F. Smith and R. H. Bradbury, A. Junius, and E. Manassewitsch. E. K. Broch calculated from the X-radiograms, the space-lattice with a=5·138 A., c=11·17 A., $a:c$=1 : 2·174; and the density, 5·347. W. Jander studied the diffusion of the molybdate and tungstate. The salt is sparingly soluble in water, freely soluble in acids, aq. ammonia, and soln. of potassium cyanide. S. H. C. Briggs obtained colourless crystals of **ammonium cadmium diamminomolybdate,** $(NH_4)_2CdMoO_4(NH_3)_2$, from an ammoniacal soln. of cadmium sulphate and ammonium molybdate as in the case of the corresponding copper salt. The salt is partially decomposed when heated.

H. Struve[12] treated potassium trimolybdate with mercurous nitrate and washed the resulting dimolybdate with water until it formed golden-yellow needles of **mercurous molybdate,** Hg_2MoO_4; the change occurs more rapidly if the precipitate and mother-liquor be boiled for a long time. C. W. Scheele said that mercuric chloride does not give a precipitate with molybdic acid; but J. J. Berzelius, and C. Hatchett observed that with potassium molybdate a yellow precipitate of **mercuric molybdate** is produced which is decomposed by nitric acid; 100 parts of water dissolve 0·167 to 0·200 part of the salt. According to C. H. Hirzel, finely-divided mercuric oxide is rapidly attacked by a conc. soln. of acid ammonium molybdate, and after boiling for some hours, a yellowish-white, granular precipitate is formed—no ammonia is given off, and no mercury passes into soln. The composition of the precipitate was not determined.

H. Struve,[13] and J. G. Gentele were unable to prepare normal **aluminium molybdate;** nor has **gallium molybdate** been obtained. The aluminium molybdates are discussed below. G. Tammann observed no reaction between alumina and molybdenum trioxide below 700°. C. Renz prepared **indium molybdate,** $In_2(MoO_4)_3.2H_2O$, by the action of ammonium molybdate on a soln. of an indium salt; the white precipitate dries to a horn-like mass; it is insoluble in water, and soluble in hydrochloric acid. M. Delafontaine prepared **thallous molybdate,** Tl_2MoO_4, by boiling thallous oxide or carbonate with water and molybdic acid; P. S. Oettinger, and H. Fleming, by double decomposition of a soln. of a thallous salt with a normal molybdate; and F. Mauro, by roasting thallous molybdenum dioxytetrafluoride at a red-heat in air. It separates from a hot aq. soln. as a crystalline powder, or in tabular crystals. It melts at a red-heat to form a yellow liquid, and partial volatilization occurs. The salt is soluble in alkali-lye; and it dissolves in hydrofluoric acid to form a soln. which when evaporated over sulphuric acid, furnishes crystals of thallous molybdenum dioxytetrafluoride.

P. Didier[14] prepared **cerous molybdate,** $Ce_2(MoO_4)_3$, by fusing a mixture of anhydrous cerous chloride and sodium molybdate; and A. Cossa observed that a soln. of a cerous salt gives a gelatinous white precipitate when treated with sodium molybdate; the precipitate becomes yellow and crystalline. H. Traube obtained crystals of cerium molybdate as a sublimate by the method indicated in connection with calcium molybdate. G. Tammann said that the reaction between cerium dioxide, and molybdenum trioxide begins at about 650°, and $Ce_2(MoO_4)_3$ is formed. The sp. gr. of the salt, which has been fused in an inert atm., is 4·56. F. Zambonini and R. G. Levi gave 5·03 for the sp. gr. According to A. Cossa, the crystals are tetragonal and are isomorphous with wulfenite; they have the axial ratios $a:c$=1 : 1·558. F. Zambonini found that the air-dried precipitate is the trihydrate, $Ce_2(MoO_4)_3.3H_2O$. He obtained crystals of the anhydrous salt by fusing the precipitated salt in an electric furnace, and slowly cooling the mass; he gave for the axial ratio of the rhombic crystals $a:b:c$=0·6631 : 1 : 0·8212. The sp. gr. of the rhombic crystals is 4·83 at 20°/20°; the mol. vol., 167·4; and the m.p., 930°. F. Zambonini also obtained a tetragonal form by heating the salt dried at 180° to 1050° and slowly cooling it from 900°—the axial ratio was $a:c$=1 : 1·5624; F. Zambonini and R. G. Levi gave for the dimensions of unit cell a=3·77 A., and c=5·81 A. F. Zambonini gave 5·03 for the sp. gr. at 18°/18°; and for the mol. vol., 151·2.

E. Cane gave 0·126 for the sp. ht. The indices of refraction and dispersions for $\lambda=667$, 570, and 533 are respectively $\omega=2·0185$, $\epsilon=2·0067$, and $\omega-\epsilon=0·0118$; $\omega=2·0403$, $\epsilon=2·0277$, and $\omega-\epsilon=0·0126$; and $\omega=2·0512$, $\epsilon=2·0375$, and $\omega-\epsilon=0·0137$. S. Prakash and N. R. Dhar obtained the hydrogel of ceric molybdate. The crystal plates obtained in preparing the tetragonal form appear to be **cerous ceric** or **cerosic molybdate,** $Ce_2(MoO_4)_3.2Ce(MoO_4)_2$. E. Herlinger studied the crystal structure. F. Zambonini prepared isomorphous mixtures of tetragonal crystals of calcium and cerous molybdates containing up to 59·1 per cent. of cerous molybdate. The axial ratios $a:c$ of the tetragonal crystals with 0, 6·5, and 59·1 per cent. of cerous molybdate are, respectively, 1 : 1·5513, 1 : 1·5492, and 1 : 1·5510. Isomorphous mixtures of crystals of cerous and strontium molybdates with up to 39·7 per cent. of the cerium salt were prepared. The refractive indices for light of wave-length λ were:

	2·4 per cent. $Ce_2(MoO_4)_3$.			39·7 per cent. $Ce_2(MoO_4)_3$.		
λ	ϵ	ω	$\epsilon-\omega$	ϵ	ω	$\epsilon-\omega$
667 . .	1·9127	1·9088	0·0039	1·940	1·937	0·003

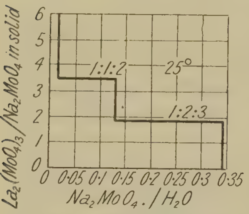

FIG. 22.—Equilibrium in the System: $La_2(MoO_4)_3$–Na_2MoO_4–H_2O.

F. T. Frerichs and E. F. Smith prepared **lanthanum trihydromolybdate,** $LaH_3(MoO_4)_3$, as a precipitate by adding ammonium molybdate to a lanthanum salt. F. R. M. Hitchcock obtained the normal **lanthanum molybdate,** $La_2(MoO_4)_3$, by adding sodium molybdate to a soln. of lanthanum chloride, and dehydrating the gelatinous precipitate. H. Traube obtained crystals as a sublimate by the method indicated for calcium molybdate. F. Zambonini fused the salt and by slow cooling obtained tetragonal, bipyramidal crystals with the axial ratio $a:c=1:1·5504$. F. Zambonini and R. G. Levi gave for the dimensions of the elementary cell, $a=3·78$ A. and $c=5·68$ A. F. Zambonini found that the optical character was negative. The sp. gr. is 4·77 at 16°/16°; the mol. vol., 158·9; and the m.p., 1181°. E. Cane gave 0·114 for the sp. ht. G. Carobbi's study of the ternary system: $La_2(MoO_4)_3$–Na_2MoO_4–H_2O at 25°, and the results, Fig. 22, show the existence of the two **sodium lanthanum molybdates:** $La_2(MoO_4)_3.Na_2MoO_4.2H_2O$, and $La_2(MoO_4)_3.2Na_2MoO_4.3H_2O$. F. Zambonini found that isomorphous mixtures were obtained with lead molybdate (*q.v.*), with up to 42 per cent. of calcium molybdate; with up to 62·5 per cent. of strontium molybdate; and with up to 86·9 per cent. of barium molybdate. F. T. Frerichs and E. F. Smith obtained **didymium trihydromolybdate,** $DiH_3(MoO_4)_3$ as in the case of the lanthanum salt. A. Cossa also prepared didymium molybdate, $Di_2(MoO_4)_3$. H. Traube obtained crystals as a sublimate by the method indicated for calcium molybdate in tetragonal crystals, which, according to F. Zambonini have the axial ratio $a:c=1:1·5489$. The sp. gr. is 4·96 at 16·5°/16·5°. The m.p. is 1125°, but it is not sharp. The double refraction is negative, and there are no optical anomalies. The index of refraction is 2·008 for the *B*-line; 2·012 for the *C*-line; 2·026 for the *D*-line; 2·039 for the *E*-line; and 2·054 for the *F*-line. Isomorphous mixtures were obtained with lead molybdate (*q.v.*), and with calcium molybdate. The crystals with about 61·2 per cent. of calcium molybdate have a feebly positive birefringence. The indices of refraction for light of wave-length λ are:

λ . .	667	599	570	533	475
ϵ . .	1·9869	1·9947	2·0020	2·0094	2·0212
ω . .	1·9902	1·0089	2·0068	2·0139	2·0258
$\epsilon-\omega$ . .	0·0033	0·0042	0·0048	0·0045	0·0046

F. R. M. Hitchcock prepared **neodymium molybdate,** $Nd_2(MoO_4)_3$; and F. Zambonini found that the air-dried substance has the composition $Nd_2(MoO_4)_3.4H_2O$. When heated with molten sodium chloride, violet crystals are formed. The axial ratio of the tetragonal crystals is $a:c=1:1·5480$. F. Zambonini and R. G. Levi gave for the dimensions of the elementary cell $a=3·74$ A., and $c=5·79$ A. F. Zambonini found that the birefringence is negative; the indices of refraction and dispersions for $\lambda=667$, 570, and 533 are respectively $\omega=2·0052$, $\epsilon=2·0038$, and $\omega-\epsilon=0·0014$; $\omega=2·0239$, $\epsilon=2·0218$, and $\omega-\epsilon=0·0021$; and $\omega=2·0313$, $\epsilon=2·0293$, and $\omega-\epsilon=0·0020$. The sp. gr. is 5·14 at 18°/18°; the mol. vol., 149·5; and the m.p., 1176°—*vide infra*, lead molybdate. F. R. M. Hitchcock prepared **praseodymium molybdate** by precipitation with praseodymium chloride and sodium molybdate soln. F. Zambonini found that when dried over sulphuric acid, the gelatinous precipitate has the composition $Pr_2(MoO_4)_3.3\frac{1}{2}H_2O$; and when heated with fused sodium chloride, the anhydrous salt furnishes tetragonal bipyramids with the axial ratio $a:c=1:1·5439$. F. Zambonini and R. G. Levi gave for the dimensions of the elementary cell, $a=3·76$ A., and $c=5·805$ A. F. Zambonini found that the sp. gr. is 4·84 at 16·5°/16·5°; the mol. vol. is 157·3; and the m.p., 1030°. The birefringence is negative; and the index of refraction $\epsilon=1·990$, 2·007, and 2·016 respectively for $\lambda=667$, 570, and 533. P. T. Cleve obtained **samarium molybdate,** $Sm_2(MoO_4)_3$, in violet, rhombic octahedra, by calcining a mixture of samarium oxalate, sodium chloride, and molybdenum trioxide. F. Zambonini and R. G. Levi found the dimensions of the unit cell to be $a=3·69$ A., and $c=5·81$ A., the axial ratio $a:c=1:1·5745$. The sp. gr. is 5·36. A. Cleve prepared **sodium samarium molybdate,** $SmNa(MoO_4)_2$, in pale red needles. The two salts can be separated by levigation in water. F. Zambonini prepared **yttrium molybdate,** $Y_2(MoO_4)_3.4H_2O$, by drying over calcium chloride the precipitate obtained by adding a soln. of sodium molybdate to one of yttrium nitrate. When melted, and slowly cooled, it furnishes greyish-white or yellow crystal plates which belong to the tetragonal system, and have the axial ratio $a:c=1:1·5422$; the (001)-cleavage is incomplete; the sp. gr. is 4·79 at 16°/16°; the mol. vol. is 137·4; the m.p. is 1347°; and the index of refraction, ϵ, for $\lambda=667$ is 2·013; for $\lambda=570$, 2·031; and for $\lambda=533$, 2·043. Isomorphous mixtures with lead molybdate (*q.v.*), and with calcium molybdate were prepared. E. Cane gave 0·159 for the sp. ht., F. Zambonini found that the crystals with 95·3 per cent. of the calcium salt had the respective indices of refraction and dispersions $\epsilon=1·986$, $\omega=1·978$, and $\epsilon-\omega=0·008$ for $\lambda=667$; $\epsilon=2·002$, $\omega=1·998$, and $\epsilon-\omega=0·004$ for $\lambda=570$; and $\epsilon=2·012$, $\omega=2·003$, and $\epsilon-\omega=0·009$ for $\lambda=533$. It was found that the presence of cerous molybdate favours the formation of isomorphous mixtures with higher proportions of calcium. Crystals containing 24·7 per cent. of yttrium molybdate, 21 per cent. of cerous molybdate and 44·3 per cent. of calcium molybdate had the axial ratio $a:c=1:1·5436$, a positive birefringence, and the indices of refraction for the *C*-, *D*-, and *E*-lines respectively $\epsilon=1·9939$, 2·0049, and 2·0208; $\omega=1·9905$, 2·0004, and 2·0163; and $\epsilon-\omega=0·0034$, 0·0045, and 0·0045. A. Cleve obtained **ytterbium oxymolybdate,** $Yb_2O_3.Yb_2O_2(MoO_4)$, as a green crystalline powder, by heating ytterbium oxide, molybdenum trioxide, and sodium chloride at a high temp.

The **silicon molybdates,** or **silicomolybdates,** were discussed in connection with the silicates—**6**. 40, 50. For the **titanium molybdates,** *vide infra.* O. Kulka[15] treated a cold, aq. soln. of ammonium paramolybdate with zirconium sulphate, and obtained a slimy precipitate which, when washed with hot water, approximated to **zirconium molybdate,** $Zr(MoO_4)_2.21H_2O$. It is insoluble in water, but soluble in hot, conc. hydrochloric acid. Zirconium hydroxide is insoluble in an aq. soln. of alkali molybdate. S. Prakash and N. R. Dhar obtained the hydrogel of zirconium molybdate. S. M. Tanatar and E. K. Kurowsky prepared **zirconium oxychloromolybdate,** $ZrCl_4.mZr_3(MoO_4)_2.nZrO_2$. J. J. Berzelius obtained **thorium molybdate** as a white precipitate by adding a soln. of an alkali molybdate to one of a thorium salt; and J. J. Chydenius, by mixing a feebly acid soln. of thorium tetrachloride with an ammoniacal soln. of ammonium molybdate. F. Zambonini obtained the anhydrous salt, $Th(MoO_4)_2$, by fusing partly-dehydrated thorium chloride with an excess of anhydrous sodium molybdate. The tetragonal crystals have the axial ratio $a : c = 1 : 0{\cdot}73565$; and the sp. gr. 4·92 at 7·5°/7·5°. They form isomorphous mixtures with those of cerous molybdate. S. Prakash and N. R. Dhar prepared the hydrogel of thorium molybdate.

The blue colour obtained by J. B. Richter[16] by mixing an alkali molybdate with stannous chloride, or by the action of tin and hydrochloric acid on molybdenum trioxide suspended in water was shown by J. J. Berzelius to be a mixture of stannic molybdate and a blue lower oxide of molybdenum. H. Schiff said that the blue pigment contains no tin, and, according to G. Denigès, it is produced by other reducing agents. J. P. Longstaff recommended the reaction as a test for tin. F. de Carli observed that a reaction between stannous oxide and molybdenum trioxide begins at 400°. J. J. Berzelius obtained **stannic molybdate,** as a grey powder insoluble in water, and soluble in hydrochloric acid with a blue or green coloration; and in potash-lye with a brown coloration. It is not decomposed by nitric acid. S. Prakash and N. R. Dhar dialyzed for 2 days a mixture of $1{\cdot}5M$-$SnCl_2$ with a 25 per cent. soln. of potassium molybdate. The clear soln. was mixed with an equal vol. of water. It set to a jelly in 5 hrs. The viscosities at 30° were:

Age .	0	3	5	10	20	30	40	60	80 min.
Viscosity	0·01272	0·01353	0·01471	0·01804	0·02300	0·03032	0·03447	0·04412	0·07505

I. Eques a Born[17] described a mineral *plumbum spatosum flavorubrum* from Annaberg, and it was also examined by N. J. von Jacquin, and F. X. Wulfen. J. B. L. Romé de l'Isle called it *plomb jaune;* A. G. Werner, *Gelbbleierz;* R. Kirwan, *yellow lead-spar* or *molybdenated lead ore;* F. S. Beudant, *melinose;* and W. Haidinger, **wulfenite**—after F. X. Wulfen. Analyses were reported by J. C. H. Heyer, M. H. Klaproth, C. Hatchett, F. Göbel, I. Domeyko, F. Jost, J. L. Smith, F. Reinitzer, C. L. Allen, C. Schmidt, C. F. Rammelsberg, G. Rose, J. F. W. Johnston, K. Schlier, V. von Zepharovich, A. Schrauf, H. Regnard, and F. Wöhler. The mineral approximates in composition to **lead molybdate,** $PbMoO_4$. The lead may be partly replaced by lime forming, according to I. Domeyko, and V. von Zepharovich, *calcium lead molybdate*, or else an isomorphous mixture. Specimens from Pribram were found by P. Groth to contain chromium—*chromowulfenite*—similarly, A. Schrauf, J. L. Smith, and G. Rose found chromium in specimens from Ruksberg, Phœnixville, etc.; and E. F. Smith, C. F. Rammelsberg, and F. Wöhler reported samples with vanadium; G. Carobbi, samples with rare earths; and H. Regnard, samples with arsenic. The mineral occurs in nature associated with other lead ores at Lackentyre, Scotland; Chalanches, and Beaujolais, France; Gorno, Italy; Sarrabus, and Gennamari, Sardinia; St. Luc, Switzerland; Bleiberg, Carinthia; Ruskitza, Austria; Rezbanya and Szaska, Hungary; Pribram, Czechoslovakia; Moldawa, Banat; Annaberg, Schneeberg, Johanngeorgenstadt, and Berggieshübel, Saxony; Badenweiler, Baden; Kirghiz Steppes, Siberia; Mindouli, French Congo; in Massachusetts, Arizona, New York, Pennsylvania, Nevada, New Mexico, and California, United States; Rio Chico, Colombia; Zacatecas, Mexico, etc. The mode of formation of wulfenite was discussed by E. Dittler, G. Bischof, A. Himmelbauer, M. Henglein, C. Schmidt, G. Cesaro, and A. W. Stelzner-Bergeat. J. F. L. Hausmann observed it as a furnace product.

F. de Carli observed that a reaction between molybdenum trioxide and lead oxide begins at 650°; W. Jander said 450°; and G. Tammann, and J. Guillissen, 460°. D. Balareff said that the maximum effect occurs at 700°. J. J. Berzelius prepared lead molybdate by mixing soln. of lead nitrate or acetate and ammonium molybdate; G. Wempe, and H. B. Weiser used acid ammonium molybdates; and L. F. Svanberg and H. Struve, T. M. Chatard, E. F. Smith and R. H. Bradbury, A. Junius, H. B. Weiser, F. M. Jäger and H. C. Germs used sodium molybdates. E. Dittler treated white-lead with a soln. of sodium hydroxide containing 6 per cent. of ammonium 5 : 12-molybdate for 90 days on a water-bath in an atm. of carbon dioxide, and washed out the carbonate with very dil. hydrochloric acid. N. S. Manross melted a mixture of sodium molybdate and lead chloride (1 : 6) in a closed crucible. F. Zambonini used a similar process. H. Traube obtained crystals as a sublimate by the method used for calcium molybdate. H. B. Weiser obtained **colloidal lead molybdate** by precipitation and washing with hot water. The colloid is peptized by the selective adsorption of molybdate ions. N. R. Dhar and S. Ghosh found that lead molybdate is peptized by ammonium molybdate. The salt was analyzed by J. J. Berzelius, L. F. Svanberg and H. Struve, N. S. Manross, E. Dittler, A. Junius, G. Wempe, and H. C. Germs, and the results agree with the formula $PbMoO_4$.

The precipitated salt is a white, or yellowish-white powder, it also appears in yellowish-white, six-sided plates, octahedra, and pyramids. The colour of wulfenite may be wax-yellow passing into orange-yellow, orange, siskin-green or olive-green, yellowish-grey; greyish-white, or almost white, brown, or bright red. J. L. Smith said the red colour is due to vanadates; G. Rose, to chromium; P. Groth, to organic matter; and E. Dittler, to colloidal molybdic oxide. M. Bamberger and R. Grengg said that the colour of the natural crystals is white at —190°. E. Dittler observed no change in colour occurs when red wulfenite is heated to 700° in a current of air; and if the finest powder of brownish-yellow wulfenite is heated to 80°, it becomes lemon-yellow. A. Coloriano converted the amorphous powder into crystals by a prolonged digestion with water; and A. Cossa said that the fused salt furnishes microscopic, doubly-refracting pyramids. Wulfenite may occur in fine or coarse granular masses, in compact masses, and in square plates sometimes extremely thin with a vicinal pyramid replacing the basal plane. The crystals are less frequently octahedral or prismatic. The prismatic faces show the characteristic hemihedrism. H. Dauber said that the crystals of wulfenite are tetragonal pyramids with the axial ratios $a : c$ =1 : 1·577; T. H. Hiortdahl gave 1 : 1·5771; L. Bach, 1 : 1·5774; E. Flint, 1 : 1·5746; and V. von Zepharovich gave 1 : 1·5744 for a calcareous variety. The (111)-cleavage is incomplete; and the (001)- and (113)-cleavages are indistinct. The crystals were examined by A. Damour and A. des Cloizeaux, V. von Zepharovich, E. Hunek, F. N. Guild and F. S. Wartmann, L. J. Spencer, P. Groth, S. Koch, E. Flint, P. Comucci, A. Maier, J. Couyat, N. von Kokscharoff, E. Artini, L. Fletcher, A. Pelloux, A. Lacroix, E. Repossi, A. Drain, O. G. Padurova, and A. Sigmund. The percussion figures were examined by M. Kuhara; and the corrosion figures, by A. P. Honess; R. G. Dickinson inferred from the X-radiograms that the space-lattice is face-centred with the atoms so located as to form a diamond arrangement, Fig. 23—the sp. gr. is 6·82, and the edge of unit cube with 8 mols. is a=22·8 A. F. Zambonini and R. G. Levi found for the dimensions of the elementary cell, a=3·80 A., and c=6·00 A., and they studied the isomorphism of the molybdates of lead and the alkaline earth metals. F. M. Jäger and H. Haga attributed the high symmetry shown by the X-radiograms of wulfenite to twinning. L. Vegard and A. Refsum gave a_0=7·656 A., c_0=12·079 A., and $a : c$=1 : 1·578; the radius of the oxygen atom is 1·18 A., of the lead atom, 1·03 A., and of the positive ion, 1·17 A. M. L. Huggins discussed the structure of the crystals. D. Vorländer and H. Hempel observed no transformation into an isotropic form with rise of temp. The sp. gr. of wulfenite ranges from 6·03 to 7·01. C. L. Allen gave 6·7 at 17·5°; and J. L. Smith, 6·95; A. Cossa gave for the artificial crystals 6·62; F. Zambonini and R. G. Levi, 6·95; V. G. Aranda, 6·6933; and N. S. Manross, 6·811.

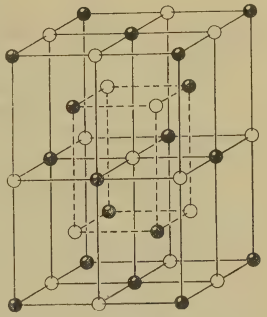

Fig. 23.—Arrangement of Atoms in Lead Molybdate: ● represents lead atom, and ○ a molybdenum atom.

J. J. Saslawsky found that the sp. gr. of wulfenite corresponds with a contraction of 0·60 to 0·68 during its formation from its elements. The hardness of wulfenite is 2·75 to 3·0. E. Jannetaz found the ratio of the heat conductivities of the crystals, α/γ, to be unity. H. Kopp gave for the mol. sp. ht. of wulfenite from Bleiberg, 0·0287 between 19° and 50°. E. Dittler observed that the m.p. in an atm. of carbon dioxide is 1070° and the optical properties of the cold mass are the same as before fusion. F. M. Jäger and H. C. Germs said that wulfenite from Arizona melts at 1064°, from La Cruces, Mexico, at 1060°; and artificial lead molybdate at 1065°. F. Zambonini gave 1065° for m.p.; the latent heat is said to be small, and the undercooling not more than 2°. E. Cane gave 0·098 for the sp. ht. G. Tammann gave 33·1 Cals. for the heat of formation of $PbMoO_4$. L. J. Spencer gave for the indices of refraction, $\omega=2{\cdot}41$, and $\epsilon=2{\cdot}32$ for yellow light. W. Schneider observed no piezoelectric effect. T. W. Case observed no electrical conductivity with wulfenite in light or in darkness. E. E. Fairbanks gave 11·7 for the dielectric constant (water 81). They found that the thermal diagram of the system: PbO–$PbMoO_4$, Fig. 24, shows only two compounds, the normal molybdate melting at 1065°; and the basic salt or **lead oxymolybdate,** $Pb_2O(MoO_4)$, melting at 951°. There are two eutectics: one at 762° corresponding with 87·5 molar per cent. PbO, and the other at 933° corresponding with 40 molar per cent. PbO. In the system: $PbSO_4$–$PbMoO_4$, Fig. 25, solid soln. are formed containing up to 6 molar per cent. of sulphate or 2 molar per cent. of molybdate. There is a eutectic at 962° and 57 molar per cent. PbO; and a transition point in the solid soln. at 879°. The thermal diagram of the system: $PbCrO_4$–$PbMoO_4$, Fig. 26, is largely hypothetical. The composition of the limiting solid soln. on the molybdate side is 48 molar per cent. $PbCrO_4$ at 830°, the eutectic temp.; and transitions occur at 799° for the γ- to β-chromate, and at 697° for the β to α-chromate solid soln. H. Schultze also obtained tetragonal isomorphous mixtures with up to 34 per cent. of lead chromate, and monoclinic mixed crystals with up to 16 per cent. The mineral *achrematite*, or *lead oxymolybdatochloroarsenate*, $3\{3Pb_3(AsO_4)_2.PbCl_2\}.4Pb_2MoO_5$, was discussed in connection with the arsenates.

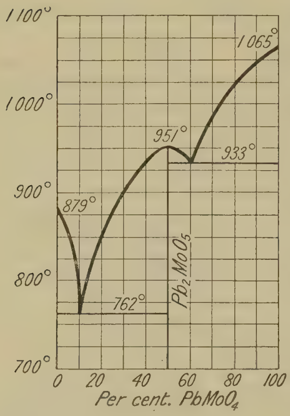

Fig. 24.—Freezing-point Curve in System: $PbMoO_4$–PbO.

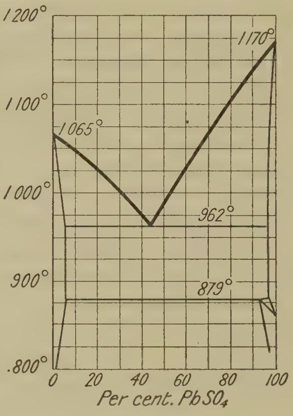

Fig. 25.—Freezing-point Curve in System: $PbMoO_4$–$PbSO_4$.

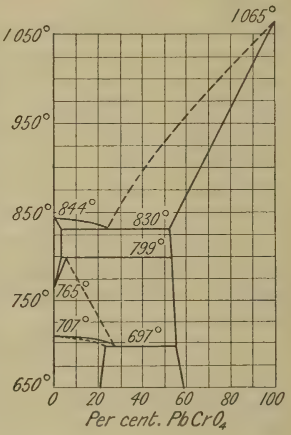

Fig. 26.—Freezing-point Curve in System: $PbMoO_4$–$PbCrO_4$.

P. Ites gave for the extinction coeff. of wulfenite for the *C*-, *D*-, and *E*-rays, respectively, 0·0486, 0·0625, and 0·455; and the indices of refraction $\omega=2{\cdot}4053$, and $\epsilon=2{\cdot}283$. According to A. des Cloizeaux, the optical character of wulfenite is negative; and the indices of refraction are $\omega=2{\cdot}402$, and $\epsilon=2{\cdot}304$ for red light.

H. C. Sorby found the mean refractive index to be 2·370, and the refractory power 0·682. A. Pochettino studied the cathodic luminescence; E. Dittler found that ultra-violet light makes the colour of chromiferous wulfenite darker; and C. Doelter observed that no change in colour occurs with radium rays. L. Francesconi and co-workers found that wulfenite from Sardinia is radioactive. R. Pohl found that when exposed to light, wulfenite becomes electrically conducting.

E. Dittler found that water at 100° very slowly dissolves colloidal molybdic acid from wulfenite—in 120 hrs. in an extraction apparatus about 5 per cent. was dissolved—no lead passed into soln. J. J. Berzelius said that alkali-lye dissolves wulfenite, but E. Dittler added that 0·1N-KOH has no action, but with a conc. soln. of the alkali, hexagonal crystals of *potassium lead molybdate* are formed. C. Bärwald obtained a complex $14NH_3.18MoO_3.3H_2O_2.18H_2O$, by the action of ammonia and hydrogen dioxide on lead molybdate. As indicated above, *calcium lead molybdate* is represented by the isomorphous mixtures in some specimens of wulfenite. J. J. Berzelius observed that conc. hydrochloric acid dissolves wulfenite, forming a soln. of lead chloride. E. Dittler, and W. Meyerhoffer said that an excess of fused sodium chloride does not convert wulfenite into sodium molybdate and lead chloride; and E. Dittler observed no action by a soln. of sodium chloride at 100°. The solubility of lead molybdate, S grms. per 100 c.c., in perchloric acid at 25°, was found by H. H. Willard and J. L. Kassner to be:

$HClO_4$	0·1M-	0·50M-	1·0M-	2·0M-	3·0M-
S.	0·0016	0·0136	0·0373	0·1176	0·2436

The effect of the presence of sodium or lead perchlorate is to depress the solubility. E. Dittler found that hydrogen sulphide colours wulfenite brown in a few minutes; and in about 12 hrs. the powdered mineral suspended in water is completely converted by hydrogen sulphide into molybdenum and lead sulphides; A. Terreil found that a boiling 10 per cent. aq. soln. of sodium sulphide decomposes wulfenite forming a liquid containing thiosulphate and molybdenum. E. F. Smith noted that heated sulphur monochloride dissolves wulfenite. J. J. Berzelius said that wulfenite is decomposed by sulphuric acid; and that treatment with warm nitric acid results in the separation of yellowish-white molybdenum trioxide. H. B. Weiser found that a hot aq. soln. of ammonium nitrate has no solvent action. H. H. Willard and J. L. Kassner found that the solubility of lead molybdate in 0·10M-, 0·50M-, and 1·0M-HNO_3 at 25° is 0·0020, 0·0244, and 0·1086 grm. per 100 c.c. respectively; the effect of lead or sodium nitrate is to depress the solubility. According to E. Dittler, water containing carbon dioxide has very little action in the cold, but at 100°, the mineral is decomposed and 3·66 per cent. passes into soln. A soln. of sodium carbonate, heated for 6 days on a water-bath, decomposes wulfenite, forming $Pb_3(OH)_2(CO_3)_2$, and some lead and molybdenum pass into soln. H. B. Weiser said that acetic acid does not dissolve freshly-precipitated lead molybdate, but soln. of ammonium or sodium acetate dissolve a little. H. C. Bolton observed that a boiling conc. soln. of citric acid decomposes wulfenite. L. Kahlenberg and W. J. Trautmann observed no reaction occurs when a mixture of silicon and lead molybdate is heated by a bunsen burner, but a slight reaction occurs in the electric arc. F. Zambonini prepared isomorphous mixtures of lead and cerous molybdates. The thermal analysis shows the following f.p.:

$Ce_2(MoO_4)_3$	0	20	30	50	70	90	95	100 per cent.
Beginning	1065°	1074°	1064°	1050°	1024°	975°	938°	973°
End .	—	—	—	1025°	1000°	—	—	—

The eutectic temp. is 938° with 95 per cent. of cerous salt. Some optical observations were made on the products. For isomorphous mixtures of lead molybdate with molybdates of lanthanum, neodymium, praseodymium, didymium, and yttrium, F. Zambonini found:

Rare earth salt		0	20	40	60	80	100 per cent.
La	Beginning	1065°	1085°	1109°	1139°	1163°	1181°
	End	—	1078°	1102°	1134°	1156°	—
Nd	Beginning	1065°	1076°	1088°	1115°	1147°	1176°
	End	—	1070°	1080°	1105°	1135°	—
Pr	Beginning	1065°	1072°	1068°	1054°	1043°	1030°
	End	—	1068°	1064°	1050°	1040°	—
Di	Beginning	1065°	1072°	1079°	1106°	1123°	1144°
	End	—	1067°	1075°	1085°	1100°	—
Sm	Beginning	1065°	1038°	1016°	1038°	1235°	1347°
	End	—	977°	976°	974°	974°	—

The **arsenic molybdates** were discussed in connection with arsenic—**9**. 51, 22; and the **antimony molybdates,** in connection with antimony—**9**. 52, 14. According to J. B. Richter,[18] when a soln. of bismuth nitrate is treated with potassium molybdate, a lemon-yellow precipitate of **bismuth molybdate,** presumably $Bi_2(MoO_4)_3$, is formed which is easily soluble in the strong acids; whilst 100 parts of water dissolve 0·2 part of the precipitate. By fusing an intimate mixture of bismuth and molybdenum trioxides, F. Zambonini obtained the salt in tetragonal crystals with the axial ratio $a:c=1:1·5636$, and sp. gr. 6·07 at 15°/15°. The mol. vol. is close to those of the molybdates of lead and the cerium metals. The m.p. is 643°. W. T. Schaller obtained greenish rectangular crystals of a mineral from Schneeberg, Saxony; he called it **koechlinite**—after R. Koechlin—and found the analysis corresponds with **bismuth dioxymolybdate,** $Bi_2O_3.MoO_3$, or **bismuthyl molybdate,** $(BiO)_2MoO_4$. The habit of the crystals is tabular, but the thin tablets vary in shape from square to elongated rectangles with diagonal striations. The axial ratios of the rhombic crystals are $a:b:c=0·9774:1:1·0026$. The (100)-cleavage is perfect. Both contact and penetration twinning occurs. The corrosion figures with cold dil. hydrochloric acid (1 : 5) suggested a deviation from holohedral symmetry. The crystals break readily under a slight press. The index of refraction is $\beta=2·55$ with Li-light. The crystals are slightly pleochroic when thick. E. F. Smith and R. H. Bradbury said that the bismuth salt is insoluble in water. Bismuth can be quantitatively precipitated as **ammonium bismuth molybdate,** $Bi(NH_4)(MoO_4)_2$, from a soln. of bismuth nitrate, feebly acid with nitric acid, by means of ammonium molybdate. Thus, E. H. Miller and F. van Dyke Cruser said that the nitric acid soln. of the bismuth is mixed with a large excess of the ordinary ammonium molybdate reagent and the liquid is neutralized with dil. aq. ammonia, using congo-red as indicator; a drop or two of dil. nitric acid is then added until the colour is lilac. The whole is diluted to about 200 c.c. and slowly heated to 50°–60°. The precipitated bismuth ammonium molybdate is washed with a 3 per cent. soln. of ammonium nitrate, and dried in an air-bath at 160°. When ignited, there remains a pale yellow mass of $Bi_2O.4MoO_3$. The reaction was studied by E. H. Miller and H. Frank, and H. S. Riederer. F. Zambonini studied the thermal diagram, Fig. 27, of the system $Bi_2(MoO_4)_3$–$PbMoO_4$. The curve descends rapidly from the m.p., 1065°, of lead molybdate to a eutectic at 615° corresponding with about 71·5 mol. per cent. of the bismuth salt. It then rises rapidly to 643°, the m.p. of bismuth molybdate. No solid soln. are formed, or else the mutual solubility in the solid state is very small.

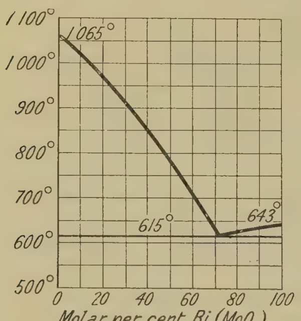

FIG. 27.—Freezing-point Curve of the System: $PbMoO_4$–$Bi_2(MoO_4)_3$.

The **vanadium molybdates** have been discussed in connection with vanadium—**9**. 54, 14; **columbium molybdate,** and **tantalum molybdate** have not been prepared; nor has the normal **chromium molybdate** been described, although A. Moberg,[19] and J. J. Berzelius, said that an apple-green precipitate is formed when ammonium molybdate is added to a soln. of chromic salt. H. Schultze could not prepare chromic molybdates by melting a mixture of chromic chloride and sodium molybdate. S. Prakash and N. R. Dhar obtained the hydrogel of chromic molybdate. The **chromatomolybdates** are discussed in connection with chromium; and some complex chromic dimolybdates are indicated below. The intermediate molybdenum oxides previously described can be regarded as molybdenum molybdates—*e.g.* Mo_5O_{14} can be represented as **molybdenyl molybdate;** $(MoO)_2(MoO_4)_3$; $Mo_{11}O_{32}$ as **molybdenum trimolybdate,** $(MoO)_2(Mo_3O_{10})_3$; Mo_9O_{26} as **molybdenyl paramolybdate,** $(MoO)_2(Mo_7O_{24})$; Mo_7O_{20} as **molybdenum molybdate,** $Mo_2(MoO_4)_5$; $Mo_{17}O_{50}$ as **molybdenum trimolybdate,** $Mo_2(Mo_3O_{10})_5$; and $Mo_{37}O_{120}$ as **molybdenum heptamolybdate,** $Mo_2(Mo_7O_{24})_5$. For the *tungsten molybdates,* see the molybdenum tungstates. A. Lancien[20] prepared **uranium molybdate,** $U(MoO_4)_2$, by reducing the paramolybdate with methyl, ethyl, or higher alcohols; and C. F. Rammelsberg obtained the *trihydrate,* as a greenish-black precipitate, by adding ammonium molybdate to an excess of uranium tetrachloride, and washing the precipitate with hot water. It loses 9·07 per cent. of water when calcined; and when melted, some molybdenum trioxide sublimes. Boiling alkali-lye extracts the molybdic acid; hydrochloric acid forms a green soln. which when diluted becomes yellow. A. Lancien prepared **uranyl molybdate,** $(UO_2)MoO_4$, as a precipitate by the addition of a soln. of ammonium molybdate to uranyl nitrate soln. When prepared in the dark, this compound forms a white, amorphous powder, which is reduced by ethyl and methyl alcohols or acetic acid to the green **uranous molybdate,** $U(MoO_4)_2$, this is then changed to a brick-red and then converted into the green oxide by prolonged boiling with alkali-lye and is rapidly dissolved with a yellowish-green fluorescence by hydrochloric, sulphuric, and nitric acids. When exposed to sunlight for thirty hours, uranyl molybdate becomes golden-yellow in colour, insoluble in nitric acid, which merely whitens it, and is no longer reduced by alcohol. Uranyl molybdate is radioactive, having an activity greater than that of the nitrate and equal to that of radium bromide of activity 40. B. Szilard prepared uranyl molybdate using an excess of uranyl nitrate, in one case, and, in the other case, an excess of ammonium molybdate, and found the radioactivity of both to be the same, and to be quite normal. The uranium molybdate obtained by P. P. Pilipenko from Bivongi was shown by G. Carobbi to be ferrimolybdate—*vide infra.*

J. B. Richter[21] treated a soln. of manganous chloride with potassium molybdate and obtained a brownish-white precipitate which dissolved in forty to fifty times its weight of water. H. Schultze prepared **manganous molybdate,** $MnMoO_4$, by melting together a mixture of sodium molybdate, sodium chloride, and manganous chloride (1 : 2 : 3), and washing the cold mass with water. Yellow, fusible monoclinic plates remain. The cold mass which has been fused contains reddish-brown plates and needles, and yellow crystals. The yellow crystals are soluble in cold, dil. hydrochloric acid, whilst the brown ones are not attacked. W. Jander discussed the lattice-structure, and the diffusion of the molybdate and tungstate, as well as the reaction $MgO+MnMoO_4=MnO+MgMoO_4$. H. Struve prepared the *hydrate,* $MnMoO_4.H_2O$, by treating manganous carbonate with potassium or sodium trimolybdate; and A. Coloriano, by treating manganous nitrate with ammonium paramolybdate, and boiling the amorphous powder in the mother-liquor so that it may crystallize. The white powder consists of microscopic prismatic plates; it loses no water at 100°; but at a higher temp., it loses water and becomes brown. It is sparingly soluble in boiling water. E. Marckwald obtained tabular crystals of the *tritapentahydrate* by allowing the decahydrate to stand exposed to air for some time; and the *decahydrate* as a white, amorphous precipitate by adding an eq. amount of sodium molybdate to a soln. of manganous sulphate.

E. Marckwald reported a number of complex salts. Orange-yellow crystals of **ammonium manganous molybdate,** $(NH_4)_2O.MnO.3MoO_3.2\frac{1}{2}H_2O$, was obtained from a cold, dil. soln. of manganese sulphate (15 grms.) and the eq. proportion of ammonium paramolybdate in 100 c.c. of water; $(NH_4)_2O.3MnO.6MnO_3.16H_2O$, in yellowish-white, prismatic crystals, from a soln. of manganese sulphate and ammonium paramolybdate in a sealed tube at 150° for 5 hrs.; $(NH_4)_2O.2MnO.6MoO_3.16H_2O$, in brownish-red needles, from cold soln. of 25 grms. of manganese sulphate and an eq. amount of ammonium paramolybdate in 50 c.c. of water; $(NH_4)_2O.2MnO.12MoO_3.22H_2O$, in hexagonal, yellow plates, from the mother-liquor of the preceding salt; and **sodium manganous molybdate,** $2Na_2O.MnO.6MoO_3.19H_2O$, in yellowish-white needles by the action of cold soln. of sodium dimolybdate and manganese sulphate. Our knowledge of the complex manganous molybdates is thus in an unsatisfactory state.

By boiling ammonium manganic molybdate with manganic hydroxide, treating the product with water, and evaporating the brown soln., H. Struve obtained brown, amorphous, **manganic molybdate,** $2Mn_2O_3.MoO_3.4H_2O$. H. Struve attempted to prepare *molybdic alums*, of the general formula $2R_2'O.R_2'''O_3.12MoO_3.nH_2O$, where R' represents K or NH_4, and R''', Fe, Al, or Cr. He obtained instead, compounds of the general type $5R'_2O.Mn_2O_3.16MoO_3.12H_2O$. Thus, by boiling a soln. of ammonium molybdate with manganic hydroxide, he obtained **ammonium manganic molybdate,** $5(NH_4)_2O.Mn_2O_3.16MoO_3.12H_2O$; and E. Péchard treated a hot soln. of ammonium molybdate and a manganous salt with a dil. soln. of potassium permanganate, and obtained red crystals of the salt $3(NH_4)_2O.MnO_2.12MoO_2.5H_2O$. C. Friedheim and M. Samelson did not agree with the analyses of either E. Péchard, or of H. Struve, and A. Rosenheim and H. Itzig represented E. Péchard's compound by the formula $2(NH_4)_2O.K_2O.Mn_2O_3.10MoO_3.5H_2O$, and by the action of potassium chloride this was converted into $3K_2O.MnO_2.8MoO_3.5H_2O$. A. Rosenheim added 2 mols of a soln. of manganous chloride to a cold, sat. soln. of ammonium paramolybdate, and obtained the complex salt $(NH_3)_3H_7[Mn''(MoO_4)_6].3H_2O$, which lost 3 mols. of water when kept for 3 days at 60°. The compound $4(NH_4)_2O.Mn_2O_3.13MoO_3.9H_2O$ was prepared by F. Zambonini and V. Cagliotti. It is said to be the compound prepared by H. Struve, C. Friedheim and M. Samelson, and C. Friedheim and O. Allemann. The manganese is said to be really present in the bi- and quadrivalent states so that, in harmony with H. Struve's opinion, the Mn_2O_3 in the formula represents MnO and MnO_2. The formula can therefore be written $(NH_4)_8[Mn^{\cdot\cdot\cdot\cdot}(Mo_2O_7)_6].Mn^{\cdot\cdot}MoO_4.9H_2O$, in harmony with E. Péchard's suggestion that the ratio $MnO_2 : MoO_3$ is 1 : 12 and that the compound is analogous to the silicomolybdates. H. Struve also obtained red crystals of **potassium manganic molybdate,** $2K_2O.MnO.MnO_2.9MoO_3.8H_2O$, by boiling a soln. of potassium trimolybdate with manganic hydroxide, or by the action of chlorine on a soln. of potassium trimolybdate and manganous sulphate. C. Friedheim and M. Samelson represented the composition of this salt by the formula $2K_2O.Mn_2O_3.16MoO_3.12H_2O$.

E. Péchard reported **permanganous molybdate,** $MnO_2.12MoO_3.10H_2O$, to be formed by treating the barium salt, suspended in water, with the theoretical quantity of sulphuric acid, and evaporating the clear liquor in vacuo. A. Rosenheim and H. Itzig denied the existence of this compound. C. Friedheim and M. Samelson, and C. Friedheim and O. Allemann prepared what they regarded as **permanganitomolybdates;** these are indicated below. As emphasized by A. Rosenheim, the test employed to determine the active oxygen of the manganese dioxide—distillation with potassium bromide and hydrochloric acid—is by no means satisfactory; and the question whether these compounds contain quadrivalent or tervalent manganese has not been satisfactorily answered. A. Rosenheim thinks that these salts may be more or less impure forms of $R_nH_{10-n}[Mn'''(MoO_4)_6]$; although complexes with quadrivalent cerium, thorium, and zirconium are known.

A mixture of a soln. of ammonium paramolybdate and manganous chloride with 18·5 per cent. of hydrogen dioxide yields **ammonium permanganitomolybdate,** $2(NH_4)_2O.MnO_2.7MoO_3.5H_2O$; a mixed soln. of potassium paramolybdate, manganous chloride and 2·5 per cent. of hydrogen dioxide yields **potassium permanganitomolybdate,**

$3K_2O.MnO_2.8MoO_3.3$ or $5H_2O$. E. Péchard also prepared this salt; a mixed soln. of ammonium permolybdate, and manganous and potassium chlorides yields **potassium ammonium permanganitomolybdate,** $3\{K_2,(NH_4)_2\}O.MnO_2.8MoO_3.4H_2O$; sodium manganous permanganitomolybdate and potassium chloride yield **sodium potassium manganous permanganitomolybdate,** $3(K_2,Na_2,Mn)O.MnO_2.8MoO_3.4H_2O$; a soln. of ammonium paramolybdate, manganous chloride, and 2·5 per cent. hydrogen dioxide yields **ammonium permanganitomolybdate,** $3(NH_4)_2O.MnO_2.9MoO_3.6$, 7, or $8H_2O$; when this salt or the ammonium manganous salt is treated with potassium chloride, it forms **potassium permanganitomolybdate,** $3K_2O.MnO_2.9MoO_3.5$ or $6H_2O$. R. D. Hall also prepared this salt; a soln. of sodium paramolybdate, manganous chloride and 3·5 per cent. hydrogen dioxide furnishes **sodium manganous permanganitomolybdate,** $3(Na_2,Mn)O.MnO_2.9MoO_3.15H_2O$; a soln. of ammonium paramolybdate, manganous chloride, and potassium persulphate yields **ammonium manganous permanganitomolybdate,** $3\{(NH_4)_2,Mn\}O.MnO_2.9MoO_3.6$ or $7H_2O$; if more potassium persulphate is used, **ammonium potassium manganous permanganitomolybdate,** $3\{(NH_4)_2,K_2,Mn\}O.MnO_2.9MoO_3.7H_2O$; and similarly, **potassium manganous permanganitomolybdate,** $3(K_2,Mn)O.MnO_2.9MoO_3.6$ or $7H_2O$, is formed. R. D. Hall also prepared this salt; and by treating it with barium chloride obtained **barium permanganitomolybdate,** $3BaO.MnO_2.9MoO_3.12H_2O$; a soln. of ammonium manganous molybdate and potassium permanganate, or a soln. of ammonium paramolybdate with potassium permanganate and alcohol yields **ammonium manganous permanganitomolybdate,** $3\{(NH_4)_2,Mn\}O.MnO_2.10MoO_3.8$ or $10H_2O$; a soln. of ammonium paramolybdate, manganous sulphate, and potassium permanganate yields **ammonium potassium manganous permanganitomolybdate,** $3\{(NH_4)_2,K,Mn\}O.MnO_2.10MoO_3.6$ or $10H_2O$; a soln. of ammonium permolybdate, and manganous chloride yields **ammonium manganous permanganitomolybdate,** $4\{(NH_4)_2,Mn\}O.MnO_2.10MoO_3.6H_2O$; a boiling soln. of ammonium paramolybdate, potassium permanganate, and alcohol yields **ammonium potassium permanganitomolybdate,** $4\{(NH_4)_2,K_2,Mn\}O.MnO_2.10MoO_3.5H_2O$; leaving a soln. of ammonium paramolybdate, and molybdic acid in contact with hydrated manganese dioxide for 4 months furnishes **ammonium manganous permanganitomolybdate,** $4\{(NH_4)_2,Mn\}O.MnO_2.11MoO_3.7H_2O$; by using more hydrogen dioxide than was employed in preparing the 3 : 1 : 9 : 6—salt **ammonium manganous permanganitomolybdate,** $4\{(NH_4)_2,Mn\}O.MnO_2.11MoO_3.8H_2O$, is obtained; and an analogous process yields **potassium manganous permanganitomolybdate,** $4(K_2,Mn)O.MnO_2.11MoO_3.11H_2O$. E. Péchard's $3K_2O.MnO_2.12MoO_3.4H_2O$ could not be prepared by A. Rosenheim and H. Itzig, or by C. Friedheim and M. Samelson. Nor could A. Rosenheim and H. Itzig prepare E. Péchard's $3Na_2O.MnO_2.12MoO_3.13H_2O$.

H. Struve,[22] and E. Steinacker found that a soln. of a molybdate or molybdic acid is reduced when treated with a ferrous salt; but H. Schultze obtained normal **ferrous molybdate,** $FeMoO_4$, by fusing a mixture of sodium chloride, ferrous chloride, and sodium molybdate. G. Tammann said that the reaction between ferrous oxide and molybdenum trioxide begins at about 320°; and that the heat of formation of $FeMoO_4$ is 13·5 Cals. C. W. Scheele obtained a brown precipitate by treating a soln. of ferric chloride with potassium molybdate; and E. Marckwald obtained normal **ferric molybdate,** $Fe_2(MoO_4)_3.42H_2O$, in this manner by treating 3 mols of sodium molybdate with 2 mols of ferric chloride. G. Tammann said that no reaction between ferric oxide and molybdenum trioxide occurs below 600°; and he added that the heat of formation of $Fe_2(MoO_4)_3.nH_2O$ is —29·3 Cals. S. Prakash and N. R. Dhar found that a soln. of 8 c.c. of M-$FeCl_3$, 4 c.c. of water, and 8 c.c. of a 10 per cent. soln. of potassium molybdate sets to a jelly in 10 hrs. The viscosities at 30° were:

Age .	0	15	32	68	128	158	188	300 min.
Viscosity	0·009966	0·01009	0·01029	0·01094	0·01442	0·01916	0·03526	0·10620

Some forms of molybdic ochre—*vide supra*, molybdenum trioxide—are mixtures of ferric molybdate and molybdic acid. P. P. Pilipenko obtained a mineral from the Alexyewsky Copper Mines of Jenissejsker, Siberia, which corresponds with $2Fe_2O_3.7MoO_3.19H_2O$, and W. T. Schaller, one from Hortense, Colorado, which corresponded with $Fe_2(MoO_4)_3.7\frac{1}{2}H_2O$, and other samples from Renfrew, Ontario, etc., approximating $Fe_2(MoO_4)_3.n(3H_2O)$, and previously regarded as molybdic ochre, or molybdite (*q.v.*). E. S. Simpson gave $(Fe_2O_3.4MoO_3.5H_2O)5H_2O$. P. P. Pilipenko named these minerals **ferrimolybdite.** G. Carobbi obtained a ferrimolybdate, $4Fe_2O_3.13MoO_3.44H_2O$, from Bivongi.

F. de Carli[23] observed that the reaction between cobaltous oxide and molybdenum trioxide begins at 410°. J. J. Berzelius obtained **cobaltous molybdate,** $CoMoO_4.nH_2O$, as a dirty yellow precipitate by adding a soln. of alkali molybdate to one of a cobaltous salt. The precipitate forms a red powder when dried, and it is decomposed by acids and alkali-lye. E. F. Smith and R. H. Bradbury found that cobalt molybdate is not formed either in cold dil. or conc. soln. By heating a conc. soln. of sodium molybdate with cobalt nitrate, a small quantity of a bluish-white precipitate is formed which dissolves again on cooling. H. Schultze obtained crystals of the anhydrous salt by melting together a mixture of normal sodium molybdate, cobaltous chloride, and sodium chloride (1 : 2 : 2). An impure cobaltous molybdate occurs as the mineral, named by W. Haidinger, **pateraite**—after A. Patera—in the Elias Mine, Joachimsthal. It was described by C. von Hauer, and J. von Jokély. An impure sample was analyzed by G. C. Laube.

A. Coloriano obtained the *monohydrate*, $CoMoO_4.H_2O$, or $HO.MoO_2.O.Co.OH$, in an amorphous state by the action of ammonium paramolybdate on a soln. of a cobaltous salt. When digested with water for a long time, it becomes crystalline. E. Marckwald said that the product is impure, and he prepared it by mixing a 6·5 per cent. soln. of cobaltous chloride with a 3·5 per cent. soln. of sodium molybdate in the cold, and in eq. proportions; the pale rose-coloured liquid was evaporated, at ordinary temp., over sulphuric acid, when the crystalline salt is formed. If the mixed soln. be heated on a water-bath with stirring a precipitate of the salt is obtained. E. Marckwald observed that the proportion of water in the salt may vary with the mode of preparation. The violet crystals lose part of their water at 150°, and all is expelled at 445°. The salt is almost insoluble in boiling water; it is decomposed by conc. acids with the separation of molybdenum trioxide, which, with more acid, may pass into soln. The salt is soluble in dil. acids. F. L. Sonnenschein digested freshly-precipitated cobaltous hydroxide with a small excess of aq. ammonia, and on evaporating the liquid obtained red, prismatic crystals of **cobaltous diamminomolybdate,** $CoMoO_4.2NH_3.H_2O$. If a large excess of aq. ammonia is employed a precipitate is produced. E. Marckwald also said that aq. ammonia dissolves cobaltous molybdate and the soln. on standing for some time deposits the diammine. S. H. C. Briggs prepared **ammonium cobaltous diamminomolybdate,** $(NH_4)_2Co(MoO_4)_2.2NH_3$, from a soln. of 20 grms. cobaltous sulphate, 50 grms. ammonium molybdate, 50 c.c. conc. aq. ammonia, and 90 c.c. of water. The liquid readily oxidizes, and it is evaporated over sulphuric acid, under reduced press. The salt is deposited in violet crystals which can be washed with dil. aq. ammonia, and dried with alcohol and ether.

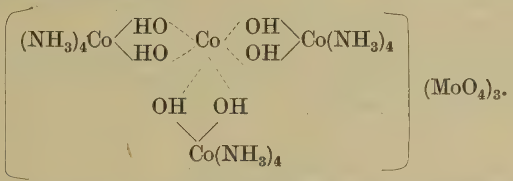
N. S. Kurnakoff prepared **cobaltic molybdates,** by the action of bromine on a soln. of potassium or sodium molybdate. These salts differ from the cobaltous molybdates in giving off chlorine when they are boiled with hydrochloric acid. C. Friedheim and F. Keller found that **ammonium cobaltic dodecamolybdate,** $3(NH_4)_2O.Co_2O_3.12MoO_3.20H_2O$, or $(NH_4)_3H_6[Co(MoO_4)_6].7H_2O$, is obtained by adding a 30 per cent. of ammonium persulphate to a mixture of cobaltous acetate and ammonium paramolybdate, acidifying with dil. acetic acid, and then slowly heating. It may also be prepared by the action of cobaltous acetate on the ammonium permolybdate. It forms green, rhombic plates and dissolves in water to give a green soln. With conc. sulphuric acid, oxygen is evolved; ammonia is evolved by the action of potassium or sodium hydroxide. It is reduced by sulphurous acid. Hydrogen peroxide causes the evolution of oxygen whilst permolybdates are formed. By adding potassium chloride to an aq. soln. of ammonium cobaltic decamolybdate, olive-green crystals of **potassium cobaltic dodecamolybdate,** $3K_2O.Co_2O_3.12MoO_3.15H_2O$, or $K_3H_6[Co(MoO_4)_6].7H_2O$, are produced. By mixing cobaltous acetate, ammonium paramolybdate, and hydrogen dioxide dark green crystals of **ammonium cobalt decamolybdate,** $2(NH_4)_2O.Co_2O_3.10MoO_3.12H_2O$, or $(NH_4)_2H_6[Co(OH(MoO_4)_5].7H_2O$, are formed; and **potassium cobaltic decamolybdate,** $3K_2O.Co_2O_3.10MoO_3.11H_2O$, is obtained either from cobaltous acetate, potassium persulphate, and potassium paramolybdate or from cobaltous acetate and ammonium permolybdate and potassium chloride, or by the addition of potassium chloride to a cold sat. aq. soln. of ammonium cobaltic dodecamolybdate. By treating an aq. soln. of ammonium cobaltic decamolybdate with barium chloride, bright green **barium cobaltic enneamolybdate,** $3BaO.Co_2O_3.9MoO_3.25H_2O$, or $Ba_3H_5[Co(OH)(MoO_4)_5].3H_2O$, is formed; and if ammonium cobaltic dodecamolybdate is similarly treated, bright green **ammonium barium cobaltic decamolybdate,** $\frac{1}{2}(NH_4)_2O.1\frac{1}{2}BaO.Co_2O_3.10MoO_3.18\frac{1}{2}H_2O$, is produced.

P. R. Ray and S. N. Maulik treated a mixture of a cobalt salt and normal sodium molybdate or molybdic acid in the presence of the calculated quantity of ammonium salt and ammonia, with a vigorous current of air, and crystallized the product from an ammoniacal soln. They thus obtained **cobaltic chloropentamminomolybdate,** $[CoCl(NH_3)_5]MoO_4$; **cobaltic hydroxypentamminomolybdate,** $[Co(OH)(NH_3)_5]MoO_4.H_2O$ (or $2{\cdot}5H_2O$); **cobaltic aquopentamminomolybdate,** $[Co(H_2O)(NH_3)_5]_2(MoO_4)_3$; **cobaltic thiocyanatopentamminomolybdate,** $[Co(SCy)(NH_3)_5]MoO_4$; and **cobaltic nitratopentamminomolybdate,** $[Co(NO_3)(NH_3)_5]MoO_4$; also **cobaltic molybdatopentamminomolybdate,** $[Co(MoO_4)(NH_3)_5]_2MoO_4$; **cobaltic aquonitritotetramminomolybdate,** $[Co(H_2O)(NO_2)(NH_3)_4]MoO_4$; and **cobaltic molybdatonitritotetramminomolybdate,** $[Co(MoO_4)(NO_2)(NH_3)_4]$.

B. K. Paul and P. V. Sarkar prepared **cobaltic dimolybdatotetramminotrimolybdate,** $[Co(NH_3)_4(Mo_2O_7)]Mo_3O_{10}.6H_2O$; **cobaltic molybdatotetramminomolybdate,** $[Co(NH_3)_4(MoO_4)]MoO_4.3H_2O$; **cobaltic molybdatotetramminotrimolybdate,** $[Co(NH_4)_4(MoO_4)]_2Mo_3O_{10}.4H_2O$; and **cobaltic nitratotetramminomolybdate,**

$[Co(NH_3)_4(NO_3)O]<^{MoO_2}_{O}$.

There are also complex salts of **cobaltic diaquotetramminomolybdatodimolybdate,** $[Co(NH_3)_4(H_2O)_2]_4(MoO_3)_3(Mo_2O_7)_3.3H_2O$; and of $[Co(NH_3)_4(H_2O)_2]_{12}(MoO_4)_{15}(Mo_2O_7)_3$. They also prepared **cobaltic hexahydroxydodecamminomolybdate,**



S. H. C. Briggs prepared **ammonium cobaltic aquopentamminomolybdate,** $[Co(NH_3)_5(H_2O)]_2(MoO_4)_3.(NH_4)_2MoO_4.2H_2O$, by allowing a soln. of ammonium cobaltous molybdate to oxidize in air when crimson needles are deposited. The salt dissolves in dil. aq. ammonia, but is slightly decomposed by water; and when boiled the soln. in potash-lye gives off ammonia and deposits cobaltic hydroxide.

F. de Carli [24] observed that the reaction between molybdenum trioxide and nickelous oxide begins about 495°. J. B. Richter, and C. Hatchett obtained a light green or white precipitate by adding potassium molybdate to a soln. of nickelous chloride. The precipitate was said to be slightly soluble in boiling water. E. Marckwald obtained **nickelous molybdate,** $NiMoO_4.\frac{2}{3}H_2O$, as a yellow mass by heating a soln. of nickelous chloride and normal sodium molybdate; with sodium dimolybdate, the precipitate was said to have $\frac{3}{4}H_2O$. This means that the precipitate from boiling soln. is probably anhydrous; if precipitated from cold soln., the salt was said to be a *pentahydrate.* The green pentahydrate forms a pale blue soln. with aq. ammonia. H. Schultze prepared monoclinic prisms of the anhydrous salt by fusing a mixture of sodium molybdate, nickelous chloride and sodium chloride, W. Jander discussed the lattice-structure; and the diffusion of the molybdate and tungstate. F. L. Sonnenschein obtained **nickelous diamminomolybdate,** $NiMoO_4.2NH_3.H_2O$, from a soln. of freshly-precipitated nickelous hydroxide or molybdate in aq. ammonia. It is decomposed by water. G. L. Clark found that **nickelous hexamminomolybdate,** $Ni(NH_3)_6MoO_4$, has a vap. press. of 760 mm. at

389°. S. H. C. Briggs prepared **ammonium nickelous diamminomolybdate,** $(NH_4)_2Ni(MoO_4)_2.2NH_3$, in green crystals, by allowing to stand in an open dish a soln. of 20 grms. of hexahydrated nickelous chloride in 15 c.c. of water, mixed with 50 grms. of ammonium molybdate in 70 c.c. of conc. aq. ammonia and 50 c.c. of water.

The **platinum molybdates** have not been prepared, but O. W. Gibbs [25] reported that complex platinic molybdates can be prepared by the action of platinic acid, platinates, or chloroplatinic acid on acid molybdates. The evidence for the individuality of these products, $R_2O : PtO_2 : MoO_3 : H_2O$, is inadequate. Two ammonium platinic molybdates were reported. The one 3 : 2 : 8 : 12 was obtained by boiling freshly-precipitated sodium platinate with a soln. of ammonium molybdate. The lemon-yellow crystals decompose when heated. The salt is sparingly soluble in water. It forms pale yellow *mercurous and mercuric salts* when treated respectively with mercurous and mercuric nitrates; pale yellow *silver salt,* by the action of silver nitrate; pale yellow *thallous salt,* by thallous nitrate; and it gives a pale yellow precipitate with cobaltic dinitritotetramminonitrate. The mother-liquid employed in the preparation of the 3 : 3 : 8 : 12-salt furnishes the 1 : 1 : 2 : $9\frac{1}{2}$-salt on evaporation. The brown oily liquid gradually dries to a dark brown mass which is decomposed by water. If hydrochloroplatinic acid be added to a boiling soln. of potassium molybdate in an excess of potash-lye, and the soln. acidified with acetic acid, it deposits a yellow, crystalline mass of **potassium platinic molybdate**—10 : 1 : 60 : 40—which is possibly a mixture of potassium hexamolybdate and the 2 : 1 : 12 : 4-salt. It decomposes when heated; it is easily soluble in hot water; a pale bluish-green *copper salt* is precipitated by cupric sulphate, and it is soluble in excess; silver nitrate gives a pale yellow crystalline *silver salt.* A soln. of platinic hydroxide forms an olive-green soln. with sodium molybdate. The soln. furnishes **sodium platinic molybdate**—4 : 1 : 10 : 29. The amber-yellow plates are very soluble in water, and it forms cryptocrystalline precipitates with metallic salt soln. When the *barium salt* is treated with dil. sulphuric acid, or the silver salt with dil. sulphuric acid, a soln. of the corresponding acid is obtained—*e.g.* $PtO_2.10MoO_3.4H_2O$, which can be regarded as a platinic molybdate. A. Rosenheim could not confirm these observations.

§ 12. The Di-, Para-, and Tri-Molybdates

L. F. Svanberg and H. Struve [1] found that the mother-liquor obtained in the preparation of ammonium molybdate, furnishes on evaporation crystals of **ammonium dimolybdate,** $(NH_4)_2O.2MoO_3$, or $(NH_4)_2Mo_2O_7$, or $NH_4O.MoO_2.O.MoO_2.ONH_4$. A. Rosenheim gave 0·530 to 0·539 for the transport number. F. Mauro prepared the monohydrate by evaporating a soln. of ammonium dioxytetrafluoride in ammonia. The colourless crystals appear to be monoclinic prisms, and, according to A. Scacchi, have the axial ratios $a : b : c = 0{\cdot}9663 : 1 : 0{\cdot}9450$, $\beta = 107^\circ 12'$. There are also triclinic plates. F. Mauro found that the crystals become turbid in air; and at 100°, begin to lose weight, ultimately forming, at higher temp., molybdenum trioxide. A. Classen prepared white, deliquescent crystals of **tetraethylammonium dimolybdate,** $\{N(C_2H_5)_4\}Mo_2O_7.3H_2O$.

F. Ephraim and M. Brand treated a soln. of 30 grms. of lithium molybdate with 42·3 c.c. of hydrochloric acid of sp. gr. 1·07, and obtained aggregates of needle-like crystals of **lithium dimolybdate,** $Li_2Mo_2O_7.5H_2O$, which at 120° lost one-third of their water of crystallization, and dissolved in water more readily than the trimolybdate. F. Hoermann found the dimolybdate has an incongruous m.p. at 532°, Fig. 13. L. F. Svanberg and H. Struve, and F. Ullik obtained what they regarded as **sodium dimolybdate,** $Na_2O.2MoO_3$, by fusing the required proportions of sodium carbonate or nitrate and molybdenum trioxide. The white mass dissolves in water, and the soln. yields small needles of what L. F. Svanberg and H. Struve regarded as the *monohydrate*, and F. Ullik, the anhydrous salt. E. Groschuff obtained the salt by melting equimolar parts of normal sodium molybdate and molybdenum trioxide. The salt melts at a dull red-heat to an oily liquid which crystallizes on cooling. F. Hoermann gave 612° for the m.p., Fig. 14. The salt is sparingly soluble in cold water but more soluble in hot water. J. J. Berzelius, F. Ullik, and L. F. Svanberg and H. Struve prepared what has been called **potassium dimolybdate** in an analogous way. M. Amadori's thermal analysis shows that potassium dimolybdate can exist. G. Canneri found that the alkali molybdates are reduced by hydrogen in accord with $R_2Mo_2O_7 + H_2 = MoO_2 R_2MoO_4 + H_2O$; reduction by tin furnishes a molybdenum blue; and electrolytic reduction gives compounds analogous with the tungsten bronzes. F. Ephraim and H. Herschfinkel obtained **rubidium dimolybdate,** $Rb_2M_2O_7.2H_2O$, by boiling a soln. of a mol of rubidium carbonate and 2 mols of molybdenum trioxide, and adding nitric acid of sp. gr. 1·20, drop by drop, to the filtered liquid until the precipitate first formed dissolves. The liquid furnishes crystals which are freely soluble in water. G. Wempe obtained this salt, $Rb_2Mo_2O_7.2\frac{1}{2}H_2O$, by evaporating the trimolybdate on a glass plate at 30° to 35°—he gave for it the formula $Rb_2MoO_4.Rb_2Mo_3O_{10}.5H_2O$.

A. Péchard reported that **silver dimolybdate,** $Ag_2Mo_2O_7$, is formed when silver permolybdate is melted. A. Junius obtained it by the action of a hot soln. of silver sulphate on a hot soln. of potassium pentamolybdate; and by the action of sodium paramolybdate on a soln. of silver nitrate. The powder consists of acicular crystals which are sparingly soluble in water, soluble in a soln. of potassium cyanide, and are decomposed by potash-lye with the precipitation of silver oxide. A. Atterberg obtained **beryllium dimolybdate,** $BeO.2MoO_3.3H_2O$, by fusing an eq. mixture of beryllic and molybdenum trioxide, extracting the mass with water, and evaporating the soln. over sulphuric acid. E. Marckwald reported **cobaltous dimolybdate,** $CoO.2MoO_3.6\frac{1}{2}H_2O$, to be formed by evaporating in the cold the soln. remaining after the precipitation of cobalt molybdate from a mixed soln. of sodium dimolybdate and cobaltous chloride. The brown needles form the *dihydrate*, $CoO.2MoO_3.2H_2O$, when heated to 100°.

By analogy with A. Laurent's [2] term paratungstates, a group of polymolybdates were designated **paramolybdates.** Owing to the difficulties involved in the preparation of the pure salts, and to the early difficulties attending the analysis of these salts, the formulæ assigned to them exhibit considerable deviations in the ratios $R_2O : MoO_3 : H_2O$—they include L. F. Svanberg and H. Struve's 4 : 9 : 6 for the potassium salt; F. E. Zenker's 4 : 9 : 28, and J. G. Gentele's 1 : 2 : 7 for the sodium salt; and L. F. Svanberg and H. Struve's and N. J. Berlin's 2 : 5 : 3, W. Delffs' and J. C. G. de Marignac's 1 : 2 : 1, and R. J. Maly's 1 : 4 : 2. W. Lotz showed that the best representative analysis is $3R_2O.7MoO_3.nH_2O$, and this formula, for example, very well represents the analyses of the ammonium salt by L. F. Svanberg and H. Struve, M. Delafontaine, F. Ullik, and A. Werncke.

A. Junius observed that with bases of higher mol. wt., *e.g.* the barium salt, the analyses agree better with the formula $5R_2O.12MoO_3.nH_2O$, and this is in harmony with the analysis of P. Klason and the observations of J. Sand and F. Eisenlohr on the $H^{\cdot}$-ion concentration when soln. of ammonium paramolybdate are titrated with alkali hydroxide. This is in agreement with the observations of A. Rosenheim and co-workers. Attempts have been made to find what proportion of the water is constitutional, and what proportion is water of crystallization, by measuring the loss of weight while the salt is gently heated at a given temp. in a current of carbon dioxide. The isothermal dehydration curves show breaks where there is a change in the properties of the salt. In harmony with the heteropoly salts like the silicododecatungstates, $R_8[Si(W_2O_7)_6]$, the phosphododecatungstates, $R_7[P(W_2O_7)_6]$, the phosphododecamolybdates, $R_7[P(Mo_2O_7)_6]$, the metatungstates, $R_6H_4[H_2(W_2O_7)_6]$, and the view that the so-called tetramolybdates are $R_6H_4[H_2(Mo_2O_7)_6]$, and the octomolybdates, $R_3H_7[H_2(Mo_2O_7)_6]$, A. Rosenheim represented the paramolybdates by the formula $R_5H_5[H_2(Mo_2O_7)_6]$. So that the tetra-, octo-, and para-molybdates are salts of the hypothetical acid $H_{10}[H_2(Mo_2O_7)_6]$. The dimolybdates are considered to be salts of the hypothetical acid $H_{10}[H_2(MoO_4)_6]$, namely $R_6H_4[H_2(MoO_4)_6]$; whilst the paramolybdates have five of the ten hydrogen atoms replaced to form $R_5H_5[H_2(MoO_4)_6]$; and the trimolybdates have four atoms of hydrogen displaced to form $R_4H_6[H_2(MoO_4)_6]$. To summarize,

Hexa-molybdates	Dimolybdates, or Tetrahydrohexamolybdates	$R_6H_4[H_2(MoO_4)_6]$
	Paramolybdates, or Pentahydrohexamolybdates	$R_5H_5[H_2(MoO_4)_6]$
	Trimolybdates, or Hexahydrohexamolybdates	$R_4H_6[H_2(MoO_4)_6]$
Dodeca-molybdates	Tetramolybdates, or Tetrahydrododecamolybdates	$R_6H_4[H_2(Mo_2O_7)_6]$
	Hexamolybdates, or Hexahydrododecamolybdates	$R_4H_6[H_2(Mo_2O_7)_6]$
	Octomolybdates, or Heptahydrododecamolybdates	$R_3H_7[H_2(Mo_2O_7)_6]$

The two hydrogen atoms in the nucleus can be replaced by a bivalent metal—copper, calcium, magnesium, manganese, nickel, or cobalt—to form salts of the hypothetical acid:

$$H_{10}[M''(MoO_4)_6].nH_2O.$$

There is also an isomorphous series of salts with a tervalent metal—aluminium, chromium, iron, cobalt, or rhodium—in the nucleus:

$$R_3H_6[M'''(MoO_4)_6].7H_2O.$$

There is a salt with a quadrivalent metal in the nucleus—*viz.* tin—represented by

$$(NH_4)_8[Sn''''(Mo_2O_7)_6].20H_2O.$$

Other hypotheses can be devised. H. Copaux suggested that the polymolybdates are derived from a hypothetical orthomolybdic acid, H_6MoO_6, by substituting the oxygen atoms one by one with the eq. Mo_2O_7-radicle. This makes the $3R_2O.7MoO_3.nH_2O$ formula for the paramolybdates assume the form $R_6[Mo(Mo_2O_7)_3O_3]$. S. Posternak obtained what he regarded as an anhydrous paramolybdate which he supposed to be $(NH_4O)_3MoO(O.MoO_2)_5O.MoO(ONH_4)_3$, and he also obtained what he regarded as $(NH_4O)_3MoO(O.MoO_2)_5O.MoO_2(OH)$, and $NH_4O(OH)_2MoO(O : MoO_2)_5O.MoO_2(OH).H_2O$. He also obtained ammonium salts of the complex $(RO)_3MoO(O.MoO_2)mO.Mo(OR)_3.nH_2O$. These condensation products reach their limit with the tridecamolybdate. He added that the classification of the molybdates into ortho-, meta-, and para-molybdates is unsatisfactory; and that there are only two groups of molybdates (i) the R_6-polymolybdates in which the ortho- and para-salts are only particular cases; and (ii), the R_4-polymolybdates formed by the hydrolytic rupture of the R_6-salts. L. Forsén regarded the molybdates as derivatives of the two acids: molybdic acid, $H_6Mo_2O_{12}$; and metamolybdic acid, $H_{12}Mo_2O_{12}$. The former is represented by

$$O{<}\begin{matrix}MoO(OH)_2.O\\MoO(OH)_2.O\end{matrix}{>}MoO(OH)_2.$$

Anhydrides like $H_4Mo_3O_{11}$, and $H_2Mo_3O_{10}$, can be formed. He regarded metamolybdic acid as a condensation product of four molecules of molybdic acid so as to form the complex $H_6[Mo_{12}O_{42}H_6]$; and obtained it by warming molybdic acid with hydrochloric acid and a little nitric acid.

A. Travers and L. Malaprade considered that the acid molybdates are derivatives of tetramolybdic and normal molybdic acids $H_2[4MoO_3.O]$ and $H_2[MoO_4]$. The trimolybdates and paramolybdates are derived from the ions $[3MoO_3,O]$ and $[7MoO_3,3O]$, respectively. These ions are considered to exist in equilibrium with the normal and tetramolybdic ions. Ammonium paramolybdate appears to have the composition $12MoO_3.4(NH_4)_2O$, but is probably composed of mixed crystals of tri- and para-molybdate in equilibrium with a mother-liquor of the same composition. The correct formula for sodium paramolybdate is taken to be $3Na_2O.7MoO_3.22H_2O$, and the ammonium salt, $5(NH_4)_2O.12MoO_3.7H_2O$, consists of an isomorphous mixture of true paramolybdate, $3(NH_4)_2O.7MoO_3$, with the trimolybdate, $3(NH_4)_2O.6MoO_3$, and the composition remains constant on recrystallization because the crystals are deposited from a mother-liquor of the same composition.

L. F. Svanberg and H. Struve prepared crystals of **ammonium paramolybdate,** or ordinary commercial ammonium molybdate, by the evaporation of a soln. of molybdic acid in aq. ammonia. Analyses by L. F. Svanberg and H. Struve, W. Delffs, J. C. G. de Marignac, H. Rose, C. F. Rammelsberg, W. Lotz, J. Terwelp, F. Westphal, M. Delafontaine, F. Ullik, and A. Werncke are in accord with the *tetrahydrate*, $3(NH_4)_2O.7MoO_3.4H_2O$, although, for reasons indicated above, other formulæ have been given which represent the analyses nearly as well. Actually J. J. Berzelius called it a diacid salt; L. F. Svanberg and H. Struve represented it by $2(NH_4)_2O.5MoO_3.3H_2O$; J. C. G. de Marignac, and W. Delffs, by $(NH_4)HMoO_4$; and P. Klason regarded it as $5NH_3.6MoO_3.6H_2O$, a complex of $(NH_4)_3H_3Mo_3O_{12}$ and $(NH_4)_2H_4Mo_3O_{12}$. The competing formulæ are $5(NH_4)_2O.12MoO_3.7H_2O$, favoured by A. Junius, and J. Sand and F. Eisenlohr; and $(NH_4)_5H_5[H_2(MoO_4)_6]$, favoured by A. Rosenheim and co-workers. According to C. F. Rammelsberg, the spontaneous evaporation of the mother-liquor from the tetrahydrate yields the *dodecahydrate*, in small monoclinic crystals with the axial ratios $a:b:c=0·4977:1:0·7461$, and $\beta=106° 35'$. It is more soluble than the tetrahydrate; the cooling of the aq. soln. yields the tetrahydrate. The colourless crystals of the tetrahydrate obtained by L. F. Svanberg and H. Struve were six-sided prisms; and G. vom Rath said that the monoclinic prisms have the axial ratios $a:b:c=0·6297:1:1·2936$, and $\beta=91° 21'$; and the (010)-cleavage is complete. H. Steinmetz discussed the crystals of this salt. M. Delafontaine said that the crystals of the *tetrahydrate* have a bluish tinge, due, according to N. J. Berlin, to the presence of a trace of blue molybdenum oxide. Observations on the crystals were also made by W. Haidinger, J. C. G. de Marignac, and C. F. Rammelsberg. N. J. Berlin said that when the salt is heated to redness, it loses water, nitrogen, and ammonia, and leaves behind a brown oxide or else, if air be present, molybdenum trioxide. F. Westphal said that half the water is lost after the salt has stood two months over conc. sulphuric acid or phosphorus pentoxide. P. Klason found that no water is lost under these conditions. F. Westphal observed that at 90°, all the water is given off; at temp. up to 150°, ammonia is gradually given off; over 190°, the evolution of ammonia is accompanied by a darkening of the mass; and at 230°, molybdenum trioxide remains. N. J. Berlin thought that in aq. soln. the trimolybdate is formed. If the freshly-prepared, cold, sat. aq. soln. is dialyzed, dimolybdate escapes, and an acidic liquor remains; if allowed to stand a long time, di- and tri-molybdates are formed: $3\{(NH_4)_2O.7MoO_3\}=(NH_4)_2O.3MoO_3+2(NH_4)_2Mo_2O_7$. If the aq. soln. is heated, some ammonia escapes; and if the soln. is heated in a sealed tube, it is supposed the reaction is that symbolized by $3\{(NH_4)_2O.7MoO_3\}=(NH_4)_2O.4Mo_3O+2(NH_4)_2O.3MoO_3$. On mixing the soln. with other chlorides—*e.g.* those of potassium, calcium, strontium, barium, or magnesium—an isomorphous mixture $m\{3(NH_4)_2O.7MoO_3\}.n\{3R_2O.7MoO_3\}$ is formed. J. N. Rakshit studied the contraction which occurs when the salt is dissolved in water. P. Klason observed that a mixture of 23·22 grms. of water and 3·5846 grms. of salt has a f.p. $-0·625°$, and one of 23·91 grms. of water and 4·1041 grms. of salt, a f.p. of $-0·665°$. This corresponds with the mol. wt. 452 and 472 respectively. A soln. of 18·9 grms. of water and 4·4281 grms. of salt has a b.p. 100·35°, and a soln. of 16·9 grms. of water and 5·4519 grms. of salt, a b.p. of 100·42°. The corresponding mol. wts. are 348 and 399. E. Darmois and J. Périn found that the mol. wt. of the salt is normal when calculated from the f.p. of its soln. in decahydrated sodium sulphate. A. Rosenheim's formula for the salt requires a mol. wt. of 1057. J. Terwelp gave for the eq. conductivity, λ mhos, of an eq. of the salt, $\frac{1}{6}\{(NH_4)_6Mo_7O_{24}.4H_2O\}$, in v litres of water at 25° :

v . .	32	64	128	256	512	1024
λ . .	105·5	119·7	131·5	142·2	154·4	170·9

The aq. soln. has an acidic reaction. J. Sand and F. Eisenlohr said that the salt —represented by A. Junius' formula $(NH_4)_{10}Mo_{12}O_4$—is slightly hydrolyzed so that, at 25°, the $H^{\cdot}$-ion conc. of a $0·01M$-soln. is $1·17\times10^{-4}$ corresponding with a 0·19 per cent. hydrolysis : $Mo_{12}O_{41}{}^{X}+3H_2O\rightleftharpoons2Mo_6O_{22}{}^{VIII}+6H^{\cdot}$. In the progressive hydrolysis of the salt the complex salt $(NH_4)_8Mo_6O_{22}$ is formed before the simple molybdate $(NH_4)_2MoO_4$. There are also indications that a second polymolybdate ion is formed. They said that the original salt ionizes normally : $(NH_4)_{10}Mo_{12}O_{41}\rightleftharpoons10NH_4{}^{\cdot}+Mo_{12}O_{41}{}^{X}$; and on progressive neutralization, there are two possibilities : (i) there is hydrolytic equilibrium, $Mo_{12}O_{41}{}^{X}+7H_2O\rightleftharpoons12MoO_4''+14H^{\cdot}$, so that the addition of sodium hydroxide will remove the $H^{\cdot}$-ions and in all stages of the process there will be equilibrium between the $Mo_{12}O_{41}{}^{X}$,MoO_4'', and the $H^{\cdot}$-ions ; or (ii) one or more polymolybdates may be formed. The position of the break in the curve representing the $H^{\cdot}$-ion conc. and the amount of sodium hydroxide added to the soln. corresponds better with the assumption that the reaction is : $Mo_{12}O_{41}{}^{X}+6OH'=4Mo_3O_{11}{}^{IV}+3H_2O$. S. Dushman found that the rate at which iodine is liberated from a mixture of potassium iodide and iodate in acidic soln. is proportional to the conc. of the iodate ion, and to the square of the conc. of the iodine and hydrogen ions, and J. Sand and F. Eisenlohr utilized the reaction to measure the $H^{\cdot}$-ion conc. in the liberation of iodine from mixtures of potassium iodide, iodate, and ammonium molybdate. Constant values are not obtained for $K=[Mo_6O_{22}{}^{VIII}]^2[H^{\cdot}]^6/[Mo_{12}O_{41}{}^{X}]$ on the assumption that $Mo_3O_{11}{}^{IV}$-ions are present, but constant values are obtained on the assumption that the ions are $Mo_6O_{22}{}^{VIII}$, and at 25°, $K=3·80\times10^{-31}$. B. Glasmann represented the end-products of the hydrolysis : $3(NH_4)_6Mo_7O_{24}+12H_2O=9(NH_4)_2MoO_4+12H_2MoO_4$, and the molybdic acid so produced reacts with the mixture of potassium iodide and iodate : $20KI+4KIO_3+12H_2MoO_4=12K_2MoO_4+12I_2+12H_2O$. S. E. Moody represented the reaction : $3(NH_4)_6Mo_7O_{24}.4H_2O=18NH_3+21H_2MoO_4$; followed by $21H_2MoO_4+35KI+7KIO_5=21K_2MoO_4+21I_2+21H_2O$. A. Junius observed that when an aq. soln. of ammonium paramolybdate is electrolyzed, ammonium tetramolybdate collects at the anode. A. Rosenheim prepared the paramolybdates of ethylamine, aniline, pyridine, and guanidine, of the type $5(CN_3H_6)_2O.12MoO_3.4H_2O$. For **hydroxylamine paramolybdates,** *vide supra.*

A. Rosenheim prepared needle-like crystals of **lithium paramolybdate,** $3Li_2O.7MoO_3.12H_2O$, by evaporating a soln. of a mol of lithium carbonate and 2 mols of molybdic acid, and allowing it to crystallize over phosphorus pentoxide. In addition to this *dodecahydrate,* F. Ephraim and M. Brand reported that the *octocosihydrate* is obtained by evaporating in the cold a soln. of 7 mols of lithium molybdate and 8 mols of nitric acid. The needle-like crystals are easily soluble in cold or hot water. M. Delafontaine, F. E. Zenker, and J. G. Gentele prepared

sodium paramolybdate, $3Na_2O.7MoO_3.22H_2O$, by treating with nitric acid a soln. of molybdic acid in one of sodium hydroxide or carbonate until the first precipitate dissolves, and the soln. has an acid reaction. The liquid deposits the salt in crystals. F. Ullik, and A. Rosenheim obtained it from a soln. of the calculated quantity of molybdic acid or an acid molybdate and the calculated proportion of sodium carbonate ; and F. Mauro obtained it from a soln. of molybdic acid in one of borax —perborate and trimolybdate are also formed. A. Junius obtained the paramolybdate by electrolyzing a soln. of 50 to 60 grms. of the normal salt in 350 c.c. of water, in a compartment cell, using a current of 4 amps. and 8 to 10 volts for 60 to 75 minutes. The anode liquor is allowed to crystallize. A. Lottermoser made a cell with a soln. of sodium molybdate in the inner anode compartment, $0 \cdot 1N$-NaOH in the outer cathode compartment, a platinum cylinder formed the anode. On electrolysis, sodium paramolybdate was found in the interior cell. The salt was analyzed by M. Delafontaine, F. Ullik, J. G. Gentele, and F. E. Zenker, and the formula approximates to $3Na_2O.7MoO_3.22H_2O$, or $5Na_2O.12MoO_3.36H_2O$, or, according to A. Rosenheim, $Na_5H_5[H_2(MoO_4)_6].15\frac{1}{2}H_2O$. F. Westphal regarded it as an *icosihydrate*, $3Na_2O.7MoO_3.20H_2O$. G. Wempe obtained what he regarded as $5Na_2O.12MoO_3.nH_2O$, with n=8, 20, 36, and 44. The colourless, monoclinic prisms were found by F. E. Zenker to have the axial ratios $a:b:c = 2 \cdot 0923 : 1 : 2 \cdot 0237$, and $\beta = 103° 25'$. The (100)-cleavage is incomplete. According to F. E. Zenker, J. G. Gentele, M. Delafontaine, and F. Ullik, the crystals are stable in air only at a low temp. ; at room temp., it effloresces giving off 8 mols. of water ; over sulphuric acid, 11 mols., and at 100°, 21 mols. F. Ullik said that the last mol. is expelled at 120°–130° ; M. Delafontaine said at 200°. H. Copaux found that one mol. remains at 100° ; 0·5 mol. at 150° ; and all is expelled at 200° ; and A. Rosenheim, that 15·5 mols. are expelled at 60°, and 18 mols. at 100°. The salt readily fuses in its water of crystallization. The dehydrated salt readily fuses—L. Ott gave 700° for the m.p.—and it is no longer completely soluble in water. When the salt which has been fused is treated with water it leaves needle-like crystals, which, according to E. Groschuff, are those of the dimolybdate. The f.p. curve of E. Groschuff, Fig. 14, shows that the fused paramolybdate is a mixture of molybdenum trioxide and sodium dimolybdate ; it is also doubtful if the dehydrated paramolybdate is a chemical individual. According to A. Rosenheim, 100 grms. of water at 30° dissolve 117·7 grms. of salt calculated as $5Na_2O.12MoO_3$, or 100 grms. of soln. contain 56·06 grms. The solubility is greater in hot soln., and hydrated paramolybdate is deposited as the soln. cools, but warm conc. soln. of the paramolybdate when boiled deposit trimolybdate. The addition of sodium carbonate to a soln. of paramolybdate forms the monomolybdate. A. Rosenheim gave for the electrical conductivity, λ mhos, of a soln. of one-tenth of a mol of $5Na_2O.12MoO_3.36H_2O$ in v litres at 25°,

v . .	16	32	64	128	256	512	1024
λ . .	89·0	99·8	108·7	116·9	124·8	135·1	146·1

L. Ott said that the molten salt dissolves iron, and when the cold mass is treated with water, ferric oxide remains undissolved. F. E. Brown and J. E. Snyder observed no action with anhydrous ammonium molybdate and boiling vanadium oxytrichloride.

L. F. Svanberg and H. Struve obtained **potassium paramolybdate,** $3K_2O.7MoO_3.4H_2O$, or may be $5K_2O.12MoO_3.7$ or $8H_2O$, by mixing a soln. of molybdic acid in potassium carbonate, drop by drop, with hydrochloric or nitric acid until a permanent turbidity is produced ; the soln. soon deposits crystals of the salt. M. Delafontaine obtained the salt by evaporating to dryness a soln. of molybdic acid in an excess of potassium carbonate, digesting the mass with water, and allowing the soln. to crystallize. A. Rosenheim fused a mixture of equimolar parts of molybdenum trioxide and potassium carbonate, added nitric acid to the aq. soln. until the liquid was neutral to litmus, and allowed the soln.

to crystallize. A. Junius electrolyzed in a diaphragm cell a soln. of 45 grms. of potassium molybdate in 350 c.c. of water for half an hour using a current of 1 to 2 amp. and 8 volts, and allowing the anode liquor to crystallize. If the electrolysis be continued too long, or if the current strength be too high, potassium trimolybdate is formed. According to J. C. G. de Marignac, the six-sided prisms are monoclinic with the axial ratios $a : b : c = 0{\cdot}621 : 1 : 0{\cdot}291$, and $\beta = 90^\circ\ 25'$, and they are isomorphous with the corresponding ammonium salt. According to L. F. Svanberg and H. Struve, and M. Delafontaine, the salt is sparingly soluble in cold water and is thereby decomposed into the normal and trimolybdate ; it loses its combined water when heated, and melts at a red-heat forming a yellow glass. The salt is stable only when quite dry, or when confined under its mother-liquor.

M. Delafontaine reported **rubidium paramolybdate,** $3Rb_2O.7MoO_3.4H_2O$—or, according to G. Wempe, $5Rb_2O.12MoO_3.nH_2O$—to be formed by melting rubidium carbonate with an excess of molybdenum trioxide, dissolving the cold mass in hot water, and cooling the soln. F. Ephraim and H. Herschfinkel used a similar process. W. Muthmann and W. Nagel obtained the paramolybdate by fusing a mol of rubidium carbonate with 3 mols of molybdenum trioxide ; dissolving the cold mass in water ; and crystallizing. F. Ephraim and H. Herschfinkel added that the crystals lose 2 mols. of water at 120°, and all the water is expelled at 180°. The six-sided prisms are said to be isomorphous with the ammonium salt and to be sparingly soluble in cold, but more soluble in hot water. It can be crystallized unchanged from its aq. soln. G. Wempe said that 100 c.c. of the aq. soln. at 24° contain 1·941 grms. of the salt. M. Delafontaine gave the formula $Rb_2O.3MoO_3.2H_2O$, using a wrong value for the at. wt. of rubidium. F. Ephraim and H. Herschfinkel added that the mother-liquor furnishes acicular crystals of $4Rb_2O.5MoO_3.12H_2O$, or $5Rb_2O.7MoO_3.14H_2O$, but the individuality of the product was not established. G. Wemple obtained **rubidium hydroparamolybdate,** $2Rb_2O.H_2O.7MoO_3.5H_2O$, from a soln. of molybdic acid saturated with rubidium carbonate. A. Rosenheim prepared **cæsium paramolybdate,** $3Cs_2O.7MoO_3,nH_2O$, or $5Cs_2O.12MoO_3.11H_2O$, by evaporating the soln. obtained by boiling a soln. of 2 mols of molybdic acid with a mol of cæsium carbonate. F. Ephraim and H. Herschfinkel using analogous proportions of molybdic acid and cæsium hydroxide obtained the 1 : 5 : 5-molybdate, not the paramolybdate.

F. Westphal prepared white needles of **ammonium calcium paramolybdate,** according to A. Rosenheim, $(NH_4)_3CaH_5[H_2(MoO_3)_6].9H_2O$, by the action of ammonium paramolybdate on a soln. of calcium chloride. F. Westphal obtained a substance of the composition $2SrO.3MoO_3$, but it was probably a mixture of **strontium paramolybdate** (3 : 7) and monomolybdate 1 : 5. It was obtained as a white amorphous mass by mixing soln. of sodium dimolybdate and strontium chloride. L. F. Svanberg and H. Struve prepared **barium paramolybdate,** $3BaO.7MoO_3.9H_2O$, or $5BaO.12MoO_3.nH_2O$, by double decomposition between barium chloride and an alkali or ammonium paramolybdate. F. Westphal said that the air-dried precipitate is the *decosihydrate.* A. Junius, working with cold soln., said that the precipitate is the *dodecahydrate,* $3BaO.7MoO_3.12H_2O$, or $5BaO.12MoO_3.20H_2O$, and when boiled it forms the *hexahydrate,* $3BaO.7MoO_3.6H_2O$, or $5BaO.12MoO_3.10H_2O$. F. Westphal obtained **ammonium barium paramolybdate,** $3(NH_4)_2O.3BaO.14MoO_3.12H_2O$, by crystallization from a clear soln. of a mol of barium chloride and 10 mols of ammonium paramolybdate.

F. Ullik prepared **magnesium paramolybdate,** $3MgO.7MoO_3.20H_2O$, by spontaneously evaporating a soln. of the normal molybdate in nitric acid. The plates and prisms are stable in air ; they lose water at a red-heat ; and are soluble in cold water and still more soluble in hot water. E. Manassewitsch could not prepare **zinc paramolybdate ;** by treating a zinc salt soln. with sodium paramolybdate, a mixed precipitate was obtained, and with ammonium paramolybdate, **ammonium zinc paramolybdate,** $2(NH_4)_2O.ZnO.7MoO_3.15H_2O$, was obtained as a white, insoluble precipitate. A. Junius could not prepare cadmium paramolybdate by double decomposition; but E. Mannassewitsch obtained **ammonium cadmium paramolybdate,** $2(NH_4)_2O.CdO.12MoO_3.9H_2O$.

A. Junius prepared **thallous paramolybdate,** $3Tl_2O.7MoO_3$, or $5Tl_2O.12MoO_3$, as a yellow, microcrystalline precipitate, by adding to an excess of a hot soln. of thallous sulphate a hot soln. of sodium paramolybdate. The salt is sparingly soluble in water; but freely soluble in a soln. of alkali hydroxide or carbonate, or in mineral acids. The salt melts to a deep brown liquid at dull redness. H. Flemming reported two acid salts to be formed by double decomposition. The one, $8Tl_2O.11MoO_3$, is supposed to be a mixture of the normal and the paramolybdate; and the other, $3Tl_2O.8MoO_3$, nearly all paramolybdate. A. Cleve prepared crystals of **ytterbium paramolybdate,** $Yb_2O_3.7MoO_3.6H_2O$, by adding a soln. of ytterbium nitrate to a soln. of ammonium paramolybdate, and allowing the soln. to stand for some time, and drying the colourless crystals at 130°.

G. A. Barbieri prepared a series of rare-earth molybdates of the general formula $(NH_4)_6R_2'''Mo_{14}O_{48}.24H_2O$, or $(NH_4)_3R'''Mo_7O_{24}.12H_2O$. The salts can be regarded as complex paramolybdates. They all furnish triclinic crystals and are isomorphous. The crystallographic data are by E. Billows. The red, triclinic prisms of **ammonium cerous molybdate,** $(NH_4)_6Ce_2Mo_{14}O_{48}.24H_2O$, have the axial ratios $a:b:c=0{\cdot}3533:1:0{\cdot}3409$, and $\alpha=102°\ 22'$; $\beta=54°\ 30'$; and $\gamma=103°\ 4'$, are soluble in water; the white crystals of **ammonium lanthanous molybdate,** $(NH_4)_6La_2Mo_{14}O_{48}.24H_2O$, have a yellow tinge, and the axial ratios $a:b:c=0{\cdot}3502:1:0{\cdot}3416$, and $\alpha=102°\ 29'$, $\beta=54°\ 18'$, and $\gamma=103°\ 10'$. These two compounds readily form isomorphous mixtures. G. A. Barbieri, and E. Billows also described **ammonium neodymium molybdate,** $(NH_4)_6Nd_2Mo_{14}O_{48}.24H_2O$, with the axial ratios $a:b:c=0{\cdot}3492:1:0{\cdot}3385$, and $\alpha=102°\ 15'$, $\beta=54°\ 8'$, and $\gamma=103°\ 39'$; **ammonium praseodymium molybdate,** $(NH_4)_6Pr_2Mo_{14}O_{48}.24H_2O$, with $0{\cdot}3514:1:0{\cdot}3461$, and $\alpha=102°\ 11'$, $\beta=54°\ 15'$, and $\gamma=103°\ 44'\ 30''$; and **ammonium samarium molybdate,** $(NH_4)_6Sa_2Mo_{14}O_{48}.24H_2O$, with $0{\cdot}3611:1:0{\cdot}3330$, and $\alpha=54°\ 45'$, $\beta=54°\ 45'$, and $\gamma=102°\ 36'\ 30''$.

A. Lancien found that when uranium nitrate is added to an excess of ammonium paramolybdate, and the resulting precipitate is boiled with molybdic acid, **uranyl paramolybdate,** $3(UO_2).7MoO_3$, is obtained as an amorphous, yellow powder. It is soluble in all mineral acids, giving a greenish-yellow, fluorescent liquid; it is decomposed by excess of water, and reduced to green uranium molybdate, $U(MoO_4)_2$, by alcohol and by acetic acid. The effect of sunlight on the heptamolybdate is to darken its colour, and to render it no longer reducible by alcohol or completely soluble in nitric acid, owing to the formation of insoluble anhydrous uranium octomolybdate, $8MoO_3,UO_3$ and the hydrated compound, $8MoO_3,UO_3,13H_2O$, was also prepared.

For **manganese paramolybdates,** *vide supra,* the molybdates. E. Marckwald could not prepare cobaltous paramolybdate, but A. Carnot obtained what appeared to be **cobaltic pentamminoparamolybdate,** $Co_2O_3.7MoO_3.5NH_3.3H_2O$, by oxidizing an ammoniacal soln. of a cobaltous salt with hydrogen dioxide, adding ammonium paramolybdate, and then acidifying the liquor with acetic acid to precipitate the salt. This compound loses ammonia and water when heated. The reaction can be used as a test for cobalt salts. E. Marckwald obtained **ammonium cobaltous paramolybdate,** $3(NH_4)_2O.3CoO.7MoO_3,nH_2O$, or $5(NH_4)_2O.5CoO.24MoO_3.nH_2O$, from soln. of cobaltous chloride and ammonium paramolybdate evaporated over sulphuric acid. Dark red prisms are obtained. He also reported a hydrated series of, probably, mixtures of ammonium paramolybdate, and cobaltous paramolybdate $(3(NH_4)_2O.7MoO_3):(3CoO.7MoO_3)=5:7$; $2:3$; $3:5$; and $1:5$. **Sodium cobaltous paramolybdate,** $Na_2O.CoO{\cdot}7MoO_3.20H_2O$, was obtained by E. Marckwald from a mixture of eq. proportions of soln. of sodium dimolybdate and cobaltous chloride, and after filtering off the precipitated normal cobaltous molybdate, concentrating by heat. The dark red crystals are slowly soluble in cold water, and without decomposition; and dissolve without decomposition in hot water, but the hot soln. soon decomposes. E. Marckwald concentrated a soln. of a mol of sodium paramolybdate and cobaltous chloride in the cold over conc. sulphuric acid and obtained dark red, prismatic needles of the composition $3Na_2O.3CoO.14MoO_3.50H_2O$. The soln. in cold water is clear and does not become turbid when heated.

According to an observation of N. J. Berlin,[3] **ammonium trimolybdate,** $(NH_4)_2O.3MoO_3.nH_2O$, is formed during the spontaneous evaporation of a soln. of ammonium paramolybdate. F. Westphal, and L. Kämmerer obtained it by keeping a conc. soln. of that salt for a long time at ordinary temp.; and P. Klason, and G. Wempe, by treating a soln. of the paramolybdate with the calculated quantity of hydrochloric acid. N. J. Berlin considered the product to be a trihydrate; and L. Kämmerer, a monohydrate. The radiating masses of acicular crystals, or crystalline crusts, according to P. Klason, lose half their water when confined over phosphorus pentoxide. The salt dissolves sparingly in cold water, and freely in hot water, and it crystallizes slowly from the aq. soln. yielding an impure product.

M. Delafontaine reported **lithium trimolybdate,** $Li_2O.3MoO_3.8H_2O$, to be formed by boiling a soln. of the acid molybdate with lithium carbonate. The *octohydrate* furnishes tetrahedral crystals—monoclinic or triclinic. The salt is not decomposed by fused sodium carbonate. F. Ephraim and M. Brand obtained the *heptahydrate* by evaporating a sat. soln. of the tetramolybdate; the molybdic acid which first separates is filtered off, and on evaporation the liquid furnishes acicular crystals which lose 4 mols. of water at 100°, and 6 mols. at 145°. The salt is sparingly soluble in cold water but more soluble in hot water. G. Wempe obtained the *monohydrate* by evaporating a soln. of 4 mols of lithium molybdate and 6 mols of hydrochloric acid. He also reported a *tetrahydrate,* and one with rather more water. F. Hoermann found that lithium trimolybdate has an incongruent m.p. at 549°—Fig. 13.

L. F. Svanberg and H. Struve obtained **sodium trimolybdate,** $Na_2O.3MoO_3.7H_2O$, by treating a conc. soln. of molybdic acid and sodium carbonate with conc. nitric acid, drop by drop, and the strongly acid soln. gradually deposited acicular crystals of the *heptahydrate* when allowed to evaporate spontaneously. F. Ullik obtained the same salt by spontaneously evaporating a soln. of a mol of sodium carbonate, and 3 mols of molybdenum trioxide—H. Struve used sodium hydroxide instead of the carbonate. A. Rosenheim said that a soln. of the paramolybdate furnishes the trimolybdate when heated a long time; and A. Junius found that if the electrolysis, in the preparation of the paramolybdate, is continued a long time, the trimolybdate is formed. F. Ullik found that the salt melts at a red-heat, and solidifies to a crystalline mass. F. Hoermann, Fig. 14, found that the salt has an incongruent m.p. at 528°. E. Groschuff observed no sign of the formation of a trimolybdate on the f.p. curve, Fig. 14. This is in harmony with L. F. Svanberg and H. Struve's, and F. Ullik's observations that the salt is reduced to brown dioxide by hydrogen, or by zinc. F. Ullik observed that the acicular crystals of the heptahydrate lose about 6 mols. of water at 100°, or at 120°. F. Ullik found that 100 grms. of a soln. sat. at 20° contain 2·96 grms. of the anhydrous salt, and at 100°, 45·86 grms. A. Rosenheim found that at 30°, 100 grms. of a sat. soln. contain 13·68 grms. of $Na_2Mo_3O_8$. According to F. Ullik, a hot conc. soln. of the heptahydrate on a glass plate in dry air at room temp. forms amorphous *tetrahydrate.* It is easily and completely soluble in water. A. Junius reported the *henahydrate* to be precipitated when the anode liquor indicated above is treated with alcohol; he also obtained the *enneahydrate* in a similar way, and G. Wempe obtained the enneahydrate from the mother-liquor in the preparation of the tetramolybdate, and he also obtained *hemidodecatrihydrate* as a crystalline crust when preparing the tetramolybdate. G. Wempe gave for the eq. conductivity, λ, of an eq. of the salt in v litres of water at 20°,

v	10	20	40	80	160
λ tetrahydrate	64·7	72·5	80·0	80·0	96·6
λ hemidodecahydrate	63·7	75·2	85·6	95·2	105·9
λ enneahydrate	76·0	90·0	104·0	112·0	131·2

L. F. Svanberg and H. Struve, and G. Wempe prepared **potassium trimolybdate,** $K_2O.3MoO_3.3H_2O$, by stirring the paramolybdate for some days with cold water, and by treating a soln. of molybdic acid and potassium carbonate with nitric acid —H. Struve used potassium hydroxide. F. Ullik melted 2 mols of potassium carbonate with a mol of molybdenum trioxide; boiled the cold cake with water, and allowed the soln. to crystallize. As in the case of the sodium salt, A. Junius obtained it by the prolonged electrolysis of a soln. of potassium molybdate; and precipitating the anode liquid with alcohol. M. Amadori's thermal analysis shows that the trimolybdate can exist. G. Jander and A. Winkel found the salt to be stable in the range $[H^{\cdot}]=10^{-6\cdot2}$ to $10^{-4\cdot6}$, and gave 0·35 for the diffusion coeff. of the anion. G. Jander described the conditions of stability of the acid. F. Hoermann, Fig. 14, found that the salt melts at 571°. L. F. Svanberg and H. Struve, M. Delafontaine, F. Ullik, and G. Wempe found that the acicular crystals are stable in air; they lose water completely at 100°; they melt at a red-heat, and form a crystalline mass on cooling; when heated in hydrogen, molybdenum dioxide is formed; the dehydrated salt expels 16·82 per cent. of carbon dioxide from molten alkali carbonate; the salt is sparingly soluble in cold water, and more easily soluble in hot water—but less so than is the case with the sodium salt. G. Wempe gave for the conductivity, λ, of an eq. of the salt in v litres of water at 20°:

v	20	40	80	160	320
λ	91·8	104·4	124·0	136·6	153·6

W. Muthmann and W. Nagel melted a mol of rubidium carbonate with 3 mols of molybdenum trioxide, dissolved the white crystalline mass in water, and evaporated the soln. over sulphuric acid. White needles of the *monohydrate* of **rubidium trimolybdate,** $Rb_2O.3MoO_3.H_2O$, were formed. According to F. Ephraim and H. Herschfinkel, an aq. soln. of rubidium paramolybdate furnishes on evaporation a crop of crystals of 3:8:6-molybdate followed by the *hemitridecahydrate* of the trimolybdate. G. Wempe obtained the *trihydrate* by evaporating the aq. soln. on a glass plate; and if the soln. be evaporated on a glass plate at 30° to 35°, the dimolybdate is formed. W. Muthmann and W. Nagel could not prepare **cæsium trimolybdate,** $Cs_2O.3MoO_3.H_2O$, by the process used for the rubidium salt, but F. Ephraim and H. Herschfinkel obtained it as a white, amorphous mass, by evaporating the mother-liquor of the most acid cæsium salt. It is possible that what is here called the trimolybdate may be the 3 : 10 : 3-molybdate.

F. Ullik obtained **copper trimolybdate,** $CuO.3MoO_3.9H_2O$, from a boiling soln. of a mol. of copper carbonate and 4 mols of molybdic acid, and allowing the filtrate to evaporate spontaneously. The pale blue masses of needles are sparingly soluble in cold water and freely soluble in hot water. If an aq. soln. be evaporated on a glass plate, a greenish-blue gummy mass, $CuO.3MoO_3.6\frac{1}{2}H_2O$, is formed. F. Ullik reported **calcium trimolybdate,** $CaO.3MoO_3.6H_2O$, to be formed by boiling an excess of molybdic acid with water having calcium carbonate in suspension, and spontaneously evaporating the clear liquid. The interlaced needles are sparingly soluble in cold water, and easily soluble in hot water. G. Wempe reported what he regarded as hemihydrated normal strontium molybdate, but his analytical data agree better with **strontium trimolybdate,** $SrO.3MoO_3.\frac{1}{2}H_2O$. It was obtained by evaporating a soln. of the octomolybdate to dryness, and washing the product with cold water. The white amorphous mass is sparingly soluble in cold water, but easily soluble in hot water. L. F. Svanberg and H. Struve prepared **barium trimolybdate,** $BaO.3MoO_3.3H_2O$, as a flocculent precipitate by adding barium chloride to a soln. of potassium trimolybdate. The more soluble sodium salt can be used. The salt loses its water when heated; it melts at a red-heat. The hydrate is slightly soluble in water.

F. Ullik obtained **magnesium trimolybdate,** $MgO.3MoO_3.10H_2O$, by spontaneously evaporating a soln. of the normal molybdate in an excess of acetic acid. The acicular crystals are sparingly soluble in cold water, but freely soluble in hot water. F. Ullik obtained a mass of acicular crystals of **zinc trimolybdate,** $ZnO.3MoO_3.10H_2O$, by spontaneously evaporating the filtrate from a soln. obtained by boiling a mol of zinc carbonate with 4 mols of molybdenum trioxide. The salt is sparingly soluble in cold water, and freely soluble in hot water. E. Manassewitsch obtained the trimolybdate by double decomposition of hot or cold soln. of sodium tetramolybdate and a zinc salt. At 120°, the salt loses 4 mols. of water, and the rest at 140°.

F. Ullik prepared **cobaltous trimolybdate,** $CoO.3MoO_3.10H_2O$, by boiling a soln. of an excess of molybdic acid with cobalt carbonate and spontaneously evaporating the filtered liquid. The rose-coloured needles are sparingly soluble in cold water, and freely soluble in hot water. E. Marckwald obtained **sodium cobaltous trimolybdate,** $Na_2O.2CoO.6MoO_3.18H_2O$, by evaporating the mother-liquor obtained in the preparation of the 3 : 3 : 14 : 50-paramolybdate, over sulphuric acid. This salt may be a mixture $Na_2O.2MoO_3+2(CoO.2MoO_3)$.

E. Marckwald prepared **nickelous trimolybdate,** $NiO.3MoO_3.18H_2O$, by evaporating a soln. of eq. proportions of nickelous chloride and sodium paramolybdate. The green crystals are sparingly soluble in cold water, and easily soluble in hot water.

§ 13. The Tetra-, Penta-, Hexa- and Hepta-Molybdates

According to A. Rosenheim and J. Felix,[1] the salt represented by N. J. Berlin as **ammonium tetramolybdate,** $(NH_4)_2O.4MoO_3.2H_2O$, is probably the trimolybdate. There is also some uncertainty about the tetramolybdate reported by F. Westphal, A. Rosenheim, and D. Asch to be formed by heating the paramolybdate for some days at 140° to 150° ; and that obtained by F. Westphal by boiling a soln. of paramolybdate, or by heating the paramolybdate in a sealed tube at 150° to 200°. This product was anhydrous, and water is an essential constituent of the tetramolybdate which A. Rosenheim and J. Felix represent by the formula $(NH_4)_6H_4[H_2(Mo_2O_7)_6].3H_2O$. P. Klason gave $3NH_3.6MoO_3.5H_2O$ for the formula of the salt, but his analysis agrees better with $(NH_4)_2Mo_4O_{13}.2\frac{1}{2}H_2O$. P. Klason prepared this salt by treating a cold soln. of ammonium paramolybdate with the calculated quantity of hydrochloric acid, crystallization begins in about 12 hrs. G. Wempe, and F. Westphal used a similar process with warm soln. ; and A. Junius electrolyzed a soln. of 60 grms. of ammonium paramolybdate in 350 c.c. of water, by a current of 4 amp. for 40 min. in a compartment cell. In all these cases, the soln. furnish crystals of $(NH_4)_2Mo_4O_{13}.2\frac{1}{2}H_2O$. A. Travers and L. Malaprade showed that the tetramolybdates are obtained by neutralizing the acid under conditions which limit the reversal of the reaction by hydrolysis—*vide supra*, molybdic acid. G. Wempe supposed that the crystals are triclinic ; and 100 grms. of a sat. soln., at 15°, 18°, and 32°, contained, respectively, 3·5200, 3·6711, and 4·5961 grms. of the hydrated salt ; and had the sp. gr. 1·03, 1·04, and 1·05, respectively. P. Klason said that the soln. in water over 35° is partially decomposed into trimolybdate. G. Wempe gave for the conductivity, λ, of an eq. of the salt in 10, 20, and 40 litres of water respectively, λ=73·2, 98·8, and 120·4. The aq. soln. reddens methyl-orange, and litmus; acids give no precipitate; barium chloride, a white precipitate; magnesia mixture, a white precipitate; stannous chloride, a green precipitate; ferrous sulphate, a bluish-white precipitate; potassium ferrocyanide, a reddish-brown coloration; and silver nitrate, a white, curdy precipitate. G. Canneri obtained a series of complex salts typified by **ammonium tetrahydroxylaminotetramolybdate,** $(NH_4)_2O.4NH_2OH.4MoO_3$; **sodium tetrahydroxylaminotetramolybdate,** $Na_2O.4NH_2OH.4MoO_3$; **potassium tetrahydroxylaminotetramolybdate,** $K_2O.4NH_2OH.4MoO_3$; and **methylamine tetrahydroxylaminotetramolybdate,** $(CH_6N_3)_2O.4NH_2OH.4MoO_3$—*vide supra.*

F. Ephraim and M. Brand obtained amorphous **lithium tetramolybdate,** $Li_2Mo_4O_{13}.7H_2O$, by F. Ullik's method for the sodium salt; but G. Wempe could not prepare this salt. F. Hoermann, Fig. 13, found that the salt has an incongruent m.p. at 568°. F. Ullik prepared **sodium tetramolybdate,** $Na_2O.4MoO_3.5\frac{1}{2}H_2O$, by putting drops of a hot, conc. soln. of the trimolybdate on a glass plate, and allowing it to evaporate spontaneously. The *hemihenahydrate* appears as a transparent gum-like mass which can be kept unchanged in a closed vessel; but in air, it becomes opaque and passes into the trimolybdate. It retains 2 mols. of water at 100°, and melts to a yellow liquid at a red-heat; the liquid forms a crystalline mass when cold. At a higher temp. molybdenum trioxide volatilizes. The salt is freely soluble in cold water, and when the aq. soln. is spontaneously evaporated, it deposits the trimolybdate. It is open to question whether this product is really a chemical individual. F. Hoermann found that the salt has an incongruent m.p. at 515°—Fig. 14. S. J. Diatschkovsky and A. V. Dumansky obtained a complex $Na_2O(MoO_3)_4$ and found its conductivity and f.p. depressions corresponded with those obtained by the gradual addition of hydrochloric acid to soln. of sodium molybdate—*vide supra,* colloidal molybdic acid. F. Ullik, however, obtained a crystalline *hexahydrate* which A. Rosenheim and J. Felix represented by $Na_2Mo_4O_{13}.6H_2O$, or $Na_6H_4[H_2(Mo_2O_7)_6.].21H_2O$. F. Ullik, and G. Wempe obtained it by treating a conc. soln. of normal sodium molybdate with the theoretical quantity of hydrochloric acid; the precipitate first formed redissolves, and the liquid soon begins to deposit crystals of the tetramolybdate. F. Ullik obtained this salt by adding one or two mols of sodium carbonate to a mol of the octomolybdate—A. Rosenheim and J. Felix used 2 mols of sodium hydroxide. G. Wempe obtained the salt by double decomposition with sodium sulphate and ammonium tetramolybdate. A. Rosenheim and J. Felix said that the salt is an *octomolybdate.* F. Ullik found that the hexahydrate consists of microscopic crystals, which dissolve slowly in cold water and quickly in hot water forming a pale yellow soln. G. Wempe said that the salt consists of masses of needle-like crystals, and that, when saturated, 100 c.c. of soln. at 21° contain 28·39 grms. of the hexahydrate, of sp. gr. 1·47. A. Rosenheim and J. Felix gave for the conductivity, λ, of an eq. of $Na_2Mo_4O_{13}$.aq. in v litres of water at 25°,

v . . .	32	64	128	256	512	1024
λ . . .	98·8	108·3	120·3	130·4	145·0	162·8 mhos.

L. F. Svanberg and H. Struve obtained **potassium tetramolybdate,** $K_2O.4MoO_3.nH_2O$, from the liquid obtained by adding nitric acid to a soln. of molybdic acid in potassium carbonate. A. Rosenheim showed that it is a heptahydrate, $K_2O.4MoO_3.7H_2O$, or, as he represented it, $K_6H_4[H_2(Mo_2O_7)_6].18H_2O$; and he found that a cold soln. of a mol of potassium carbonate and 4 mols of molybdic acid passes quickly into one of the trimolybdate, particularly when warm; and G. Wempe always obtained trimolybdate from a soln. of molybdic acid and sodium carbonate treated with the quantity of hydrochloric acid theoretically required to form the tetramolybdate. M. Amadori's thermal analysis shows that the tetramolybdate can exist. A. Rosenheim and J. Felix obtained crystals of the salt by warming for a few minutes a soln. of sodium octomolybdate and potassium chloride. The microcrystalline powder of the heptahydrate retains a mol. of water at 100°. It is sparingly soluble in cold water, and is decomposed by boiling water with the separation of trimolybdate.

G. Wempe prepared **rubidium tetramolybdate,** $Rb_2O.4MoO_3.4H_2O$, by filtering a hot soln. of rubidium carbonate and an excess of molybdic acid, and rapidly evaporating the liquid. The *tetrahydrate* is an amorphous, white powder which is readily soluble in cold water. G. Wempe also obtained crystals of the anhydrous salt by evaporating on the water-bath a soln. of rubidium paramolybdate treated with the calculated amount of hydrochloric acid. If the crystalline scales are really anhydrous, the formula does not fit A. Rosenheim's theory of the constitution of these salts. F. Ephraim and H. Herschfinkel, however, found that the salt is a *hemihydrate*, $Rb_2Mo_4O_{13}.\frac{1}{2}H_2O$, if obtained from boiling soln.; and the mother-liquor deposits crystals of the paramolybdate, but if it be treated with nitric acid of sp. gr. 1·20, added drop by drop, the *hemipentahydrate* is formed. W. Muthmann and W. Nagel obtained **cæsium tetramolybdate,** $Cs_2O.4MoO_4$, by melting a mol of cæsium carbonate with 3 mols of molybdenum trioxide, and boiling the cold mass repeatedly with water; evaporation over sulphuric acid of the hot extract furnishes quadratic plates of the *dihydrate*, $Cs_2O.4MoO_3.2H_2O$. G. Wempe obtained a *trihydrate*, $Cs_2O.4MoO_3.3H_2O$, by evaporating rapidly on a glass plate drops of a hot filtered soln. of cæsium carbonate and an excess of molybdic acid.

G. Wempe prepared **silver tetramolybdate,** $Ag_2O.4MoO_3.6H_2O$, by treating a hot soln. of ammonium tetramolybdate with an excess of a hot soln. of silver sulphate. The white, flocculent precipitate is coloured green when heated, and it melts to a liquid which, on cooling, forms a yellow crystalline mass. It is decomposed by hot water, with the separation of molybdenum trioxide.

F. Ullik prepared **calcium tetramolybdate,** $CaMo_4O_{13}.9H_2O$, by the action of molybdic acid on calcium carbonate suspended in water. The crystalline salt has not been obtained, otherwise the calcium and sodium salts have analogous properties. F. Ullik obtained **barium tetramolybdate,** $BaMo_4O_{13}.5H_2O$, by the action of hot water on the octohydrate; and A. Rosenheim and J. Felix, by the action of barium chloride on a soln. of sodium octomolybdate, and warming the clear soln. The microcrystalline precipitate loses four-fifths of its water at 120° in agreement with the formula $Ba_3H_4[H_2(Mo_2O_7)_6].12H_2O$. G. Wempe obtained $BaMo_4O_{13}.3{\cdot}5H_2O$, as an amorphous precipitate by the action of barium chloride on a soln. of sodium tetramolybdate. A. Travers and L. Malaprade obtained $BaO.4MoO_3.9H_2O$, from soln. of barium metatungstate and tetramolybdic acid at 70°. G. Wempe could not prepare **magnesium tetramolybdate** by the action of magnesium carbonate on an excess of a boiling soln. of molybdic acid—the product appeared to be the normal molybdate. F. Ullik reported that **zinc tetramolybdate,** $ZnMo_4O_{13}.8H_2O$, is formed as in the case of the calcium salt.

G. Canneri obtained **ammonium dimolybditotetramolybdate,** $2(NH_4)_2O.Mo_2O_5.4MoO_3.8H_2O$; as well as **sodium dimolybditotetramolybdate,** $Na_2O.Mo_2O_5.4MoO_3.10H_2O$; and **potassium dimolybditomolybdate,** $2K_2O.Mo_2O_5.4MoO_3.5H_2O$. By reducing alkali dimolybdates (*q.v.*), he also prepared **lithium hypomolybditotetramolybdate,** $Li_2O.4MoO_3.MoO_2$; **sodium hypomolybditotetramolybdate,** $Na_2O.4MoO_3.MoO_2$; **sodium hypomolybditopentamolybdate,** $Na_2O.5MoO_3.MoO_2$; and **potassium hypomolybditopentamolybdate,** $K_2O.5MoO_3.MoO_2$. By the action of hydrogen chloride near 600°, compounds of the type $O:Mo[O.MoO_2.O.MoO_2.O.R.]_2$, where R denotes Na or Li; and $O:Mo(OR)[O.(MoO_2.O)_5.R]$, where R denotes Na or K, were obtained.

F. Jean [2] reported **ammonium pentamolybdate,** $2(NH_4)_2O.5MoO_3.H_2O$, to separate as an amorphous precipitate when a boiling soln. of ammonium molybdate is treated with ammonium chloride. This result has not been confirmed, and a similar remark applies to L. F. Svanberg and H. Struve's report of the formation of **potassium pentamolybdate** by the action of nitric acid on a soln. of molybdic acid in one of potassium carbonate.

L. F. Svanberg and H. Struve reported **silver pentamolybdate,** $2Ag_2O.5MoO_3$, to be formed by treating a soln. of potassium trimolybdate with silver nitrate. The mass had a variable composition, and was somewhat soluble in water. A. Junius could not prepare it; and it is doubtful if it is a chemical individual. E. Dittler obtained **lead pentamolybdate,** $2PbO.5MoO_3$, by adding a hot, conc. soln. of lead chloride to a hot, 6 per cent. soln. of ammonium 5 : 12-molybdate so long as an additional drop produced no turbidity. The yellowish-green, amorphous product forms bluish-green, hexagonal or trigonal prisms at 115°. They are optically negative, insoluble in water; soluble in nitric acid; soluble in hydrochloric acid (1 : 80); and soluble in a soln. of sodium carbonate, and the soln. on standing deposits basic lead carbonate, $Pb_3(OH)_2(CO_3)_2$.

E. Marckwald obtained **ammonium cobaltous pentamolybdate,** $9\{2(NH_4)_2O.5MoO_3\}$-$5\{2CoO.5MoO_3\}.118H_2O$, as a red crystalline mass, by evaporating the filtrate after boiling a mixed soln. of eq. proportions of cobaltous chloride and ammonium paramolybdate; he also obtained red crystals of $4(NH_4)_2O.2CoO_3.15MoO_3.20H_2O$.

For some hexamolybdates, *vide infra*, dodecamolybdates. The **ammonium hexamolybdate,** $3NH_3.6MoO_3.5H_2O$, of P. Klason[3] was shown previously to be more probably a tetramolybdate. P. Klason also reported that a sample of commercial molybdic acid was best represented by $NH_3.3MoO_3.\frac{1}{2}H_2O$, and it is obtained by evaporating a mixture of ammonium paramolybdate with an excess of nitric acid. This product—if the statements are correct—can be regarded as anhydrous ammonium hexamolybdate, $(NH_4)_2O.6MoO_3$. P. Klason also reported what he regarded as *ammonium pentahydrotrimolybdate*, $(NH_4)H_5Mo_3O_{12}$, or $NH_3.3MoO_3.3H_2O$, but may be also regarded as a *pentahydrate*, $(NH_4)_2O.6MoO_3.5H_2O$. It was obtained by adding the calculated quantity of N-HCl to a cold soln. of ammonium paramolybdate, and crystallizing. The needle-like crystals lose 2 mols. of water over phosphorus pentoxide at ordinary temp. They are sparingly soluble in cold water, and more soluble in hot water—but with partial decomposition. A. Rosenheim regarded the hexamolybdates as hexahydrododecamolybdates, *e.g.* $(NH_4)_4H_6[H_2(Mo_2O_7)_6].nH_2O$. G. Jander and A. Winkel found the alkali hexamolybdate, $R_5[HMo_6O_{21}]$, to be stable in the range $[H^{\cdot}]=10^{-4\cdot5}$ to $10^{-1\cdot6}$; and gave for the diffusion coeff. of the anion, 0·28. G. Jander described the conditions of stability of the acid. According to E. Marckwald, a soln. of sodium di- or para-molybdate and nickelous chloride gives prismatic crystals of **sodium nickelous hexamolybdate,** $Na_2O.2NiO.6MoO_3$, in prismatic crystals which dissolve without decomposition in cold water, but are decomposed by hot water.

S. Posternak prepared **ammonium hydroheptamolybdate,** $(NH_4O)_3MoO(O.MoO_2)_5O.MoO_2(OH)$, from a boiling soln. of ammonium molybdate with molybdic oxide; and **ammonium trihydroheptamolybdate,** $(NH_4O)(HO)_2MoO(O.MoO_2)_5O.MoO_2.OH.H_2O$, as a crystalline crust by warming a soln. of ordinary ammonium molybdate on a water-bath. He supposed the anhydrous paramolybdate (*q.v.*) to be $(NH_4O)_3Mo(O.MoO_2)_5O.MoO(ONH_4)_3$. A. Travers and L. Malaprade discussed the constitution of the salts of $H_6[7MoO_3.3O]$.

§ 14. The Octo-, Ennea-, and Deca-Molybdates

F. Mylius [1] added the theoretical quantity of hydrochloric, sulphuric, or nitric acid to a soln. of ammonium paramolybdate, and obtained colourless needles which he represented by the formula $NH_3.4MoO_3.6H_2O$, or $(NH_4)_2O.8MoO_3.11H_2O$, but which A. Rosenheim regarded as **ammonium octomolybdate,** $(NH_4)_2O.8MoO_3.13H_2O$, and A. Rosenheim and J. Felix, as *ammonium heptahydrododecamolybdate*, $(NH_4)_3H_7[H_2(MoO_7)_6].20H_2O$. A. Rosenheim obtained his salt by the action of sulphur dioxide on ammonium tetramolybdate suspended in water, and crystallizing the soln. over sulphuric acid. As indicated by the formulæ there are differences of opinion as to the water-content. F. Mylius said that when the salt is warmed the expulsion of the water is attended by the loss of some ammonia, and when all the ammonia is driven off, the product is green owing to some reduction. The salt is sparingly soluble in cold water, and rather more soluble in hot water, and at about 60°, a salt containing less water slowly separates. A. Rosenheim suggested that this is the *heptahydrate* reported by P. Klason to be formed by treating a warm soln. of the decamolybdate with ammonium chloride, and which P. Klason regarded as $3NH_3.12MoO_3.12H_2O$. F. Mylius added that the aq. soln. of ammonium octomolybdate has an acidic reaction ; it liberates carbon dioxide from carbonates ; it coagulates albumen ; and, unlike normal molybdates, it gives no precipitate with nitric acid—the soln., however, gradually deposits a salt with less ammonia, or a hydrated molybdenum trioxide.

G. Wempe obtained **lithium octomolybdate,** $Li_2O.8MoO_3.11H_2O$, from a conc. soln. of ammonium tetramolybdate and an excess of lithium sulphate. The transparent needles are soluble in water, and when strongly heated, lose some molybdenum oxide. F. Ephraim and M. Brand could not make this salt. F. Ullik prepared **sodium octomolybdate,** $Na_2O.8MoO_3.17H_2O$, by mixing a soln. of normal sodium molybdate with the calculated quantity of hydrochloric acid, and spontaneously evaporating the clear liquid. A. Rosenheim and J. Felix, and G. Wempe employed a similar mode of preparation. A. Rosenheim and J. Felix also obtained it from a soln. of the normal molybdate sat. with molybdic acid ; and they represented it by the formula $Na_3H_7[H_2(Mo_2O_7)_6].21H_2O$. S. J. Diatschkovsky and A. V. Dumansky prepared the complex $Na_2O(MoO_3)_8$ and found that its conductivity and f.p. depression corresponded with those obtained by adding hydrochloric acid gradually to a soln. of sodium molybdate when colloidal particles appear—*vide supra*, colloidal molybdic acid. According to V. von Zepharovich, the *heptadecahydrate* crystallizes in monoclinic crystals with the axial ratios $a:b:c=1{\cdot}975:1:$—, and $\beta=96°\ 1'$. The crystals are stable at 0°, but at room temp., in air, they lose water and decompose. The loss of water is completed at 160°–180°. The heptadecahydrate is readily soluble in cold or hot water, and crystallizes unchanged when the aq. soln. is evaporated spontaneously ; but if the crystals have lost water by efflorescence, the salt becomes sparingly soluble, and if washed with water, sodium decamolybdate remains. A. Rosenheim and J. Felix found the conductivity, λ mhos, of an eq. of the salt in v litres of water at 25° to be :

v .	16	32	64	128	256	512	1024
λ .	144·8	196·9	303·6	349·3	377·9	406·4	410·6

The large increase in the conductivity indicates that an acid salt rapidly forms hydrogen ions with increasing dilution. The change in the sp. conductivity, *K*, of 25 c.c. of $\frac{1}{32}N$-$Na_2Mo_2O_{25}$ at 25°, when $\frac{1}{102}N$-NaOH is gradually added to 25 c.c. of $\frac{1}{32}N$-$Na_2Mo_8O_{25}$, is as follows, where NaOH represents the number of mols of sodium hydroxide added per mol of $Na_2Mo_8O_{25}$:

NaOH .	0	0·378	1·260	1·764	2·015	2·267	3·023	3·525
K . .	0·04708	0·04418	0·03411	0·02967	0·03018	0·03030	0·03332	0·03550

This means that with the addition of alkali, the acid is neutralized and the conductivity decreases, and when about 2 mols of alkali per mol of salt have been added, sodium tetramolybdate is formed, and the conductivity increases, owing to the increasing alkalinity of the soln. Aq. soln. of the octomolybdate are as unstable as the solid salt, and at their b.p. the liquid becomes turbid owing to the separation of decamolybdate. *Vide infra*, the hexadecamolybdates, for a polymerized form.

F. Ullik prepared **potassium octomolybdate,** $K_2O.8MoO_3.13H_2O$, by dissolving potassium trimolybdate in a soln. of molybdic acid ; the precipitate dissolves when the liquid is warmed, and when the filtered soln. is cooled, the salt separates out in crystals. A. Rosenheim, A. Rosenheim and J. Felix, and D. Asch obtained it by passing sulphur dioxide into an aq. soln. of the tetramolybdate, and crystallizing the liquid over sulphuric acid ; and G. Wempe, by the action of potassium sulphate on a hot soln. of ammonium tetramolybdate. It is not formed when potassium molybdate is treated with the calculated quantity of hydrochloric acid, because the trimolybdate is formed instead. According to F. Ullik, the prismatic crystals are decomposed by water forming a sparingly-soluble powder ; when the salt is heated, water is given off, and at a red-heat, the product fuses. G. Wempe said that the salt forms monoclinic needles, which easily dissolve in warm water. These properties as well as the mode of preparation made A. Rosenheim doubt if G. Wempe's salt is really the octomolybdate. A. Rosenheim and J. Felix regarded it as *potassium heptahydrododecamolybdate,* $K_3H_7[H_2(Mo_2O_7)_6].15H_2O$. G. Wempe reported **rubidium octomolybdate,** $Rb_2O.8MoO_3.4H_2O$, to be formed as in the case of the potassium salt ; and the needle-like crystals are said to be probably monoclinic. They effloresce in air ; and are sparingly soluble in cold water, and readily soluble in hot water. The corresponding **cæsium octomolybdate** has not been prepared.

According to F. Ullik, **calcium octomolybdate,** $CaMo_8O_{25}.18H_2O$—A. Rosenheim and J. Felix gave $(\frac{1}{2}Ca)_3H_7[H_2(Mo_2O_7)_6].22H_2O$—is formed by the action of the calculated quantity of hydrochloric acid on normal calcium molybdate, and allowing the liquid to evaporate spontaneously. A. Rosenheim and J. Felix obtained it in a similar manner. The small, prismatic crystals are very similar to those of the other octomolybdates. The salt gives off water when heated, and the residue begins to fuse at a red-heat. The salt is almost insoluble in cold water, but in hot water it is soluble. G. Wempe represented the amorphous salt obtained by mixing soln. of eq. quantities of sodium tetramolybdate and calcium chloride, by the formula $CaMo_8O_{25}.17H_2O$. He also obtained what he regarded as **strontium octomolybdate,** $SrMo_8O_{25}.7H_2O$—although his data agree better with $SrMo_{10}O_{31}.12H_2O$—by the action of strontium chloride soln. on one of ammonium tetramolybdate. The acicular crystals are monoclinic or triclinic. F. Ullik prepared **barium octomolybdate,** $BaMo_8O_{25}.18H_2O$—A. Rosenheim and J. Felix gave the formula $(\frac{1}{2}Ba)_3H_7[H_2(Mo_2O_7)_6].22H_2O$—by the action of a warm soln. of molybdic acid on barium carbonate ; by the action of a mol of barium chloride on a soln. of a mol of sodium octomolybdate ; and by pouring a soln. of barium chloride into an aq. soln. of molybdic acid. The filtered soln. is evaporated for crystallization. A. Rosenheim and J. Felix obtained it by the action of 1·75 mols of hydrochloric acid on a mol of normal barium molybdate suspended in water ; the soln. crystallized at ordinary temp. The prismatic crystals decompose with the loss of water when heated, and the residue melts at a dull red-heat. The salt is sparingly soluble in cold water, and is decomposed into the tetramolybdate by hot water. G. Wempe obtained an amorphous powder as a precipitate on treating ammonium tetramolybdate with barium chloride; he represented it by the formula $BaMo_8O_{25}.15H_2O$, and said that it is soluble in cold or hot water. G. Wempe's idea of this compound does not agree with the observations of F. Ullik.

F. Ullik prepared **magnesium octomolybdate,** $MgMo_8O_{25}.20H_2O$, as in the case of the sodium salt, by mixing a mol of normal magnesium molybdate with 1·75 mols of hydrochloric acid. G. Wempe obtained it by the action of magnesium sulphate on a soln. of a molybdate, and represented it by the formula $MgMo_8O_{25}.21H_2O$. V. von Zepharovich said that the prismatic crystals are probably triclinic. The salt effloresces in air; it is dehydrated by heat; it melts at a red-heat; dissolves in cold water, and resembles the other octomolybdates in general properties. G. Wempe also reported **zinc octomolybdate,** $ZnMo_8O_{25}.15H_2O$, to be formed as in the analogous case of magnesium octomolybdate; and similarly also with **cadmium octomolybdate,** $CdMo_8O_{25}.7H_2O$.

A. Lancien obtained anhydrous **uranyl octomolybdate,** $UO_3.8MoO_3$, by the action of sunlight on the paramolybdate (*q.v.*); and the *tridecahydrate,* $UO_3.8MoO_3.13H_2O$, is obtained as prismatic needles when ammonium paramolybdate is precipitated by uranium nitrate and the product treated with excess of acetic acid; the substance obtained is extremely sensitive to light. He measured the rate of change of this substance when exposed to light of various wave-lengths.

A. Meinhard obtained well-defined salts of quadrivalent manganese by the action of potassium fluopermanganite on a paramolybdate. Thus, there were produced **potassium permanganous octomolybdate,** $3K_2O.MnO_2.8MoO_3.7H_2O$, and **ammonium permanganous octomolybdate,** $3(NH_4)_2O.MnO_2.8MoO_3.7\frac{1}{2}H_2O$.

L. F. Svanberg and H. Struve [2] treated barium molybdate with dil. nitric acid and obtained from the liquid six-sided prisms of **barium enneamolybdate,** $BaO.9MoO_3.4H_2O$. The salt is insoluble in cold or hot water, or in water acidulated with nitric acid; and it is incompletely decomposed by sulphuric acid, or by a mixture of sulphuric acid with nitric or hydrochloric acid. R. D. Hall reported **potassium percobaltic enneamolybdate,** $3K_2O.CoO_2.9MoO_3.6\frac{1}{2}H_2O$, to be obtained by boiling a soln. of cobaltous sulphate and potassium paramolybdate with potassium persulphate. E. Marckwald prepared **ammonium nickelous enneamolybdate,** $(NH_4)_2O.3NiO.9MoO_3.25H_2O$, from the mother-liquor of the 6 : 3 : 16 : 29 salt. R. D. Hall reported **potassium pernickelic enneamolybdate,** $3K_2O.NiO_2.9MoO_3.6\frac{1}{2}H_2O$, to be formed by boiling a mixed soln. of potassium paramolybdate and nickelous sulphate with potassium persulphate. A boiling soln. of ammonium molybdate, nickelous sulphate and potassium persulphate furnishes dark purple crystals of **ammonium pernickelic enneamolybdate;** and by adding barium chloride to a soln. of this salt, **barium pernickelic enneamolybdate,** $3BaO.NiO_2.9MoO_3.12H_2O$, is formed.

P. Klason [3] prepared **ammonium decamolybdate,** which he represented by the formula $3NH_3.12MoO_3.12H_2O+MoO_3.8H_2O$, but which can be better represented by $(NH_4)_2O.10MoO_3.13H_2O$. He obtained this salt from a soln. of ammonium paramolybdate mixed with the calculated quantity of *N*-HCl. A. Rosenheim and J. Felix with the same mode of preparation obtained the *enneadecahydrate.* The white powder consists of microscopic prisms which dissolve freely in hot water. The salt can be crystallized unchanged from its aq. soln. evaporated at ordinary temp. If a large porportion of the salt is warmed with a little water, it gradually forms the *trihydrate.* The trihydrate is also produced when a soln. of the normal salt is heated with the necessary amount of hydrochloric acid in a closed vessel at 40°, and likewise by dehydration of the enneadecahydrate over phosphorus pentoxide. The six-sided prisms of the trihydrate are sparingly soluble in water. The solid phase of the enneadecahydrate in contact with water for 20 hrs. is all trihydrate. The solubility of the trihydrate at 25° is 0·33 per cent., and at 100° is 0·447 per cent. of $(NH_4)_2Mo_{10}O_{31}$. The low proportion of water of crystallization found by P. Klason shows that his salt had been partially transformed into the trihydrate.

The transformation of the enneadecahydrate is shown by its decreasing solubility, *S*, per cent. $(NH_4)_2Mo_{10}O_{31}$, when the aq. soln. is kept at 25°.

Time . .	6	16	20	30	40 hrs.
S . .	6·01	2·30	0·33	0·33	0·38 per cent.

F. Ullik obtained **sodium decamolybdate,** $Na_2O.10MoO_3.21(\text{or } 22)H_2O$, from a soln. of sodium trimolybdate or carbonate in the calculated quantity of molybdic acid; and A. Rosenheim and J. Felix, by treating an ice-cold, conc. soln. of normal sodium molybdate with more than the calculated quantity of hydrochloric acid, and evaporating over sulphuric acid. F. Ullik found that the *henicosihydrate* furnishes prismatic crystals which V. von Zepharovich regarded as monoclinic with the axial ratios $a:b:c=1·840:1:—$, and $\beta=93° 32·5'$. When kept for some time, the crystals become turbid and wax-like. The crystals dissolve slowly but copiously in water, and they can be recovered from the soln. unchanged. F. Ullik obtained the *dodecahydrate* by evaporating on a water-bath the clear liquid from a soln. of normal sodium molybdate mixed with the theoretical quantity of hydrochloric acid. The white crystalline powder is dried between bibulous paper; it is sparingly soluble in water. A. Rosenheim and I. Davidsohn prepared the heptahydrate, but A. Rosenheim and J. Felix showed that it is probably the *hexahydrate*, $Na_2Mo_{10}O_{31}.6H_2O$. It was obtained by the prolonged heating in a closed vessel at 40° of a soln. of a mol of sodium molybdate and 2 mols of hydrochloric or nitric acid; A. Rosenheim and J. Felix also obtained it by boiling a soln. of the henacosihydrate. The salt separates in microscopic, six-sided prisms, which are only sparingly soluble in cold or hot water; a sat. soln. at 100° contains 0·842 per cent. $Na_2Mo_{10}O_{31}$. The dodecahydrate of F. Ullik may be the partially dehydrated henacosihydrate.

According to A. Rosenheim and I. Davidsohn, and A. Rosenheim and J. Felix, when a soln. of a mol of normal potassium molybdate and 2 mols of hydrochloric acid is heated for a long time in a closed vessel at 40°, a microcrystalline powder of **potassium decamolybdate,** $K_2O.10MoO_3.9H_2O$, separates out. The *enneahydrate* is sparingly soluble in water; at 100°, the soln. contains 0·682 per cent. of $K_2Mo_{10}O_{31}$. If a cold, conc. aq. soln. of normal potassium molybdate be mixed with an eq. amount of hydrochloric acid, it deposits microscopic six-sided prisms of the *pentadecahydrate*, which is fairly soluble in cold water. If the soln. be warm, the less soluble enneahydrate is formed. The facts do not justify the assumption suggested by A. Rosenheim and J. Felix that the easily- and the sparingly-soluble forms are polymeric; they are explained by the existence of hydrates of different solubilities.

The individuality of F. Ephraim and H. Herschfinkel's *rubidium henamolybdate*, $Rb_2O.11MoO_3.5·5H_2O$, obtained from mixtures of rubidium tetramolybdate and nitric acid, has not been established; similar remarks apply to their *rubidium tridecamolybdate*, $Rb_2O.13MoO_3.4H_2O$.

F. Parmentier reported crystals of **potassium aluminium decamolybdate,** $2K_2O.Al_2O_3.10MoO_3.15H_2O$, to be formed by heating aluminium hydroxide with potassium dimolybdate in a sealed tube at 150°. A. Meinhard prepared **sodium ceridecamolybdate,** $4Na_2O.CeO_2.10MoO_3.5H_2O$; **guanidinium thoridecamolybdate,** $4(CN_3H_6)_2O.ThO_2.10MoO_3$; and **ammonium manganous decamolybdate,** $3(NH_4)_2O.2MnO.10MoO_3.14H_2O$, by the action of a manganous salt on ammonium paramolybdate.

D. N. Artemeéff, and M. K. Eliaschevitsch described the rhombic, prismatic crystals of **ammonium cobaltic decamolybdate,** $3(NH_4)_2O.Co_2O_3.10MoO_3.10H_2O$; and of those of **potassium cobaltic decamolybdate,** $3K_2O.Co_2O_3.10MoO_3.10H_2O$. E. Marckwald obtained **ammonium nickelous decamolybdate,** $3(NH_4)_2O.2NiO.10MoO_3.14H_2O$, by mixing a hot soln. of ammonium paramolybdate and nickelous chloride, and, after the nickelous molybdate has separated, evaporating over sulphuric acid.

§ 15. The Dodeca-, and Higher Molybdates

G. Jander and A. Winkel[1] found the range of stability of **sodium dodecamolybdate,** $Na_3(H_7Mo_{12}O_{41})$.aq., to correspond with $[H^{\cdot}]=10^{-1\cdot5}$ to $10^{-0\cdot9}$; and they gave 0·20 for the diffusion coeff. of the anion. G. Wempe treated a soln. of ammonium tetramolybdate with calcium chloride in eq. proportions, and evaporated the liquid on a water-bath. The resulting monoclinic or triclinic prisms were regarded as **calcium dodecamolybdate,** $CaMo_{12}O_{37}.23H_2O$. The crystals effloresce in air; they are almost insoluble in cold water, but readily soluble in hot water.

R. D. Hall prepared crystals of **ammonium aluminium dodecamolybdate,** $3(NH_4)_2O.Al_2O_3.12MoO_3.19H_2O$, or $(NH_4)_3Al(Mo_2O_7)_3.9\frac{1}{2}H_2O$, by boiling 100 grms. of ammonium paramolybdate with 33 grms. of aluminium sulphate in 1·5 litres of water, and cooling the hot liquid. H. Struve regarded it as a decahydrate. The salt was also prepared by E. Marckwald. Attempts by A. Rosenheim and H. Schwer to resolve the ammonium strychnine salt into optical isomerides failed. The electrical conductivity, λ, of $\frac{1}{3}(NH_4)_3H_6[Al(MoO_4)_6].7H_2O$, in v litres of water, at 25°, is:

v . .	32	64	128	256	512	1024
λ . .	100·56	108·5	116·0	122·9	132·8	143·3

J. G. Gentele prepared **sodium aluminium dodecamolybdate,** $Na_3Al(Mo_2O_7)_3.11H_2O$, by treating a soln. of potash-alum with sodium molybdate in excess. The needle-like crystals are easily soluble in water; they effloresce in air; and lose about half their water of crystallization over sulphuric acid. The salt melts when heated, and the cold crystalline mass dissolves slowly in hydrochloric acid. H. Struve boiled freshly-precipitated aluminium hydroxide for many hours with a soln. of potassium trimolybdate, replacing water as it evaporates. The hot liquid is filtered and cooled for the crystals of **potassium aluminium dodecamolybdate,** $3K_2O.Al_2O_3.12MoO_3.20H_2O$, or $K_3Al(Mo_2O_7)_3.10H_2O$. The same salt was obtained by treating a soln. of potash-alum with a normal molybdate—say, magnesium molybdate; and R. D. Hall also obtained it by the action of aluminium sulphate or potash-alum on a molybdate. H. Struve said that the hot soln. furnishes four-sided plates on cooling. The crystals are stable in air; 100 parts of water at 17° dissolve 0·025 part of the salt. The original salt can be obtained by crystallization from the aq. soln. The salt melts at a red-heat, and when cold, the mass is sparingly soluble in water and acids. A. Rosenheim and H. Schwer discussed the hypotheses as to their constitution (i) that they are constituted $R_3[Al(Mo_2O_7)_3].nH_2O$, or $R_3[Al(H_2O)_2(Mo_2O_7)_3].(n-2)H_2O$; or (ii) that they are derivatives of the nonavalent (AlO_6)-radicle. The way the potassium salt loses water, when it is heated, agrees with the hypotheses that the potassium salt is constituted in accord with $K_3H_6[Al(MoO_4)_6].7H_2O$. The percentage loss of water is as follows:

	100°	110°	120°	130°	150°	170°	Red-heat
Loss .	9·90	10·22	10·32	10·32	10·54	11·47	14·68
	$7H_2O$						$10H_2O$

The electrical conductivity, λ, of an eq., $\frac{1}{3}K_3H_6[Al(MoO_4)_6].7H_2O$, in v litres of water, at 25°, is:

v . .	32	64	128	256	512	1024
λ . .	97·42	105·93	113·34	121·04	130·97	140·02

R. D. Hall reported that if an eq. amount of silver nitrate be added to an alkali aluminium dodecamolybdate, only part of the alkali is replaced, but if an excess of the silver salt be employed, **silver aluminium oxydodecamolybdate,** $Ag_2O.Ag_6Al_2(Mo_2O_7)_6.16H_2O$, is formed. If a still larger excess of silver salt be used, **silver aluminium dioxymolybdate,** $2Ag_2O.Ag_6Al_2(Mo_2O_7)_6.nH_2O$, is produced; **barium aluminium oxydodecamolybdate,** $BaO.Ba_3Al_2(Mo_2O_7)_6.14H_2O$, is formed by boiling barium chloride with a soln. of the salt $K_3Al(Mo_2O_7)_3.10H_2O$; and also **ammonium barium aluminium oxydodecamolybdate,** $0·85(NH_4)_2O.2·15BaO.Al_2O_3.12MoO_3.20H_2O$, by the action of barium chloride on the ammonium salt. R. D. Hall prepared **lead aluminium oxydodecamolybdate,** $PbO.Pb_3Al_2(Mo_2O_7)_6.21H_2O$, as in the case of the corresponding silver salt.

G. A. Barbieri prepared a series of **ceriododecamolybdates** of the general formula $R_8[Ce(Mo_2O_7)_6].nH_2O$, derived from the ceridodecamolybdic acid, $H_8[Ce(Mo_2O_7)_6]$. These salts are stable towards hydrogen dioxide, and give a precipitate with oxalic acid only after prolonged boiling. Yellow crystals of **ammonium ceric dodecamolybdate,** $(NH_4)_8[Ce(Mo_2O_7)_6].8H_2O$, were obtained by adding a soln. of conc. ammonium nitrate to a soln. of ammonium paramolybdate, and the product, when treated with dil. sulphuric acid furnished pale yellow crystals of **ammonium ceric dihydrododecamolybdate,** $(NH_4)_6H_2[Ce(Mo_2O_7)_6].10H_2O$; A. Meinhard obtained **sodium ceric dodecamolybdate,** $4Na_2O.CeO_2.1M2oO_3.6H_2O$; while G. A. Barbieri obtained orange-yellow, crystals of **silver ceric dodecamolybdate,** $Ag_8[Ce(Mo_2O_7)_6]$; and yellow crystals of *aniline ceric dodecamolybdate* were prepared by double decomposition with the ammonium salt and silver nitrate.

E. Péchard prepared a series of complex **titanidodecamolybdates,** of the general formula $R_8[Ti(Mo_2O_7)_6].nH_2O$. He obtained **titanidodecamolybdic acid,** $H_8[Ti(Mo_2O_7)_6].18H_2O$, by adding hydrochlorous acid to mercurous titanimolybdate, or by agitating with ether an aq. soln. of the ammonium salt acidified with hydrochloric acid, and allowing the heavier liquid to evaporate spontaneously. The golden-yellow octahedra melt at 60°, and are very soluble in water. He prepared **ammonium titanidodecamolybdate,** $2(NH_4)_2O.TiO_2.12MoO_3.10H_2O$, *i.e.* $(NH_4)_4H_4[Ti(Mo_2O_7)_6].8H_2O$, by adding a soln. of ammonium fluotitanate to a soln. of ammonium molybdate until the yellow colour no longer increases in intensity, and then adding hydrochloric acid. The salt is insoluble in soln. of ammonium salts, but dissolves in water and in acids. It furnishes yellow octahedra which act on polarized light. If a hot, conc. soln. of this salt be treated with potassium chloride and allowed to cool, efflorescent prisms of **potassium titanidododeca-**

molybdate, $K_4H_4[Ti(Mo_2O_7)_6].14H_2O$, are deposited. If a mercurous salt soln. be added to an aq. soln. of one of these two salts, **mercurous titanidodecamolybdate** is formed. E. Péchard prepared **zirconidodecamolybdates,** $R_8[Zr(Mo_2O_7)_6].nH_2O$, in an analogous manner; **ammonium zirconidodecamolybdate,** $(NH_4)_4H_4[Zr(Mo_2O_7)_6].8H_2O$, yields brown octahedra; and **potassium zirconidodecamolybdate,** $K_4H_4[Zr(Mo_2O_7)_6].16H_2O$, brown prisms.

G. A. Barbieri obtained a series of **thoridodecamolybdates,** $R_8[Th(Mo_2O_7)_6].nH_2O$. They do not give a precipitate with oxalic acid in the cold, but, on boiling, thorium oxalate is slowly deposited. When 10 grms. of anhydrous thorium sulphate dissolved in 200 c.c. of water are added to 250 c.c. of a 30 per cent. soln. of ammonium heptamolybdate, a white precipitate of **ammonium thoridodecamolybdate,** $(NH_4)_8[Th(Mo_2O_7)_6].8H_2O$, is deposited. A. Meinhard also prepared this salt. G. A. Barbieri showed that if the nitric or hydrochloric acid soln. of this salt be treated with a conc. soln. of an ammonium salt, **ammonium dihydrothoridodecamolybdate,** $(NH_4)_6H_2[Th(Mo_2O_7)_6].11H_2O$, is deposited; similarly with **sodium thoridodecamolybdate,** $Na_8[Th(Mo_2O_7)_6].15H_2O$, which forms needle-like crystals, and with **sodium dihydrothoridodecamolybdate,** $Na_6H_2[Th(Mo_2O_7)_6].17H_2O$—A. Meinhard also prepared the former salt. According to G. A. Barbieri, the addition of silver nitrate to a soln. of one of these salts furnishes **silver thoridodecamolybdate,** $Ag_8[Th(Mo_2O_7)_6]$, as a white powder. Precipitates of **magnesium thoridodecamolybdate,** and of **zinc thoridodecamolybdate** are similarly produced. A. Rosenheim obtained **ammonium stannidodecamolybdate,** $(NH_4)_8[Sn(Mo_2O_7)_6].20H_2O$, as a microcrystalline, white powder, by the action of a soln. of ammonium paramolybdate on ammonium chlorostannate. A. Meinhard also prepared **ammonium hydrostannidodecamolybdate,** $(NH_4)_3H_5[Sn[Mo_2O_7)_6].4H_2O$, which was regarded as a salt of **stannidodecamolybdic acid,** $H_8[Sn(Mo_2O_7)_6]$.

A series of complex **chromidodecamolybdates,** $3R_2O.Cr_2O_3.12MoO_3.nH_2O$, or $R_3[Cr(Mo_2O_7)_3].nH_2O$, was prepared by H. Struve, E. Marckwald, and R. D. Hall. H. Struve prepared rose-red plates of **ammonium chromidodecamolybdate,** $3(NH_4)_2O.Cr_2O_3.12MoO_3.20H_2O$, or $(NH_4)_3H_6[Cr(MoO_4)_6].7H_2O$, by boiling a soln. of ammonium trimolybdate with hydrated chromic oxide; and R. D. Hall, by boiling a soln. of ammonium chrome-alum and ammonium paramolybdate. E. Marckwald obtained the hexacosihydrate. A. Rosenheim and H. Schwer prepared two guanidine salts; and an attempt to resolve the ammonium strychnine salt into optical isomerides failed. Similarly with the rose-red plates of **potassium chromidodecamolybdate,** $3K_2O.Cr_2O_3.12MoO_3.20H_2O$, or $K_3H_6[Cr(MoO_4)_6].7H_2O$. The salt undergoes no change on dialysis. At 17°, 100 grms. of water dissolve 2·6 grms. of the salt. The percentage loss in weight is:

	100°	110°	120°	130°	150°	170°	Red-heat
Loss .	9·66	10·04	10·08	10·08	10·34	12·71	14·39

A. Rosenheim and H. Schwer found that the electrical conductivity, λ, of a soln. of an eq. of the normal salt, $\frac{1}{3}K_3H_6[Cr(MoO_6)].7H_2O$, in v litres of water, at 25°, is:

v . .	32	64	128	256	512	1024
λ . .	97·91	106·6	114·3	121·8	131·2	140·3

If the potassium salt be crystallized from soln. containing varying proportions of potassium hydroxide a series of **potassium chromioxydodecamolybdates** is formed, *viz.* 7 : 2 : 24 : 32 ; 4 : 1 : 12 : 15 ; and 4 : 1 : 12 : 20. A. Rosenheim and H. Schwer consider that these products are mixtures. H. Struve obtained **sodium chromidodecamolybdate,** $3Na_2O.Cr_2O_3.12MoO_3.21H_2O$, as in the case of ammonium salt. By adding the respective salts of the base to a soln. of potassium chromidodecamolybdate, R. D. Hall prepared **silver chromidodecamolybdate,** $5Ag_2O.Cr_2O_3.12MoO_3.17H_2$, by using an excess of silver nitrate, if otherwise, **potassium silver chromidodecamolybdate,** $2\frac{1}{4}Ag_2O.\frac{3}{4}K_2O.Cr_2O_3.12MoO_3.18H_2O$, is formed; **barium chromioxydodecamolybdate,** $4BaO.Cr_2O_3.12MoO_3.15H_2O$, as well as the hexadecahydrate is formed by using an excess of barium chloride, if otherwise, **potassium barium chromidodecamolybdate,** $2{\cdot}15BaO.0{\cdot}85K_2O.Cr_2O_3.12MoO_3.20H_2O$; and with an ammonium salt, **ammonium barium chromidodecamolybdate,** $2BaO.(NH_4)_2O.Cr_2O_3.12MoO_3.20H_2O$; by using a mixture of an excess of barium chloride and barium hydroxide, in the cold, **barium chromidioxydodecamolybdate,** $5BaO.Cr_2O_3.12MoO_3.12H_2O$, is formed; A. Rosenheim and H. Schwer reported the formation of $Ba_2H_5[Cr(MoO_4)_6].5H_2O$; and they consider that the basic salts here described are impure normal salts. R. D. Hall found that an excess of mercurous nitrate furnishes **mercurous chromipentoxydodecamolybdate,** $8Hg_2O.Cr_2O_3.12MoO_3.16H_2O$; with the theoretical amount of lead nitrate, **lead chromioxydodecamolybdate,** $4PbO.Cr_2O_3.12MoO_3.24H_2O$, was formed, and with five times this amount of lead nitrate, the docosihydrate was produced. If the mercurous salt be decomposed with dil. hydrochloric acid, and the filtrate evaporated to a small bulk over a water-bath, and then to dryness, over sulphuric acid, **chromidodecamolybdic acid,** $Cr_2O_3.12MoO_3.28H_2O$, is formed as a green powder.

A. Rosenheim and J. Pinsker prepared **ammonium manganous dodecamolybdate,** $3(NH_4)_2O.2MnO.12MoO_3.22H_2O$; and by the action of salts of tervalent manganese on alkali paramolybdates, A. Meinhard obtained **ammonium manganic dodecamolybdate,** $4(NH_4)_2O.Mn_2O_3.12MoO_3.9H_2O$, and also **potassium manganic dodecamolybdate,** $4K_2O.Mn_2O_3.12MoO_3.30H_2O$. These salts are analogous with the corresponding $4R_2O.Fe_2O_3.12WO_3.nH_2O$.

F. Zambonini and V. Caglioti prepared **ammonium manganic tridecamolybdate,** $4(NH_4)_2O.Mn_2O_3.13MoO_3.9H_2O$, where Mn_2O_3 may also be regarded as $MnO.MnO_2$. This salt is considered to be one member of a series of isomorphous complex salts of the type: $[Mn^{\cdot\cdot\cdot\cdot}(Mo_2O_7)_6]R_8Mn^{\cdot\cdot}MoO_4.9H_2O$, where R is the third basal element —*vide supra*, permanganitomolybdates. The ammonium salt is produced by adding 100 c.c. of a conc. soln. of manganous chloride (75 grms. $MnCl_2$ per 1000 c.c. of water) to 1800 c.c. of a hot soln. of ammonium paramolybdate (250 grms. of salt per litre), and then adding 800 c.c. of hydrogen dioxide. The soln. is filtered whilst hot, and on cooling red crystals are deposited. The crystals were decanted, washed with water, and dried in air on a porous tile. The triclinic crystals have uniaxial birefringence without optical anomalies, they are pleochoric, and have a sp. gr. 3·028. By adding potassium chloride to a soln. of the ammonium salt at 80°, isomorphous orange-red crystals of **potassium manganic tridecamolybdate,** $4K_2O.Mn_2O_3.13MoO_3.9H_2O$, of sp. gr. 3·43, were produced. The crystals have a positive, uniaxial birefringence without optical anomalies, and they are pleochroic. The corresponding **rubidium manganic tridecamolybdate,** $4Rb_2O.Mn_2O_3.13MoO_3.9H_2O$, was obtained in a similar manner and furnished orange-red, strongly pleochroic crystals. This salt was probably also made by H. Struve in 1854. F. Zambonini and V. Caglioti found that if sodium chloride is employed in place of potassium chloride, the soln. after standing some months deposits orange-red, pleochroic, monoclinic crystals of **sodium ammonium manganic tridecamolybdate,** $2Na_2O.2(NH_4)_2O.Mn_2O_3.13MoO_3.9H_2O$. A boiling soln. of the alkali salt to which nickel sulphate and ammonium persulphate are added, yields purple-black triclinic crystals of **ammonium nickelic tridecamolybdate,** $[Ni^{\cdot\cdot\cdot\cdot}(Mo_2O_7)_6](NH_4)_8NiMoO_4.9H_2O$, isomorphous with the corresponding manganic salt. The corresponding **magnesium, cupric, and cadmium salts** appear as isomorphous mixtures with the ammonium salt. The corresponding **chromic and cobaltic salts** were obtained, but no solid soln. with the manganic salt could be prepared. If the potassium, or ammonium, or sodium manganic salt is treated with barium chloride, at 80°, rose-yellow **barium manganic dodecamolybdate,** $Ba_4[Mn(Mo_2O_7)_6].nH_2O$, is formed; and with the potassium manganic salt and silver nitrate, flesh-coloured crystals of **silver manganic dodecamolybdate,** $Ag_8[Mn(Mo_2O_7)_6].nH_2O$, are produced.

According to E. Marckwald, **ammonium ferric dodecamolybdate,** $3(NH_4)_2O.Fe_2O_3.12MoO_3.20H_2O$, is produced by treating ferric chloride with ammonium paramolybdate. The salt $Fe_2O_3.5MoO_3.nH_2O$ is first deposited, and afterwards white plates of the complex salt, which are decomposed by water. The same salt was prepared by H. Struve, and R. D. Hall. The latter gave $19H_2O$ for the proportion of combined water; and A. Rosenheim and H. Schwer represented it by $(NH_4)_3H_6[Fe(MoO_4)_6].7H_2O$. R. D. Hall also obtained **potassium ferric dodecamolybdate,** $3K_2O.Fe_2O_3.12MoO_3.20H_2O$. A. Rosenheim and H. Schwer represented it by $K_3H_6[Fe(MoO_4)_6].7H_2O$; they found the percentage loss of water:

	100°	110°	120°	130°	150°	170°	Red-heat
Loss . .	9·70	10·01	10·06	10·06	10·40	11·70	14·28
	$7H_2O$						$10H_2O$

They found the conductivity, λ of $K_3H_6[Fe(MoO_4)_6].7H_2O$ in v litres of water, at 25°,

v . .	32	64	128	256	512	1024
λ . .	97·88	103·0	115·64	124·11	136·9	153·75

E. Marckwald prepared **sodium cobaltous dodecamolybdate,** $Na_2O.CoO.12MoO_3.14H_2O$, by heating a soln. of a mol of sodium paramolybdate with 3 mols of cobaltic chloride. The violet precipitate does not appear homogeneous under the microscope and is thought to be a mixture of sodium trimolybdate and normal cobaltous molybdate. E. Marckwald also obtained $3Na_2O.2CoO.12MoO_3.27H_2O$, or $4CoO.6Na_2O.25MoO_3.54H_2O$, from a soln. of eq. quantities of sodium tetramolybdate and cobaltous chloride. The yellowish-red crystals may be a mixture of $2(2CoO.5MoO_3)+3(2Na_2O.5MoO_3)$. He also reported a yellowish-red crystalline mass of $4Na_2O.6CoO.25MoO_3.68H_2O$, by evaporating over sulphuric acid the filtrate from a soln. of a mol of sodium paramolybdate, and 3 mols of cobaltous chloride.

G. A. Barbieri[2] prepared a couple of complex rhodic molybdates analogous to to be those obtained with tervalent aluminium, chromium, iron, and cobalt. These are: **ammonium rhodic dodecamolybdate,** $3(NH_4)_2O.Rh_2O_3.12MoO_3.20H_2O$, or $(NH_4)_3H_6[Rh(MoO_4)_6].7H_2O$, in minute, yellow plates; and **potassium rhodic dodecamolybdate,** $3K_2O.Rh_2O_3.12MoO_3.20H_2O$, or $K_3H_6[Rh(MoO_4)_6].7H_2O$, also in small yellow plates.

E. Marckwald[3] prepared **nickel tetradecamolybdate,** $5NiO.14MoO_3.70H_2O$, from the mother-liquor of the 8 : 6 : 31-molybdate. The green crystals are sparingly soluble in cold water and easily soluble in hot water. When recrystallized from water, the 57-hydrate is produced. G. Wempe prepared **lithium hexadecamolybdate,** $Li_2Mo_{16}O_{49}.9.5H_2O$, by treating a mol of normal lithium molybdate with 1·5 mols of hydrochloric acid. The precipitate first formed redissolves, and the soln. deposits, on standing, rhombohedral crystals which are probably triclinic. They dissolve in warm water; and melt when strongly heated. L. F. Svanberg and H. Struve described a commercial sodium molybdate which approximated **sodium hexadecamolybdate,** $Na_2O.16MoO_3.9H_2O$; and F. Ullik prepared it by boiling for a long time a rather conc. soln. of sodium molybdate with nitric acid of sp. gr. 1·5. The composition of the white precipitate seemed to be independent of the relative proportions of the constituents. It should be washed with dil. nitric acid because it is peptized by water alone. When the salt is treated with sodium carbonate, it forms the octomolybdate. F. Ephraim and H. Herschfinkel boiled an acid cæsium molybdate with nitric acid of sp. gr. 1·20 and obtained a yellow, amorphous substance to which the formula for **cæsium hexadecamolybdate,** $Cs_2O.16MoO_3.8H_2O$, was assigned. F. Ullik regarded this product as $2Na_2O.16MoO_3.8H_2O$, a polymerized form of the octohydrate. F. Ullik also prepared **magnesium hexadecamolybdate,** $MgO.16MoO_3.30H_2O$, in an analogous manner. The microscopic crystals are sparingly soluble in cold water, but easily soluble in hot water. The salt loses water when heated, and melts with decomposition at a dull red-heat. If a mixture of eq. proportions of soln. of ammonium paramolybdate and nickelous chloride be evaporated in the cold, **ammonium nickelous hexadecamolybdate,** $6(NH_4)_2O.3NiO.16MoO_3.29H_2O$, is formed in green crystals, which are sparingly soluble in cold and readily soluble in hot water without decomposition.

E. Marckwald also evaporated a soln. with a great excess of nickelous chloride and obtained **ammonium nickelous henitricontamolybdate,** $8(NH_4)_2O.6NiO.31MoO_3.63H_2O$; and the mother-liquor from the decamolybdate furnishes **ammonium nickelous tetratricontamolybdate,** $3(NH_4)_2O.9NiO.34MoO_3.120H_2O$. R. D. Hall prepared **ammonium nickelous hexadecamolybdate,** $5(NH_4)_2O.3NiO.16MoO_3.16H_2O$, by heating a soln. of nickelous sulphate and ammonium molybdate with hydrogen dioxide; and also **potassium nickelous hexadecamolybdate,** $5K_2O.3NiO.16MoO_3.21H_2O$, from a soln. of potassium paramolybdate and nickelous sulphate alone or in the presence of hydrogen dioxide, chlorine, and bromine.

According to G. A. Barbieri,[4] rhodium forms complex molybdates analogous to the tervalent aluminium, iron, chromium, and cobalt complexes. Thus, **ammonium rhodic dodecamolybdate,** $3(NH_4)_2O.Rh_2O_3.12MoO_3.20H_2O$, forms yellow laminæ, and similarly with **potassium rhodic dodecamolybdate,** $3(NH_4)_2O.Rh_2O_3.12MoO_3.20H_2O$.

G. Canneri[5] obtained a series of hypomolybdatomolybdates by heating for a long time a mixture of hydroxylamine chloride and a soln. of an alkali molybdate. The salts are constituted:

$$R_4[(Mo_2O_5)(Mo_2O_7)_2].nH_2O.$$

The red salt, **ammonium hypomolybdatomolybdate,** $2(NH_4)_2O.Mo_2O_5.4MoO_3.8H_2O$, forms a red soln. with water; **sodium hypomolybdatomolybdate,** $2Na_2O.Mo_2O_5.4MoO_3.10H_2O$, is brick-red; red **potassium hypomolybdatomolybdate,** $2K_2O.Mo_2O_5.4MoO_3.5H_2O$, forms an orange-red soln. with water.

C. G. Grossup[6] prepared germanomolybdic acid, $H_8[Ge(Mo_2O_7)_6].25H_2O$, analogous to silicomolybdic acid.

Five grms. of germanic oxide were dissolved in 200 ml. of water containing 7 grms. of sodium hydroxide, and the soln. brought to boiling, whereupon 70 grms. of molybdic oxide were slowly added with stirring. Rapid dissolution of the molybdic oxide took place until about half the amount had been added. Almost complete precipitation occurred at this point, followed by re-solution with continued addition of the molybdic oxide. An intense yellow colour developed after this mid-point of reaction. Gentle boiling was continued for five minutes, the soln. filtered and allowed to cool. Several hundred ml. of ether were added, followed by an excess of cold $9N$-H_2SO_4. An intermediate turbidity disappeared when sufficient acid had been added. Heavy yellow oily drops separated and settled, forming the third layer common to such extractions. This lower layer—an ether soln. of the complex acid—was removed and evaporated at 40°. After powdering, the residue was dissolved in a small vol. of water and the extraction with ether and sulphuric acid repeated. The ether was removed as before, the residue dissolved in water, the soln. filtered, and then allowed to crystallize at room temp. (18°–28°). The major portion of mother-liquor was removed by filtration and the crystals dried as rapidly as possible by pressing between filter paper, after which they were kept in tightly stoppered weighing bottles or weighed out at once for analysis. In spite of the high solubility, the soln. crystallized well.

A guanidine salt, $(CN_3H_5)_4H_4[Ge(Mo_2O_7)_6]$, was prepared.

§ 16. Permolybdic Acid and Permolybdates

R. Brandes,[1] G. C. Wittstein, and L. F. Svanberg and H. Struve reported *hyperacid molybdates*, but they probably meant polymolybdates and not **permolybdates** as these terms are understood to-day. G. Werther observed that acid soln. of the molybdates, when treated with hydrogen dioxide, give a yellow coloration which, according to C. Bärwald, is not extracted by ether, and which, according to G. Denigès, is not affected by heating the liquid. The analytical possibilities of the reaction were discussed by L. Schönn, A. Weller, L. Crismer, G. Denigès, A. C. Stark, etc. T. Fairley showed that the colour is due to the formation of permolybdic acid or acids in soln. The yellow, or orange-yellow acid soln. gradually deposits an insoluble yellow compound. E. Péchard said that **permolybdic acid,** $HMoO_4$, or $Mo_2O_7.5H_2O$, is isolated by decomposing the barium salt with sulphuric acid; by heating dihydrated molybdenum trioxide with a soln. of hydrogen dioxide; or, by the action of hydrogen dioxide on molybdenum, or its blue oxide. If the soln. obtained by one of these methods is evaporated in vacuo at ordinary temp., it yields a yellow, crystalline powder, soluble in water. The aq. soln. can be boiled without decomposition; with hydrochloric acid there is an evolution of chlorine. Reducing agents like stannous chloride and ferrous sulphate first yield molybdenum trioxide, and then the blue oxide. At 100°, the acid loses $4H_2O$, and, at a higher temp., it simultaneously loses both the remaining water and oxygen. The composition of the salts shows that the acid is monobasic, and this is all in agreement with the formula $HMoO_4.2H_2O$. The direct neutralization of permolybdic acid by sodium hydroxide develops $+24{\cdot}2$ Cals., and by potassium hydroxide $+24{\cdot}0$ Cals. The action of sulphuric acid on sodium permolybdate develops $+6{\cdot}9$ Cals., and the result is the same whether the sulphuric acid is added all at once or in successive portions. The whole of the molybdic acid is not displaced. but a very acid molybdate is formed, its formation corresponding with the evolution of 0·6 Cal. The action of hydrogen dioxide on a mixture of sodium molybdate with sulphuric acid in mol. proportion develops $+5{\cdot}4$ Cals., a quantity which may be regarded as the sum of the heat developed by the decomposition of the hydrogen dioxide and that absorbed by the formation of the permolybdate. It follows that the heat of formation of the permolybdate is $-16{\cdot}2$ Cals. The direct neutralization of permolybdic acid develops with sodium hydroxide $+11{\cdot}2$ Cals., and with potassium hydroxide $+11{\cdot}1$ Cals. It follows that permolybdic acid will displace carbonic acid, but is itself displaced by the strong acids. The action of alkaline hydroxides on the permolybdates, with production of molybdates, gives for the heat of formation of permolybdic acid from molybdic acid $-15{\cdot}9$ Cals., a number almost identical with that obtained by the action of hydrogen dioxide. The energy necessary for the formation of the permolybdic acid is derived from the decomposition of the hydrogen dioxide. According to J. Bruhat and H. Dubois, yellow salts of the acid, $Mo_2O_7.H_2O$, or $HMoO_4$, are produced by the action of perborates on molybdates; and, according to F. Fichter and A. Goldach, permolybdic acid is produced by the action of fluorine on a hydrofluoric acid soln. of molybdic acid.

According to W. Muthmann and W. Nagel, the analytical methods employed by E. Péchard are unsatisfactory. What they called *ozomolybdic acid*, $H_2MoO_5.1\frac{1}{2}H_2O$, was obtained by digesting molybdenum trioxide with a 25 per cent.

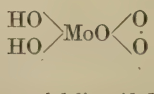
soln. of hydrogen dioxide, on a water-bath, filtering, and concentrating the filtrate under reduced press. The orange-red product is amorphous; it reduces permanganates, silver oxide, and hypochlorites; it liberates halogens from their hydrogen compounds. The salts—ozomolybdates—are obtained by dissolving molybdates in a 25 per cent. soln. of hydrogen dioxide with the aid of heat. They believe that these salts are not true permolybdates, for the heat of the reaction shows that the apparent addition of oxygen to molybdic acid really consists in the replacement of one atom of oxygen by two linked atoms of oxygen as in hydrogen dioxide or ozone. Hence, the proposed term ozomolybdates, and ozomolybdic acid. L. Pissarjewksy, also, repeated E. Péchard's mode of preparing permolybdic acid, and when the ratio of molybdenum to active oxygen in the product was determined by titration with potassium permanganate in sulphuric acid soln., it was found to be 1 : 1 in agreement with **permonomolybdic acid,** $H_2MoO_5.2H_2O$, or $MoO_3.H_2O_2.2H_2O$. J. B. Cammerer also found that when purified molybdenum trioxide is boiled with a soln. of hydrogen dioxide, it gradually dissolves with the evolution of oxygen. When the yellow liquid is evaporated spontaneously, a thickish orange-red mass is obtained, and this can be dried to a yellow powder. The analysis corresponds with $2MoO_3.H_2O.H_2O_2$. The hydrogen dioxide cannot be expelled by heat at 100°. The powder is sparingly soluble in cold water, but is freely soluble in hot water. The compound is not precipitated when the soln. in hot water is cooled. The aq. soln. reacts strongly acid; it combines with acids to form nearly colourless products; and decomposes alkaline carbonates forming colourless salts.

J. Brode measured the distribution of hydrogen dioxide between ether and an acid soln. of molybdate. The result is independent of the amount of hydrogen dioxide and of the conc. of the acid being always in the proportion $MoO_3 : H_2O_2 = 1 : 2$. In the presence of an excess of hydrogen dioxide, the soln. contains $H_2MoO_6 = MoO_2(OOH)_2$; the intensity of the coloration with the gradual addition of hydrogen dioxide reaches a maximum when the ratio is 1 : 1. This is taken to mean that the soln. contains $H_2MoO_5 = MoO_2(OH)(OOH)$. L. Pissarjewsky also found the thermal effect, Q Cals., of dissolving molybdenum trioxide in aq. hydrogen dioxide, to be:

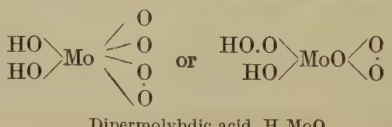
Mols H_2O_2 per mol MoO_3	1	2	3	5
Heat developed, Q	8·08	12·33	12·33	12·44 Cals.

The first reaction is assumed to be $H_2MoO_4 + H_2O_2 = H_2MoO_5 + H_2O + 8084$ cals.; and the second $H_2MoO_5 + H_2O_2 = H_2MoO_6 + H_2O + 4300$ cals. Additions of hydrogen dioxide to the second acid have no thermal effect. Consequently, the heats of formation of the two permolybdic acids are $(H_2MoO_4,O) = 13·516$ Cals.; $(H_2MoO_4,2O) = 30,812$ Cals.; and $(H_2MoO_5,O) = 17·295$ Cals. The heat of neutralization of permolybdic acid, H_2MoO_5, with 2NaOH is 13,248 Cals. A. Mazzucchelli and G. Zangrilli measured the f.p. of the permolybdic acids produced by adding successive quantities of hydrogen dioxide. The results show that the number of dissolved molecules increases only slightly until the ratio $MoO_3 : H_2O_2$ is approximately 1 : 1; and after the formation of H_2MoO_5 is completed a further quantity of hydrogen dioxide enters into combination. Owing to dissociation, and the formation of colloidal complexes, the results are not very reliable. A. Mazzucchelli and C. Barbero found that hydrogen dioxide in a soln. of a mol of MoO_3 in 10 litres of N-H_2SO_4, gives an oxidation potential of 1·008 to 1·025 volts with platinum electrodes.

The general results show that there are two permolybdic acids: **permonomolybdic acid,** H_2MoO_5, or $MoO_3.H_2O_2$, and **perdimolybdic acid,** H_2MoO_6, or $MoO_3.2H_2O_2$, whose constitutions, according to L. Pissarjewsky, can be written:



Monopermolybdic acid, H_2MoO_5



Dipermolybdic acid, H_2MoO_6

They can also be formulated :

$$\begin{matrix} HO.O \\ HO \end{matrix} > Mo < \begin{matrix} O \\ O \end{matrix}$$

Monopermolybdic acid, H_2MoO_5

$$\begin{matrix} HO.O \\ HO.O \end{matrix} > Mo < \begin{matrix} O \\ O \end{matrix}$$

Dipermolybdic acid, H_2MoO_6

According to A. Mazzucchelli and G. Zangrilli, if potassium dihydroarsenatomolybdate be dissolved in water and treated with hydrogen dioxide, and the liquid allowed to stand for some time, an orange-yellow powder of **potassium monopermolybdate,** $K_2MoO_5.3H_2O$, is formed. It is almost insoluble in cold water, and the colloidal soln. is opalescent, but it becomes clear when the water is warmed. P. G. Melikoff and L. Pissarjewksy treated a cold soln. of this salt with a soln. of potassium hydroxide and hydrogen dioxide, and added alcohol to the red liquid. The pale brick-red precipitate of **potassium dipermolybdate,** $K_2MoO_6.H_2O$, or $K_2O_2.H_2O_2.MoO_3$, becomes yellow when exposed to air, and oxygen is given off. The compound explodes when triturated ; and gives off oxygen when treated with water. W. Muthmann and W. Nagel found the salt too unstable to analyze satisfactorily. The corresponding **sodium dipermolybdate** could not be obtained pure enough for analysis.

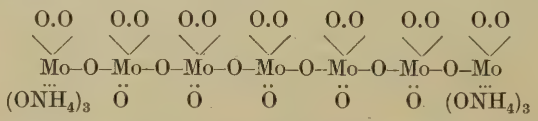
C. Bärwald suggested complex formulæ for the permolybdates which he prepared, but, according to W. Muthmann and W. Nagel, these formulæ are very unlikely. A. Mazzucchelli and G. Zangrilli studied complexes of the permolybdates and oxalates ; and A. Mazzucchelli and C. Ranucci, complexes with organic acids. A. Piccini, and P. Kasanezky obtained fluoroxypermolybdates as indicated below.

The permolybdates can be very roughly classed by means of the ratio R_2O : Mo =1 : 1 ; 1 : 2 ; 3 : 7 ; 1 : 3 ; 3 : 10 ; and 1 : 4. J. Möller reported anhydrous **ammonium permolybdate,** NH_4MoO_4, to be formed by the action of hydrogen dioxide on ammonium paramolybdate, and drying the product in vacuo. A. Fock gave for the axial ratios of the monoclinic prisms $a : b : c$=0·4693 : 1 : 0·2956, and β=112° 37·5′. E. Péchard said that by evaporating the soln. in vacuo, the *dihydrate* is formed in yellow monoclinic prisms which, according to H. Dufet, have the axial ratios $a : b : c$=1·4682 : 1 : 1·0259, and β=105° 45′. J. Möller found that the f.p. of aq. soln. of 0·6353, 1·0807, and 1·1406 grms. per 100 grms. of water are, respectively, —0·65°, —0·110°, and —0·113° ; whilst the electrical conductivities of aq. soln. of a mol of the salt in 15·65, 16·6, and 28·14 litres of water are, respectively, 67·88, 88·12, and 109·01. The data are taken to mean that the mol. wt. corresponds with the doubled formula $(NH_4)_2Mo_2O_8$. As indicated above, W. Muthmann and W. Nagel consider that both E. Péchard's, and J. Möller's analyses are wrong—*vide infra.* E. Péchard said that the salt swells up and decomposes when heated. It is sparingly soluble in water, but more soluble in alcohol. Alcohol extracts the salt from its aq. soln. J. Möller obtained anhydrous **potassium permolybdate,** $KMoO_4$, by the action of 20 per cent. hydrogen dioxide on powdered potassium trimolybdate which has been fused. The orange-coloured soln. deposits crystals of the salt in a few days. J. Möller preferred the doubled formula. E. Péchard reported the *dihydrate.* W. Muthmann and W. Nagel consider that the analyses of both J. Möller, and E. Péchard are wrong—*vide infra.* E. Péchard said that the crystals of the dihydrate are monoclinic prisms. The salt does not change its vol. when heated ; and it decomposes. It is sparingly soluble in cold water, and more soluble in hot water ; the aq. soln. is stable at ordinary temp., but, when boiled, it deposits potassium dimolybdate. It behaves like the ammonium salt towards alcohol. P. Blackman gave for the conductivity, μ, of $\frac{1}{2}K_2MoO_4$ in v litres of water at 25° :

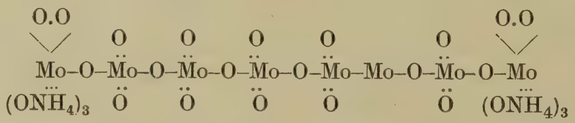
v . .	32	64	128	256	512	1024
μ . .	123	129	133	138	140	144

E. Péchard reported **sodium permolybdate,** $NaMoO_4.3H_2O$, to be formed by dissolving the dimolybdate in hydrogen dioxide and evaporating the soln. in vacuo. The yellow, prismatic crystals begin to melt in their water of crystallization, and near 200°, oxygen is given off. The salt is sparingly soluble in water, and insoluble in alcohol. E. Péchard prepared **copper permolybdate,** $Cu(MoO_4)_2.H_2O$, by double decomposition of the ammonium salt with a soln. of a cupric salt. The greenish-yellow powder is insoluble in water; soluble in aq. ammonia; and freely soluble in acids. The soln. in hydrochloric acid slowly evolves chlorine in the cold. It decomposes when heated. E. Péchard, and C. Bärwald similarly prepared **silver permolybdate,** $AgMoO_4$, in yellow, microscopic octahedra, which give off oxygen when heated. E. Péchard reported **barium permolybdate,** $Ba(MoO_4)_2.2H_2O$, to be formed from a soln. of barium dimolybdate in hydrogen dioxide, or by warming at 80° a soln. of ammonium permolybdate and barium chloride. The yellow, microscopic octahedra are decomposed when heated. C. Bärwald reported monoclinic prisms of the composition $8BaO.19MoO_3.2H_2O_2.13H_2O$ to be formed by the action of barium chloride soln. on $7(NH_4)_2O.18MoO_3.3H_2O_2.11H_2O$. The analysis is thus a close approximation to that of E. Péchard's salt. E. Péchard obtained **magnesium permolybdate,** $Mg(MoO_4)_2.10H_2O$, by a process like that used for the barium salt. The needle-like crystals melt at 70°, and decompose at about 200°. The salt is sparingly soluble in water, and less so in alcohol. E. Péchard prepared by double decomposition **mercurous permolybdate,** $HgMoO_4$, as an orange-yellow powder insoluble in a soln. of ammonium nitrate; and similarly also with **thallous permolybdate,** which is a yellow powder, insoluble in water, and which melts with the evolution of oxygen.

W. Muthmann and W. Nagel prepared **ammonium perparamolybdate,** $3(NH_4)_2O.7MoO_4.12H_2O$, by saturating a 20 per cent. soln. of hydrogen dioxide with ammonium paramolybdate, and evaporating the yellowish-red liquid. The orange-red, monoclinic crystals can be recrystallized from a soln. in a small proportion of water, but they are completely decomposed at 105°. The graphic formula for the orange-red salt is:



Another salt, $3(NH_4)_2O.5MoO_3.2MoO_4.6H_2O$, was prepared by W. Muthmann and W. Nagel by evaporating the mother-liquor. The salt decomposes at 170°. The formula for the lemon-yellow salt is:



It is probable that the salt prepared by C. Bärwald by the action of a dil. soln. of hydrogen dioxide on ammonium paramolybdate which he represented by $14NH_3.18MoO_3.3H_2O_2.18H_2O$, as well as that prepared by E. Péchard, as indicated above, and represented by the formula $NH_4MoO_4.2H_2O$, are impure forms of the perparamolybdate. In addition to the properties just indicated, C. Bärwald said that the sp. gr. of the crystals is 2·975, and that of the soln. sat. at 17·4° is 1·486. A. Mazzucchelli and C. Barbero found that the oxidation potential with a $2N$-soln. and platinum electrodes is 0·827 to 0·841 volt. W. Muthmann and W. Nagel obtained yellow, monoclinic crystals of **rubidium perparamolybdate,** $3Rb_2O.5MoO_3.2MoO_4.6H_2O$, from a soln. of rubidium paramolybdate in 5 per cent. hydrogen dioxide.

W. Muthmann and W. Nagel reported **potassium pertrimolybdate,** $K_2O.2MoO_3.MoO_4.3H_2O$, to be formed by evaporation over phosphorus pentoxide of a soln. of potassium trimolybdate in 20 per cent. hydrogen dioxide. A salt prepared in a similar manner by the action of dil. or conc., cold or hot hydrogen dioxide on potassium paramolybdate was represented by C. Bärwald by $6K_2O.16MoO_3.4H_2O_2.13H_2O$; and the salt, indicated above, prepared by E. Péchard, and represented by $KMoO_4.2H_2O$, was probably this compound. The yellow crystals have the properties indicated above. J. Möller found that soln. of 1·0144, 1·0892, and 1·6058 grms. of the salt in 100 grms. of water have the respective f.p. −0·086°, +0·101°, and −0·138°; and the electrical conductivities of soln. with 12·49, 18·32, and 19·67 mols $KMoO_4$ per litre are, respectively, 85·4, 90·5, and 92·1. W. Muthmann and W. Nagel prepared **rubidium pertrimolybdate,** $Rb_2O.2MoO_3.MoO_4.3H_2O$, from the mother-liquor of the 3 : 10-salt. The lemon-yellow, monoclinic crystals effloresce in air.

W. Muthmann and W. Nagel prepared **rubidium pertetramolybdate,** $Rb_2O.3MoO_3.MoO_4.4H_2O$, by allowing a dil. soln. of rubidium trimolybdate in 5 per cent. hydrogen dioxide to stand for some time. Pale, lemon-yellow crystals are formed. A hot soln. of cæsium tetramolybdate in 25 per cent. hydrogen dioxide gives orange-red, amorphous **cæsium pertetramolybdate,** $Cs_2O.4MoO_4.6H_2O$. When the soln. in hot water is rapidly cooled, it deposits the salt unchanged.

W. Muthmann and W. Nagel digested 10 grms. of anhydrous rubidium trimolybdate with 30 c.c. of warm, 25 per cent. hydrogen dioxide, and allowed the liquid to stand over sulphuric acid for 24 hrs. The resulting yellowish-red, amorphous mass of **rubidium perdecamolybdate,** $3Rb_2O.10MoO_4.14H_2O$, was washed with alcohol and ether. The evaporation of the mother-liquor obtained in the preparation of cæsium pertetramolybdate furnished yellow crystals of **cæsium perdecamolybdate,** $3Cs_2O.7MoO_3.3MoO_4.4H_2O$.

§ 17. Molybdenum Fluorides

J. J. Berzelius[1] obtained an aq. soln. of **molybdenum trifluoride** by dissolving hydrated molybdic oxide in hydrofluoric acid; the liquid forms a sticky, soluble, purple-red mass when evaporated, and when heated becomes brown and is then no longer soluble in water. Neither the anhydrous salt nor a hydrate has been obtained solid. A. Rosenheim and H. J. Braun added ammonium fluoride to a soln. of potassium molybdenum fluoride in hydrochloric acid, and obtained **ammonium molybdenum tetrafluoride,** $(NH_4)MoF_4.H_2O$, as a violet precipitate, which is more soluble than the potassium salt, and is hydrolyzed by water. If the violet soln. of this salt is allowed to stand over sulphuric acid, bluish-violet crystal plates of

ammonium molybdenum enneafluoride, $2MoF_3.3NH_4F$, or $(NH_4)_3Mo_2F_9$, are formed. This salt is readily hydrolyzed by water. J. J. Berzelius observed that a rose-red precipitate is formed when potassium fluoride is added to a soln. of molybdenum trifluoride. By electrolyzing soln. of molybdenum trioxide in conc. hydrofluoric acid, using a mercury cathode and adding the alkali fluorides to the soln., A. Rosenheim and T. H. Li prepared ammonium molybdenum enneafluoride, $(NH_4)_3Mo_2F_9.2H_2O$, as well as **potassium molybdenum enneafluoride,** $K_3Mo_2F_9.2H_2O$. A. Rosenheim and H. J. Braun obtained **potassium molybdenum tetrafluoride,** $KMoF_4.H_2O$, by the electro-reduction of a soln. of molybdenum trioxide in hydrochloric acid, and adding potassium fluoride to the liquor. The violet crystalline precipitate is gradually decomposed by water. It was not possible to prepare **sodium molybdenum tetrafluoride** pure enough to justify analysis.

J. J. Berzelius obtained a red soln. of **molybdenum tetrafluoride,** MoF_4, by the action of hydrofluoric acid on hydrated molybdenum dioxide. When slowly evaporated, the liquid becomes blue if the acid is not in excess, and it leaves a black crystalline residue which forms a red soln. with water. It is decomposed if more strongly heated. The blue molybdenum oxide gives a blue soln. with hydrofluoric acid, which does not crystallize. Complex salts have not been reported; although J. J. Berzelius observed that a precipitate is formed when potassium fluoride is added to the soln.

According to O. Ruff and F. Eisner,[2] they could not prepare **molybdenum pentafluoride,** MoF_5; but **molybdenum hexafluoride,** MoF_6, can be obtained by the action of hydrogen fluoride on molybdenum pentachloride, as well as from molybdenum pentachloride and antimony pentafluoride. It is best obtained by the action of fluorine on finely-divided molybdenum at 60° to 70°, and collecting the product in a glass receiver at −70°. It can be purified by redistillation. The white crystalline mass has a m.p. of 17°, and a b.p. of 35° at 760 mm. It is not affected by air. It is easily reduced to a blue fluoride; the presence of dust from the air is sufficient for this purpose. It forms a colourless soln. with an excess of water; moist air, or a little water, forms a blue molybdenum oxide. The salt does not react with chlorine; but with iodine it forms a brown product; it forms an orange product with sulphur; and it is indifferent towards sulphur dioxide. It reacts vigorously with gaseous ammonia, forming a brown powder. It is absorbed by aq. ammonia; with phosphorus it forms a pale blue substance, and it reacts with phosphorus trichloride and with phosphoryl chloride; it forms yellowish-brown crystals with arsenic trichloride; and it also reacts with antimony pentachloride. It is reduced by organic substances—like paraffin, blotting paper, animal skin, etc.—and becomes indigo-blue. Metals—copper, lead, iron, etc.—react forming coloured substances; but gold, and platinum have no action. It is absorbed by alkali-lye, and forms complex salts with alkali fluorides, but they have not been described. N. V. Sidgwick discussed the electronic structure of this salt.

§ 18. Molybdenum Oxyfluorides

W. Wardlaw and R. L. Wormell[1] prepared a salt of tervalent molybdenum, namely, molybdenyl fluoride, $MoOF.3\frac{1}{2}H_2O$, or $MoOF.4H_2O$, by double decomposition of the oxychloride with ammonium fluoride in an air-free, aq. soln. The insoluble, buff-coloured precipitate has similar properties to the corresponding chloride and bromide, [$MoOR.4H_2O$]. The solubility, and ease of hydrolysis increase with increasing at. wt. of the halogen atom. The univalent molybdenyl radical, MoO, appears to persist in aq. soln. The oxygen atom seems to be firmly attached to the molybdenum nucleus and the whole behaves like a univalent metal. This conception is supported by the existence of other insoluble molybdenyl salts, such as the benzoate, phosphate, salicylate.

The salt of quinquevalent molybdenum, **molybdenum oxytrifluoride,** $MoOF_3$, has not been prepared. There is some doubt whether the **molybdenum trioxytetrafluoride,** $Mo_2O_3F_4$, of E. F. Smith and V. Oberholtzer contains quinquevalent or sexivalent molybdenum. It was obtained in red, needle-like crystals, by the action of hydrogen fluoride on molybdenum trioxide at 300° to 400°. It attacks glass; and gradually decomposes, forming blue oxide. It is deliquescent, and easily soluble in hydrofluoric acid, but not in water. Indications of other products were obtained.

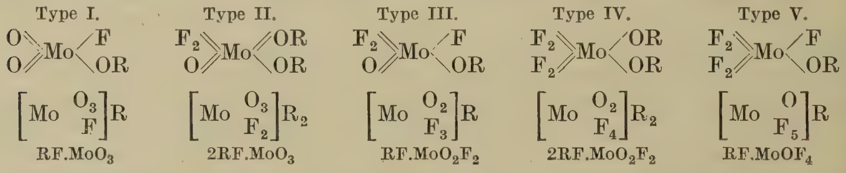
Although molybdenum oxytrifluoride is unknown, a number of complex salts has been prepared. These are of two types: $5RF.3MoOF_3$, and $2RF.MoOF_3$. F. Mauro found that a soln. of ammonium molybdenum oxypentafluoride in hot hydrofluoric acid, when concentrated and cooled, furnishes sky-blue needles of **ammonium molybdenum trioxytetradecafluoride,** $5NH_4F.3MoOF_3.H_2O$, which, under the microscope, appear as hexagonal crystals. The salt is decomposed by water, and acts as a reducing agent. The crystals are isomorphous with the corresponding sexivalent salt, $5NH_4F.3MoO_2F_2.H_2O$. The analogous **potassium molybdenum trioxytetradecafluoride,** $5KF.3MoOF_3.H_2O$, was prepared in a similar manner.

F. Mauro and R. R. Panebianco dissolved molybdenum dioxide in hydrofluoric acid and added ammonia until the soln. became brownish-red; hydrofluoric acid was then added until the soln. became green. The liquid was then evaporated when sky-blue plates of **ammonium oxypentafluomolybdate,** $2NH_4F.MoOF_3$, or $(NH_4)_2[MoOF_5]$, were formed. A soln. of this salt was also obtained by the electrolysis of $2NH_4F.MoO_2F_2$. E. Scacchi gave for the axial ratios of the rhombic bipyramids $a:b:c=0·4214:1:1·0260$. The crystals are isomorphous with those of $2NH_4F.MoO_2F_2$. L. P. Liechti and B. Kempe observed that the addition of molybdenum pentachloride to a soln. of potassium fluoride gives a precipitate presumably **potassium oxypentafluomolybdate,** $2KF.MoOF_3.H_2O$, a salt obtained by F. Mauro by adding potassium fluoride to a soln. of hydrated molybdenum dioxide in hydrofluoric acid; and also by the electrolysis of a soln. of $2KCl.MoO_2F_2$. E. Scacchi gave for the axial ratios of the monoclinic prisms, $a:b:c=0·9997:1:1·0320$, and $\beta=99° 4'$. The (010)-cleavage is indistinct. F. Mauro added that the salt changes very little on exposure to air, and when heated, it gives off water, etc., forming normal potassium molybdate. The salt is decomposed by water or dil. hydrochloric acid, but not by dil. hydrofluoric acid. It reduces soln. of salts of copper, silver, and gold. F. Mauro also prepared **copper molybdenum pentafluomolybdate,** $CuF_2.MoOF_3.4H_2O$, in blue, six-sided monoclinic plates which, according to E. Scacchi, have the axial ratios $a:b:c=1·4745:1:1·0929$, and $\beta=85° 43'$, and are isomorphous with $CuF_2.MoO_2F_2.4H_2O$. The salt can be crystallized unchanged from hydrofluoric acid; but it is decomposed by water. Likewise also with **zinc molybdenum oxypentafluomolybdate,** $ZnF_2.MoOF_3.6H_2O$, which furnishes blue, deliquescent trigonal crystals isomorphous with $ZnF_2.MoO_2F_2.6H_2O$, and with the axial ratio $a:c=1:0·5136$. F. Mauro also prepared **thallous molybdenum oxypentafluomolybdate,** $2TlF.MoOF_3$, in dark green rhombic bipyramids with the axial ratios $a:b:c=0·4329:1:1·0295$. The salt begins to decompose at 240°.

O. Ruff and F. Eisner[2] said that **molybdenum oxytetrafluoride,** $MoOF_4$, is formed in the action of fluorine on a molybdenum oxide; and they prepared it by distilling hydrogen fluoride into a well-cooled vessel containing molybdenum oxytetrafluoride; the product is warmed to 30°, and, when the reaction is ended, it is distilled from a sulphuric acid bath at 230°. The white, hygroscopic solid becomes blue when exposed to air, and deliquesces. Its sp. gr. is 3·001 at 20°; it sinters at 96°; melts at 97° to 98° and boils at about 180°. It dissolves with a hissing noise in water, and forms a colourless soln.; and similarly with alcohol. When the aq. soln. is evaporated, molybdenum trioxide remains. The salt dissolves with the evolution of a gas in chloroform and ether, forming green or yellow soln.; it is sparingly soluble in benzene, and carbon disulphide; and insoluble in toluene. It is reduced by soln. of organic substances. With sulphuric acid it forms a colourless soln. giving off hydrogen fluoride; and it gives brown soln. with phosphorus trichloride, phosphoryl chloride, arsenic trichloride, sulphur monochloride, and pyridine. G. Marchetti observed that when potassium molybdate, or potassium dioxytetrafluomolybdate is treated with conc. hydrofluoric acid, it furnishes **potassium oxypentafluomolybdate,** $KF.MoOF_4$, or $K[MoOF_5]$, or

$$\begin{matrix}F_2\\F_2\end{matrix}\!>\!\mathrm{Mo}\!<\!\begin{matrix}F\\OK\end{matrix}$$

J. J. Berzelius[3] found that molybdenum trioxide dissolves freely in hydrofluoric acid, forming a colourless soln. which has a sour, and metallic taste; the liquid shows no signs of crystallization when it is evaporated, and it acquires a green or blue tinge owing to reduction by particles of organic dust. The dried mass is only partially soluble in water; the insoluble portion consists of molybdenum trioxide mixed with a little fluoride. H. O. Schulze observed that molybdic acid reacts with metal fluorides, forming **molybdenum dioxydifluoride,** MoO_2F_2; whilst O. Ruff and F. Eisner obtained it by the action of hydrogen fluoride on molybdenum dioxydichloride as in the case of the preparation of the oxytetrafluoride (*q.v.*). The white crystalline sublimate has a faint blue tinge; it has a sp. gr. 3·494 at 19°; it begins to sublime at 265°, and at 271° sublimation rapidly occurs. It is very hygroscopic, and in moist air it forms hydrofluoric and molybdic acids. It forms a colourless soln. with water; if only a small proportion of water is used, the soln. is blue. It is also soluble in methyl and ethyl alcohols; sparingly soluble in chloroform, carbon tetrachloride, and ether; and insoluble in toluene. The hot soln. in pyridine deposits on cooling a white, microcrystalline substance. It is soluble in sulphuryl chloride, phosphorus and arsenic trichlorides; and in silicon tetrachloride—when these soln. are warmed, a gas is developed. A number of **oxyfluomolybdates** has been prepared. Starting from the normal molybdate, $(RO)_2MoO_2$, there are:



Type I.	Type II.	Type III.	Type IV.	Type V.
$\begin{matrix}O\\O\end{matrix}\!>\!\mathrm{Mo}\!<\!\begin{matrix}F\\OR\end{matrix}$	$\begin{matrix}F_2\\O\end{matrix}\!>\!\mathrm{Mo}\!<\!\begin{matrix}OR\\OR\end{matrix}$	$\begin{matrix}F_2\\O\end{matrix}\!>\!\mathrm{Mo}\!<\!\begin{matrix}F\\OR\end{matrix}$	$\begin{matrix}F_2\\F_2\end{matrix}\!>\!\mathrm{Mo}\!<\!\begin{matrix}OR\\OR\end{matrix}$	$\begin{matrix}F_2\\F_2\end{matrix}\!>\!\mathrm{Mo}\!<\!\begin{matrix}F\\OR\end{matrix}$
$\left[\mathrm{Mo}\begin{matrix}O_3\\F\end{matrix}\right]R$	$\left[\mathrm{Mo}\begin{matrix}O_3\\F_2\end{matrix}\right]R_2$	$\left[\mathrm{Mo}\begin{matrix}O_2\\F_3\end{matrix}\right]R$	$\left[\mathrm{Mo}\begin{matrix}O_2\\F_4\end{matrix}\right]R_2$	$\left[\mathrm{Mo}\begin{matrix}O\\F_5\end{matrix}\right]R$
$RF.MoO_3$	$2RF.MoO_3$	$RF.MoO_2F_2$	$2RF.MoO_2F_2$	$RF.MoOF_4$

Representatives of Type I have not been obtained; and Type V has been discussed above. Type II is represented by **ammonium trioxydifluomolybdate,** $NH_4[MoO_3F_2]$, or $2NH_4F.MoO_3$, which F. Mauro[4] obtained by mixing a soln. of the dioxypentafluomolybdate with ammonia. The precipitate is dissolved in a hot ammoniacal soln. of ammonium fluoride, and the soln. evaporated spontaneously in air or over sulphuric acid. The rhombic bipyramids were found by A. Scacchi to have the axial ratios $a:b:c=0·5746:1:0·6771$; and to exhibit twinning and trilling. U. Alvisi found that the salt is insoluble in water, and, added F. Mauro, water decomposes the salt. It is not changed at 100°, but at a higher temp. decomposition sets in. F. Mauro prepared **thallous dioxytrifluomolybdate,** $Tl[MoO_2F_3]$, or $TlF.MoO_2F_2$, from a soln. of the dioxytetrafluomolybdate in conc. hydrofluoric acid. The salt begins to decompose at 240°. A. Scacchi found that the monoclinic prisms have the axial ratios $a:b:c=0·6199:1:1·3976$, and $\beta=93° 53'$, and are isomorphous with the ammonium salt.

Type III is represented by **ammonium dioxytrifluoride,** $NH_4[MoO_2F_3]$, or $NH_4F.MoO_2F_2$, prepared by F. Mauro by evaporating over sulphuric acid a hydrofluoric acid soln. of the hexoxyhenafluomolybdate, and U. Alvisi, by the action of hydrofluoric acid on 1 : 24-phosphomolybdic acid or its ammonium salt. The colourless, monoclinic prisms were found by A. Scacchi to have the axial ratios $a:b:c=0\cdot6302:1:0\cdot4255$, and $\beta=94° 7'$, and to be isomorphous with the thallium salt. The salt turns green on exposure to air. M. Delafontaine described a *hydrate,* $NH_4F.MoO_2.H_2O$, obtained in rhombic crystals by the action of hydrofluoric acid on dioxytetrafluomolybdate, or an acid ammonium molybdate. The form of the crystals is the same as that of the dioxypentafluomolybdate, and M. Delafontaine's determination of the contained molybdenum applies to either salt, hence F. Mauro believed that M. Delafontaine's hydrate is really the dioxypentafluomolybdate. M. Delafontaine also reported prismatic crystals of **potassium dioxytrifluomolybdate,** $K[MoO_2F_3].H_2O$, or $KF.MoO_2F_2.H_2O$, to be formed by the action of hydrofluoric acid on an acid potassium molybdate, or the dioxytetrafluomolybdate. G. Marchetti could not prepare this salt, and he regarded the product as a mixture of the dioxytetrafluomolybdate with another salt as well as $KF.MoOF_4$. There are similar doubts about M. Delafontaine's **rubidium dioxytrifluomolybdate,** $RbF.MoO_2F_2.H_2O$.

Type IV is represented by **ammonium dioxytetrafluomolybdate,** $2NH_4F.MoO_2F_2$, or $(NH_4)_2[MoO_2F_4]$, prepared by F. Mauro by evaporating a soln. of ammonium trioxydifluomolybdate, and U. Alvisi obtained it from the mother-liquid obtained in the preparation of this salt. The colourless plates or prisms are isomorphous with the corresponding oxyfluocolumbate and oxyfluotungstate. The rhombic bipyramids were found by A. Scacchi to have the axial ratios $a:b:c=0\cdot4207:1:0\cdot0164$. F. Mauro found that the salt is unchanged at 100°, but is decomposed at a higher temp. It is freely soluble in water, and the evaporation of the aq. soln. gives the salt unchanged. M. Delafontaine reported that the monohydrate is produced by evaporating a soln. of ammonium paramolybdate in hydrofluoric acid and ammonium fluoride. The crystals are said to be triclinic like the analogous potassium salt with which they are isomorphous. It is rather more soluble than the potassium salt. By evaporating a soln. of ammonium dioxytetrafluomolybdate or trioxydifluomolybdate in ammonia over sulphuric acid or in air, F. Mauro obtained octahedral crystals of **ammonium trioxytrifluomolybdate,** $(NH_4)_2O.NH_4F.MoO_2F_2$, or $MoO_3.3NH_4F$, or $F_3Mo(ONH_4)_3$, or $(NH_4)_3[MoO_3F_3]$; these crystals are isomorphous with the corresponding tungstate. They are stable at 100°, and when roasted furnish molybdenum trioxide. The salt can be crystallized unchanged from its aq. soln. L. Pauling found that there are four molecules per unit face-centred, cubic lattice. The space-lattice has $a=9\cdot10$ A., and the interatomic distances Mo to $F=1\cdot9$ A., and F to F, 5·3 A. The octahedral cleavage is perfect.

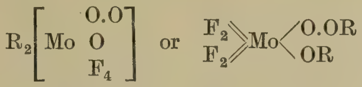
M. Delafontaine prepared **sodium dioxytetrafluomolybdate,** $Na_2[MoO_2F_4].\frac{1}{2}H_2O$, or $2NaF.MoO_2F_2.\frac{1}{2}H_2O$, from a soln. of normal sodium molybdate in a small excess of hydrofluoric acid. The crystals lose their water when heated in a closed vessel; and are decomposed when heated in air forming normal sodium molybdate. J. J. Berzelius mixed potassium fluoride with a soln. of molybdenum trioxide in hot hydrofluoric acid, and obtained a precipitate of what was probably **potassium dioxytetramolybdate,** $K_2[MoO_2F_4].H_2O$, or $2KF.MoO_2F_2.H_2O$; G. Marchetti added the theoretical proportion of potassium hydroxide instead of the fluoride; J. J. Berzelius, and M. Delafontaine obtained the salt from a soln. of normal potassium molybdate in a small excess of hydrofluoric acid; and U. Alvisi, from a soln. of potassium hydrofluoride and 1 : 24-phosphomolybdic acid. The tabular or scaly crystals were said by J. J. Berzelius to resemble the crystals of boric acid, and those of the corresponding tungsten salt; M. Delafontaine also noted their resemblance to those of the oxyfluo-columbates, titanates, and tungstates; the crystals were said to be triclinic, but A. Scacchi showed that they are monoclinic prisms with the axial ratios $a:b:c=1\cdot0006:1:0\cdot9994$, and $\beta=103° 29'$. G. Marchetti said that the anhydrous salt is obtained by heating the hydrate to 100° ; or by crystallization from a soln. in hot hydrofluoric acid. M. Delafontaine, and J. J. Berzelius said that the crystals are stable in air ; and they lose about 6 per cent. of water at about 60° ; and they melt without further decomposition when heated, forming a yellowish-brown mass. When roasted in air, normal potassium molybdate is formed. Hydrofluoric acid is given off when the salt is heated with conc. sulphuric acid. The salt dissolves freely in boiling water, and the cooling soln. deposits the unchanged crystals.

F. Mauro prepared **copper dioxytetrafluomolybdate,** $CuF_2.MoO_2F_2.4H_2O$, or $Cu[MoO_2F_4].4H_2O$, by evaporating a hydrofluoric acid soln. of a mol each of copper oxide and molybdenum trioxide. The pale blue monoclinic plates were found by A. Scacchi to have the axial ratios $a:b:c=1·4828:1:1·0987$, and $\beta=85° 9'$, and to be isomorphous with the corresponding copper oxyfluotungstate and columbate, as well as with the copper fluosilicate, titanate and stannate. F. Mauro said the salt is stable in dry air ; in moist air, water is absorbed ; at 115°, it loses its water and becomes pale green ; and at 130°, the evolution of hydrofluoric acid begins. M. Delafontaine prepared **zinc dioxytetrafluomolybdate,** $Zn[MoO_2F_4].6H_2O$, or $ZnF_2.MoO_2F_2.6H_2O$, by evaporating a hydrofluoric acid soln. of eq. proportions of zinc oxide and molybdenum trioxide. The trigonal prisms have the axial ratio $a:c=1:0·5166$, and the salt is isomorphous with the oxypentafluomolybdate and columbates of magnesium, zinc, cadmium, manganese, cobalt, and nickel, and with the corresponding fluosilicates, fluotitanates, and fluostannates. H. Grimm studied the miscibility of these crystals with those of zinc fluostannate. B. Gossner gave 2·151 for the sp. gr. When roasted, normal zinc molybdate is formed. M. Delafontaine also prepared **cadmium dioxytetrafluomolybdate,** $Cd[MoO_2F_4].6H_2O$, or $CdF_2.MoO_2F_2.6H_2O$, as in the case of the zinc salt. The trigonal prisms have the axial ratio $a:c=1:0·5159$. M. Delafontaine prepared **thallous dioxytetrafluomolybdate,** $Tl_2[MoO_2F_4]$, or $2TlF.MoO_2F_2$, by the double decomposition of thallous sulphate and potassium dioxytetrafluomolybdate, or from a hydrofluoric acid soln. of normal thallous molybdate, or eq. proportions of thallous oxide and molybdenum trioxide. M. Delafontaine said that it is monohydrated, and F. Mauro that it is anhydrous. It does not lose in weight at 200° ; but when roasted in air, it forms normal thallous molybdate. A. Scacchi found that the rhombic bipyramids have the axial ratios $a:b:c=0·4276:1:1·0247$. M. Delafontaine prepared dark red, hexagonal crystals of **cobalt dioxytetrafluomolybdate,** $Co[MoO_2F_4].6H_2O$, or $CoF_2.MoO_2F_2.6H_2O$, which are stable in dry air ; and **nickel dioxytetrafluomolybdate,** $Ni[MoO_2F_4].6H_2O$, or $NiF_2.MoO_2F_2.6H_2O$.

F. Mauro reported **ammonium hexoxyhenafluomolybdate,** $5NH_4F.3MoO_2F_2.H_2O$, to be formed by the evaporation of the hydrofluoric acid soln. of ammonium dioxytetrafluo- or trioxydifluo-molybdate. The colourless, six-sided, hexagonal prisms soon become opaque in air ; they lose part of their water at 100°, and at a higher temp., they decompose. The aq. soln. has an acidic reaction ; and gives off hydrofluoric acid when heated. F. Mauro also prepared **ammonium dioxypentafluomolybdate,** $3NH_4F.MoO_2F_2$, or $(NH_4)_3Mo.O_2F_5$, by evaporating soln. of ammonium paramolybdate in an excess of hydrofluoric acid and ammonium fluoride. The colourless, rhombic prisms were found by A. Scacchi to have the axial ratios $a:b:c=0·5452:1:0·8767$. F. Mauro observed that the salt decomposes when heated ; it dissolves in water with an acidic reaction ; and A. Miolatti and U. Alvisi showed that the electrical conductivity of the aq. soln. indicates that the salt is hydrolyzed. The eq. conductivity, λ, of a soln. with $(3NH_4F.MoO_2F_2)$ in v litres :

v . .	32	64	128	256
λ . .	107·5	117·9	133·4	143·2

There is a series of salts—the **oxyfluopermolybdates**—which is related to the oxyfluomolybdates much as the permolybdates are related to the molybdates. They were prepared by A. Piccini[5] by the action of hydrogen dioxide on the oxyfluomolybdates. They can be regarded as oxyfluomolybdates in which an oxygen atom is replaced by a bivalent C·O-group:



$$R_2\left[Mo\begin{matrix}O.O\\O\\F_4\end{matrix}\right]$$

The yellow salts crystallize well, and are stable. Their aq. soln. give the typical reaction of hydrogen dioxide. A. Piccini prepared **ammonium trioxypentafluomolybdate,** $3NH_4F.MoO_3F_2$, or $(NH_4)_3[MoF_5O(O_2)]$, by evaporating a soln. of ammonium paramolybdate and fluoride in hydrogen dioxide and hydrofluoric acid; or by treating ammonium dioxypentafluoride with hydrogen dioxide. The yellow prisms or plates become opaque in air; they are not changed at 100°; they are very soluble in water; and in platinum vessels, the aq. soln. decomposes with the evolution of oxygen.

A. Piccini prepared **potassium trioxytetrafluopermolybdate,** $F_4Mo(OOK)(OK).H_2O$, or $K_2[F_4MoO(O_2)].H_2O$, by cooling a warm 4 per cent. soln. of hydrogen dioxide soln. of the dioxytetrafluomolybdate, and recrystallizing the product from dil. hydrogen dioxide. The yellow, monoclinic plates have the axial ratios $a : b : c = 0{\cdot}9958 : 1 : 0{\cdot}9780$, and $\beta = 102° 13'$. The crystals are isomorphous with those of the rubidium salt, with the corresponding tungstate, as well as with those of the dioxytetrafluomolybdate and oxypentafluomolybdate. The (010)-cleavage is incomplete. The salt is stable in air; it loses some water at 100°; and at 150°, it gives off oxygen; and at a higher temp., it forms normal potassium molybdate. It gives off no fluorine if dry in vacuo. It is sparingly soluble in cold water, and freely soluble in hot water; and it separates unchanged from its aq. soln., and its soln. in hydrofluoric acid. According to A. Mazzucchelli and C. Barbero, a mol of the salt in 15 litres of water has an oxidation potential 0·881 to 0·933 volt with platinum electrodes; and after the addition of an equal vol. of a soln. of potassium dioxytetrafluomolybdate of the same concentration, the oxidation potential is 0·872 to 0·920 volt. If a mol of this salt be treated with 4 mols of hydrogen dioxide, P. Kasanetzky found that microscopic, rhombic crystals of **potassium pentoxydifluopermolybdate,** $K_2[F_2MoO_3(O_2)].H_2O$, are formed. With the continued action of hydrogen dioxide, all the fluorine is displaced, and potassium permolybdate is formed. A. Piccini prepared **rubidium trioxytetrafluopermolybdate,** $Rb_2[F_4MoO(O_2)].H_2O$, or $F_4Mo(ORb)(OORb).H_2O$, by mixing a soln. of rubidium chloride in hydrogen dioxide with a soln. of molybdenum trioxide in hydrofluoric acid, and recrystallizing the product from a soln. of hydrogen dioxide. The yellow, monoclinic plates have the axial ratios $a : b : c = 1{\cdot}0260 : 1 : 0{\cdot}9938$, and $\beta = 102° 15'$. This salt is isomorphous with the corresponding potassium salt; but is more easily soluble, otherwise, it behaves like the potassium salt. A. Piccini also prepared **cæsium trioxytetrafluopermolybdate,** $Cs_2[F_4MoO(O_2)].H_2O$, or $F_4Mo(OCs)(OOCs).H_2O$, as in the case of the rubidium salt with which it is quite similar.

§ 19. Molybdenum Chlorides

Five chlorides of molybdenum have been reported in which the molybdenum is bi-, ter-, quadri-, quinque-, and sexivalent. L. F. Svanberg and H. Struve,[1] and C. J. Keyser prepared **molybdous chloride,** or **molybdenum dichloride,** $MoCl_2$, containing bivalent molybdenum. The compound was investigated by C. W. Blomstrand, and A. Atterberg. The analyses by C. W. Blomstrand, and by L. P. Liechti and B. Kempe agree with the empirical formula $MoCl_2$, but the mol. wt. calculated from its effect on the b.p. of alcohol was found by W. Muthmann and W. Nagel to agree with the formula $(MoCl_2)_3$, or Mo_3Cl_6. C. W. Blomstrand also interpreted the chemical behaviour to agree best with the assumption that the bivalent molybdenum forms the polymerized chloride, Mo_3Cl_6. He prepared it by heating the trichloride in a current of dry carbon dioxide, and L. P. Liechti and B. Kempe, and W. Muthmann and W. Nagel showed that it is necessary to exclude air and moisture, and to regulate the temp. carefully. C. W. Blomstrand also prepared the dichloride by heating a mixture of molybdenum and mercurous chloride—a large proportion of trichloride is formed at the same time ; by passing chlorine, largely diluted with carbon dioxide over the moderately-heated metal ; and as a by-product in the preparation of molybdenum pentachloride. According to K. Lindner and co-workers, the best method of preparation is to pass carbonyl chloride vapour over the powdered metal heated between 600° and 620°. The result at 400° is to form some trichloride which does not volatilize ; at 490°, the boat contains some trichloride, and a little trichloride sublimes ; at 520°, the boat contains both di- and trichlorides, and some of the latter sublimes ; at 590°, the boat contains the dichloride, and the tri- and pentachlorides sublime ; at 610° and 620°, the boat contains the dichloride, and the sublimate a little pentachloride ; at 670°, the boat contains some dichloride, and molybdenum pentachloride sublimes ; and between 700° and 1000°, there is a sublimate of the pentachloride. The heavy yellow layer of the dichloride which forms on the molybdenum protects the metal from attack by the carbonyl chloride. The dichloride is then extracted with conc. hydrochloric acid and the residual metal is again treated with carbonyl chloride. The compound, $HMo_3Cl_7.4H_2O$, separates almost quantitatively from the acid soln. in the form of long, yellow needles. Less favourable but useful results are obtained by the reduction of molybdenum pentachloride with finely-divided aluminium in the presence of ignited quartz powder (to moderate the violence of the reaction). The product is subsequently extracted with hydrochloric acid. The yield is considerably diminished by the reduction of molybdenum pentachloride to other chlorides. The dichloride prepared by C. W. Blomstrand was amorphous, and matte ; and, according to L. P. Liechti and B. Kempe, after treatment with nitric acid, it is yellow. C. J. Keyser, and C. W. Blomstrand said that it is stable in air, and very difficult to volatilize. W. Biltz and C. Fendius gave 3·714 for the sp. gr. at 25°/4°, and 44·9 for the mol. vol. L. P. Liechti and B. Kempe found that when heated in air, it gives a sublimate of molybdenum trioxide and a black residue, which, on continued roasting, also volatilizes as molybdenum trioxide. When heated in hydrogen, the dichloride is reduced to the metal. C. J. Keyser, and C. W. Blomstrand said that the dichloride is insoluble in water ; but it dissolves easily and completely in hydrochloric, and the other halogen acids ; it is also soluble in sulphuric acid. L. P. Liechti and B. Kempe found that aq. ammonia dissolves the dichloride, and then transforms it into a brown, nitrogenous powder. The dichloride dissolves in alcohol, and ether without undergoing chemical action. K. Lindner and co-workers observed that when a sat. alcoholic soln. of the dichloride is mixed with twice its vol. of ether, ice-cold, and treated with ammonia gas, a pale yellow, voluminous precipitate of **molybdenous diamminochloride,** $Mo_3Cl_6(NH_3)_2.2C_6H_5OH$, is formed. It decomposes at 100°. When molybdenous dichloride is dissolved in ether containing 5 per cent. of ethyl alcohol, and the soln. evaporated in vacuo, the compound $Mo_3Cl_6.C_2H_5OH$ remains as light yellow powder stable in air; the alcohol cannot be removed by heating in an inert atmosphere without decomposition. Addition of alcoholic silver nitrate to the alcoholic soln. precipitates silver chloride; the mother-liquor deposits the compound $Mo_3Cl_4(NO_3)_2.EtOH$ on keeping, but on immediate treatment of the filtrate with ether, the nitrate, $Mo_3Cl_4(NO_3)_2$, is obtained. W. Hampe found that an ethereal soln. of the dichloride does not conduct the electric current; the alcoholic soln. conducts a little, probably in consequence of the formation of a little hydrochloric acid. Hydrogen is liberated from the cathode, and a black oxide is gradually deposited. W. Muthmann and W. Nagel added that the electrolysis of a soln. in 96 per cent. alcohol furnishes hydrogen and molybdenum tetrachlorodihydroxide at the cathode, and at the anode, aldehyde and ethyl chloride. C. W. Blomstrand, and K. Wolf found that a soln. of potassium or sodium hydroxide dissolves the dichloride forming a yellow soln.; and with boiling alkali-lye, molybdenum dihydroxide, $Mo(OH)_2$, is formed. The yellow soln. in alkali-lye slowly absorbs carbon dioxide from the air, and when carbon dioxide is passed through the soln., or acetic acid is added, molybdenum tetrachlorodihydroxide is formed.

C. W. Blomstrand, and A. Atterberg supposed that molybdous chloride contained the group Mo_3Cl_4. This is evidenced by the products obtained by C. W. Blomstrand by the action of strong acids on molybdous chloride, namely $(Mo_3Cl_4)X_2$, where X represents Cl, Br, or I, associated with ammonium or potassium halide; and by the various mixed salts obtained by C. W. Blomstrand, and A. Atterberg, namely, $Mo_3Br_4X_2.nH_2O$, where X_2 denotes F_2, Cl_2, Br_2, I_2, MoO_4, SO_4, CrO_4, $(H_2PO_4)_2$, and C_2O_4. According to I. Koppel, the bivalency of the contained molybdenum is illustrated by the development of hydrogen when the bromide $Mo_3Br_4(OH)_2$ is treated with alkali-lye; and by the precipitation of silver from an ammoniacal silver soln. when treated with $(Mo_3Cl_4)HCl.4H_2O$. The effect of the salt on the b.p. of alcohol agrees with the formula $(MoCl_2)_3$. The electrical conductivity of soln. of all the soluble derivatives is explained by assuming that the Mo_3Cl_4 is usually the cation, and hydrolysis proceeds as far as the Mo_3Cl_4-group. The dehydration phenomenon supports the same hypothesis. The radicle Mo_3Cl_4 is amphoteric acting either as a basic or as an acidic radicle. I. Koppel also emphasized the great stability of the Mo_3Cl_4-radicle; and the resistance it offers to oxidation. These results are in accord with some hypothesis analogous to A. Werner's co-ordination theory. This subject was discussed by K. Lindner, and W. Biltz.

C. W. Blomstrand said that a *trihydrate*, $Mo_3Cl_6.3H_2O$, is deposed in pale, yellow, insoluble scales from a soln. of the anhydrous chloride in moderately dilute hydrochloric acid. If a soln. in hot hydrochloric acid be evaporated on a water-bath, pale yellow needles or prisms are formed; these are soluble in water, alcohol, and ether. The compound was regarded by C. W. Blomstrand as a *hexahydrate*, $Mo_3Cl_6.6H_2O$; by L. P. Liechti and B. Kempe, as a *hemienneahydrate*, $Mo_3Cl_6.4\frac{1}{2}H_2O$; and by A. Rosenheim and F. Kohn, as $Mo_3Cl_3.HCl.4H_2O$. The last hypothesis is confirmed by the fact that when exposed to air, the crystals lose hydrogen chloride and become green, but the yellow colour is restored in an atmosphere of hydrogen chloride. The reaction with an ammoniacal soln. of silver is in agreement with the bivalency of the contained molybdenum. When this compound is heated at 100° or 130° in an atm. of hydrogen chloride, a yellow residue of the *monohydrate*, $Mo_3Cl_6.H_2O$, is formed. The compound $Mo_3Cl_6.HCl.4H_2O$ behaves as if it were **chloroaquomolybdous acid,** $H[Mo_3Cl_7(H_2O].3H_2O$. Water removes only one atom of chlorine, but when a soln. in potash-lye is treated with acetic acid, **molybdous diaquotetrachlorodihydroxide,** $Mo_3Cl_4(OH)_2.8H_2O$, or $[Mo_3Cl_4(H_2O_2)](OH)_2.6H_2O$, is precipitated. This formula is based on the fact that when heated to 100°, six mols. of water are given off; another mol. is given off below 300°; and the final product which resists further dehydration has the composition of **molybdous diaquotetrachloroxide,** $[Mo_3Cl_4(H_2O)_2]O$. Again, when treated with hydrobromic acid, the hydroxide furnishes chlorobromides—*vide infra*—K. Lindner discussed the constitution of these compounds.

Hydrolysis occurs when either of the compounds $Mo_3Cl_6.H_2O$ or $H[Mo_3Cl_7(H_2O)].3H_2O$ is treated with water. The latter, for instance, forms a yellow soln. with the minimum quantity of cold water necessary for soln., and in a few seconds, a crystalline separation occurs forming a product with Mo : Cl=3 : 6. The product is represented as **molybdenum tetrachlorodiaquodichloride,** $[Mo_3Cl_4(H_2O)_2]Cl_2.2H_2O$; and when dehydrated, $[Mo_3Cl_4(H_2O)_2]Cl_2$, in which two of the six chlorine atoms are ionizable and replaceable by other anions. When chloroaquomolybdous acid is treated with more water, say 50 c.c. of water per 0·3 grm. of the substance, an amorphous precipitate is formed with Mo : Cl=3 : 5—**molybdenum hydroxypentachloride,** $Mo_3Cl_5(OH)$; and with a large proportion of boiling water, the amorphous precipitate has Mo : Cl=3 : 4—molybdenum diaquotetrachlorodihydroxide, $[Mo_3Cl_4(H_2O)_2](OH)_2.6H_2O$, indicated above. Ethyl alcohol also forms the 3 : 4 salt.

When chloroaquomolybdous acid is treated with pyridine and an excess of hydrogen chloride in alcoholic soln., pyridine alcoholates are formed as yellow, crystalline solids, *e.g.* with methyl alcohol, dimorphous $C_6H_5N.H[Mo_3Cl_7(H_2O)].CH_3OH$ is formed; and with ethyl alcohol, $C_6H_5N.H[Mo_3Cl_7(H_2O)].C_2H_5OH$. If the reaction occurs in amyl alcohol soln., the resulting salt, $C_6H_5N.H[Mo_3Cl_7(H_2O)]$, is free from alcohol. If this salt be crystallized from the lower alcohols, the alcoholates are formed. The mol. wt. of the pyridine salt calculated from its effect on the f.p. of nitrobenzene is 717, while 634 is required for $C_6H_5N.H[Mo_3Cl_7(H_2O)]$. The mother-liquors employed in the preparation of the alcoholates, by varying the conditions, give a series of compounds in which the anion varies from Mo : Cl=3 : 7 to 3 : 9, representing complexes of the acids $H_{1+n}[Mo_3Cl_{7+n}]$ with pyridine, etc. Thus, with a large excess of hydrogen chloride, the pyridine alcoholates $(C_6H_5N)_3H_3Mo_3Cl_9.3CH_3OH$; and $(C_5H_5N)_3H_3Mo_3Cl_9.3C_2H_5OH$; as well as $(C_6H_5N)_3H_3Mo_3O_9.C_5H_{11}OH$, were obtained, and when heated, these compounds furnish $C_5H_5N.H[Mo_3Cl_7]$ indicated above. Salts of the **heptachloromolybdous acid,** $H[Mo_3Cl_7]$, are indicated below and complexes with aniline, $C_6H_5NH_2.H[Mo_3Cl_7].9H_2O$; with urea, $Co(NH_2)_2.H[Mo_3Cl_7].3H_2O$; and with ethylenediamine, $C_2H_4(NH_2)_2.2H[Mo_3Cl_7].6H_2O$ were also obtained. Complexes of **octochloromolybdous acid,** $H_2[Mo_3Cl_8]$, were also prepared—*e.g.* with pyridine, $2C_5H_5N.H_2[Mo_3Cl_8].C_2H_5OH$; and with triaminopropane, $2C_3H_{11}N_3.3H_2[Mo_3Cl_8].45H_2O$. A. Rosenheim and F. Kohn, and K. Lindner and co-workers prepared complexes with **enneachloromolybdous acid,** $H_3[Mo_3Cl_9]$, namely $C_5H_5N.H_3[Mo_3Cl_9]$-H_2O; $3C_5H_5N.H_3[Mo_3Cl_9].3CH_2OH$; $3C_5H_5N.H_3[Mo_3Cl_9].C_2H_5OH$; and $3C_5H_5N.H_3[Mo_3Cl_9].C_5H_{11}OH$. K. Lindner also prepared still higher complexes of the acids $H_{3+n}[Mo_6Cl_{15+n}]$ with pyridine. Thus, **pentadecachloromolybdous acid,** $H_3[Mo_6Cl_{15}]$, furnishes $3C_5H_5N.H_3[Mo_6Cl_{15}].2H_2O$, $4C_5H_5N.H_3[Mo_6Cl_{15}]$, and $5C_5H_5N.H_3[Mo_6Cl_5].2C_2H_5OH$; and **heptadecamolybdous acid,** $H_5[Mo_6Cl_{17}]$, furnishes $5C_5H_5N.H_5[Mo_6Cl_{17}].2C_5H_{11}OH$.

C. W. Blomstrand reported **potassium molybdous octochloride,** $[Mo_3Cl_4]Cl_2.2KCl.2H_2O$, to be formed by evaporating a soln. of molybdenum dichloride in alkali-lye saturated with hydrogen chloride. Only half the contained chloride is precipitated by silver nitrate from the nitric acid soln. of the straw-yellow crystals. The salt is decomposed by water into potassium chloride and molybdous chloride. The corresponding **ammonium molybdous octochloride,** $[Mo_3Cl_4]Cl_2.2NH_4Cl.2H_2O$, was obtained in an analogous manner. A. Rosenheim and F. Kohn could not confirm C. W. Blomstrand's formula for the ammonium salt; and they showed that the corresponding pyridinium salt has the composition $3C_5H_5N.H_3Mo_3Cl_9.3H_2O$, as indicated above. K. Lindner, E. Haller and H. Helwig found that if a soln. of heptachloromolybdous acid, $H[Mo_3Cl_7]$, in a minimum quantity of hydrochloric acid be treated with conc. soln. of the metal chlorides, there are formed salts like **ammonium molybdous heptachloride,** $K[Mo_3Cl_7].1\frac{1}{2}H_2O$, and **potassium molybdous heptachloride,** $K[Mo_3Cl_7].3H_2O$, as well as the pyridinium salts, etc., indicated above.

J. J. Berzelius[2] prepared **molybdenum trichloride,** $MoCl_3$, and regarded it as *Molybdändichlorid,* but C. W. Blomstrand showed that it is a trichloride, and this has been confirmed by the analyses of L. P. Liechti and B. Kempe, and of A. Rosenheim and H. J. Braun. By analogy with chromic chloride, $CrCl_3$, this salt can be called **molybdic chloride,** although the affixes " ous " and " ic " are not so useful with multivalent elements which form so many compounds as in the case of vanadium and molybdenum—*vide* **9**. 54, 6. Some such system as that suggested by A. Werner is required, *e.g.* molybd**o**- for bivalent molybdenum; molybd**i**- for tervalent molybdenum; molybd**e**- for quadrivalent molybdenum; molybd**an**- for quinquevalent molybdenum; and molybd**on**- for sexivalent molybdenum.

J. J. Berzelius prepared molybdenum trichloride by passing the vapour of molybdenum pentachloride over heated molybdenum; C. W. Blomstrand said that it is not possible to obtain a homogeneous product by this process, and he recommended passing the vapour of the pentachloride, freed from oxychloride, and mixed with carbon dioxide or hydrogen through a hot tube at 250°. This method was also employed by L. P. Liechti and B. Kempe, by K. Wolf, and A. Rosenheim and H. J. Braun. A. Chilesotti obtained a red soln. of this chloride by the electrolytic reduction of a hydrochloric acid soln. of molybdenum trioxide using a mercury cathode, and a current density of 1 to 2 amp. per sq. dm.—*vide supra,* the electrolysis of molybdenum trioxide. G. G. Henderson obtained the red soln. by reduction with potassium amalgam.

A. Chilesotti showed that by varying the conc. of the acid in hydrochloric acid soln. of molybdenum trioxide, red or green soln. of molybdic chloride can be obtained, and he postulated the existence of isomerides analogous to the green and violet chromic chlorides. This hypothesis was supported by F. Förster and E. Fricke's observations on the potential of soln. of tervalent molybdenum; and by those of W. Wardlaw and R. L. Wormell on the molybdenyl chlorides—*vide infra.* The electrolysis of soln. of molybdenum trioxide in $9N$-HCl gave red or brown soln., and with $2{\cdot}7N$- to $4N$-HCl, green soln. The static potential of the red soln. is 0·12 volt at 24°–26°; and that of the green soln. under similar conditions is —0·18 volt. The red soln. are stable in air, but the green soln. are readily oxidized by air and water—especially in contact with platinum—with the evolution of hydrogen. G. Bredig and J. Michel found that the green soln. reduces perchloric acid 2000 times more quickly than the red soln.

J. J. Berzelius said that the trichloride forms a dark red powder; and L. P. Liechti and B. Kempe likened its appearance to that of red phosphorus. C. W. Blomstrand added that when sublimed, it forms a dark brick-red, crystalline, mass. W. Biltz and C. Fendius gave 3·578 for the sp. gr. at 25°/4°, and 56·6 for the mol. vol. L. P. Liechti and B. Kempe said that the trichloride is stable in dry air, and that when heated to dull redness in an atmosphere of carbon dioxide, it is decomposed into the di- and tetra-chlorides. A. Rosenheim and H. J. Braun observed that in humid air, the trichloride begins to give off hydrogen chloride, and, attracting moisture, it partly dissolves forming a brown liquid. L. P. Liechti and B. Kempe found that when heated in air, a white sublimate first appears, this becomes brownish-red, and a dark blue vapour appears—impure molybdenum dichloride remains behind. The pure trichloride was found by J. J. Berzelius, and A. Rosenheim and H. J. Braun to be insoluble in water; and L. P. Liechti and B. Kempe added that boiling water is gradually coloured brown. J. J. Berzelius said that the trichloride is decomposed by alkali-lye forming molybdic hydroxide. The trichloride is not decomposed by cold (J. J. Berzelius), or boiling (L. P. Liechti and B. Kempe) hydrochloric acid, unless, added A. Rosenheim and H. J. Braun, air has access to the liquid. L. P. Liechti and B. Kempe found that conc. sulphuric acid dissolves the trichloride forming a blue soln. which becomes emerald-green when heated. W. Wardlaw and N. D. Sylvester observed that with powdered sulphur in a soln. of tervalent molybdenum, the colour of the soln. gradually changes from green to brown, and hydrogen sulphide is evolved—particularly with warm soln. W. A. Miller said that hydrogen sulphide slowly produces a brown precipitate of hydrated molybdenum sulphide, soluble in ammonium hydrosulphide; whilst W. Wardlaw and N. D. Sylvester observed no visible effect on the green soln. of tervalent molybdenum during 2 or 3 hrs.' action, but if the sat. soln. be sealed in a flask, a black precipitate—possibly Mo_2S_3—forms in the course of a few days. A soln. of sodium tetrathionate in a soln. of tervalent molybdenum, in the presence of $3N$-H_2SO_4, in a current of nitrogen so as to remove hydrogen sulphide as it is formed, gives a brown precipitate which is a decomposition product of molybdenum tetrathionate; sodium trithionate reacts similarly. For the action of ammonia gas, *vide* molybdenum nitride, **8**. 49, 12; and molybdenum amides, **8**. 49, 21. Aq. ammonia was found by C. W. Blomstrand to act very slowly in the cold, and when heated, L. P. Liechti and B. Kempe observed that a brown powder is formed —*vide* **8**. 49, 21. The trichloride is readily dissolved by warm nitric acid. W. Hampe said that the trichloride is almost insoluble in alcohol and ether.

According to W. Wardlaw and R. L. Wormell, and in agreement with A. Chilesotti, and F. Förster and E. Fricke, the green soln. of tervalent molybdenum obtained by reducing a soln. of molybdenum trioxide in hydrochloric acid, can be made to furnish the *trihydrate* of molybdenum trichloride, $MoCl_3.3H_2O$, as well as complex salts—$R_2MoCl_5.H_2O$ and R_3MoCl_6—of tervalent molybdenum. The trihydrate was obtained in the following manner:

A soln. of 10 grms. of molybdenum trioxide in 400 c.c. of hydrochloric acid of sp. gr. 1·16, was heated on a water-bath for some hours, made up to 600 c.c., and electrolyzed in a diaphragm cell with smooth, platinum electrodes until the cathode soln. was red. This soln. was then evaporated to dryness at 70°–80° under reduced press. in an air-free flask. The residue was a copper-coloured, crystalline substance, which undoubtedly contained a portion of hydrolyzed material, and on analysis gave values of the order 1 : 2·5 for the ratio Mo : Cl. 400 c.c. of pure ether, cooled in a freezing mixture of ice and salt, and sat. with dry hydrogen chloride, were drawn into the flask by releasing the vacuum, and the red soln. obtained was evaporated to dryness under diminished press., whereupon a dark red, crystalline substance separated. In order to ensure the complete conversion of any hydrolyzed salt into the normal chloride, this operation was repeated. The substance finally obtained was quickly transferred in an atm. of dry carbon dioxide to a desiccator containing phosphoric oxide. The product was extremely hygroscopic, and exceptional precautions had to be taken to exclude moisture.

Trihydrated molybdenum trichloride separates in dark, copper-coloured crystals, very soluble in water, acetone, or cold absolute alcohol, giving intensely red solns. It rapidly reduces soln. of copper, silver, or mercuric salts. Sodium and ammonium hydroxides give black precipitates, soluble in acids; these are probably the trihydroxide. If potassium chloride is added to a soln. of the substance in alcohol, the pink complex chloride, K_2MoCl_5,H_2O, is deposited on warming.

It is not possible to get the anhydrous trichloride into aq. soln., but, as indicated above, A. Chilesotti obtained a red soln. by electrolytic reduction, and G. G. Henderson, by reduction with potassium amalgam. The evaporation of the aq. soln. gives a brown residue soluble in water and alcohol. J. J. Berzelius, and C. W. Blomstrand dissolved molybdic hydroxide in hydrochloric acid, and obtained a dark brown soln. which, on evaporation, gave a black, tough mass probably an impure oxychloride. If the red soln. is formed in the presence of alkali chlorides, complex salts are produced. These are precipitated by passing hydrogen chloride into the soln. These salts are red, or black and crystalline. They give a blue colour with ferric chloride, a dark brown colour with potassium ferricyanide, and precipitates with mercurous, lead, copper, and silver salts. G. G. Henderson could not prepare the complex salt with sodium chloride, but **ammonium molybdenum pentachloride,** $(NH_4)_2MoCl_5.H_2O$, was obtained by A. Chilesotti, and W. R. Bucknall and co-workers as a brick-red powder freely soluble in water. It was obtained by adding 25 grms. of ammonium chloride in 10 per cent. aq. soln. to 175 c.c. of a 33 per cent. soln. of molybdic chloride, concentrating the soln. under reduced press. at 70° until the bright, brick-red crystals are formed. G. Carobbi found that the crystals of the monohydrate are pleochroic, being brownish-red longitudinally and wine-red normally. The sp. gr. is 2·175 at 18°. The rhombic crystals have the axial ratios $a : b : c = 0{\cdot}6862 : 1 : 0{\cdot}71666$, and they are isomorphous with the corresponding ferric salt. Solid soln. are formed with a maximum of 90 per cent. of $(NH_4)_2FeCl_5.H_2O$. W. R. Bucknall and co-workers found that the mol. wts. of soln. with 0·863, 2·115, and 5·391 grms. of salt per 100 grms. of water were respectively 105·6, 116·8, and 141·7; and soln. with v litres per mol of water at 1° had the mol. conductivity, μ:

v	16·37	33·76	54·96	101·4	251·3
μ	107	110	132	140	175

when time=0. The conductivities increase with the age of the soln. owing to a series of hydrolytic changes resulting in the formation of molybdenyl chloride (*q.v.*). W. R. Bucknall and co-workers, F. Förster and E. Fricke, and A. Rosenheim and T. H. Li prepared **ammonium molybdenum hexachloride,** $(NH_4)_3MoCl_6.H_2O$, in rose-red needles. To prepare this salt, 80 c.c. of a soln. of 33 per cent. molybdic chloride were sat. with hydrogen chloride, added to a sat. aq. soln. of 20 grms. of ammonium chloride, and the mixture conc. to the crystallizing point. The pentachloride thus formed was removed, and the filtrate again sat. with hydrogen chloride until cold. Small rose-coloured crystals separated which, after washing free from hydrochloric acid with aq. alcohol, were dried in vacuo. G. Carobbi said that the crystals are monoclinic. W. R. Bucknall and co-workers found that an aq. soln. with 48·11, 64·44, and 157·9 grms. of the salt $(NH_4)_3MoCl_6.H_2O$, per litre at 1°, had the mol conductivities 208, 210, and 225 respectively when time=0. The conductivity increases with age owing to hydrolysis. G. Carobbi treated a soln. of 22·5 grms. of ammonium chloride with a soln. of molybdenum trichloride, and saturated it with hydrogen chloride. When the soln. was allowed to stand, it deposited monoclinic crystals of **ammonium molybdenum heptachloride,** $(NH_4)_4MoCl_7.H_2O$, of sp. gr. 1·905. A. Chilesotti, A. Rosenheim and T. H. Li, and W. R. Bucknall and co-workers obtained **potassium molybdenum hexachloride,** K_3MoCl_6, as a red powder very soluble in water. In preparing this salt, 350 c.c. of a soln. of 35 grms. of molybdenum trioxide in 8*N*-HCl were reduced to the tervalent state, conc. to 150 c.c. to make a 33 per cent. soln. of molybdic chloride, and sat. with hydrogen chloride. One-half to three-quarters of the theoretical amount of potassium chloride—30 to 40 grms.—was added as a 10 per cent. soln. in air-free water and the mixture conc. at 70° under reduced press., until crystallization commenced. The liquid was filtered and the filtrate sat. with hydrogen chloride until cold, whereupon the double salt separated. The crystals were washed with conc. hydrochloric acid, alcoholic hydrochloric acid, and finally with alcohol, and dried in vacuo. The mol. wts. of aq. soln. with 0·498, 1·470, and 3·045 were respectively 110·3, 120·5, and 167·0 by the f.p. process; and the mol. wt. decreases from 167·0 with a freshly prepared soln. to 117·3 after the lapse of 155 min. The mol. conductivities, μ, of a soln. of a mol. of the salt in v litres of water at 0°, are:

v	15·67	58·97	95·84	153·3	222·0
μ	155	195	220	230	245

when time=0. The conductivities increase with age owing to hydrolysis. D. M. Bose discussed the magnetic properties; P. Ray and H. G. Bhar found the magnetic susceptibility to be $13{\cdot}1 \times 10^{-6}$ at 25°. G. G. Henderson obtained the *dihydrate,* $K_3MoCl_6.2H_2O$, in red prisms. W. R. Bucknall and co-workers found that liquid ammonia does not react with the tripotassium molybdenum hexachloride, thus supporting the view that the ammonia replaces the molecule of water in diammonium molybdenum pentachloride. A. Chilesotti obtained a thiocyanate, $K_3Mo(CyS)_3$, by the action of potassium thiocyanate. F. Förster and E. Fricke, and W. R. Bucknall and co-workers prepared **potassium molybdenum pentachloride,** $K_2MoCl_5.H_2O$. 100 c.c. of the red soln. containing tervalent molybdenum, prepared by the electrolysis of a soln. of 10 grms. of molybdenum trioxide in 100 c.c. of $8N$-HCl, were added to 25 c.c. of a soln. of a gram of potassium chloride and the mixture was conc. in an air-free flask at 60°–70° under reduced press. to a vol. of about 20 c.c. Air-free, absolute alcohol was now admitted and a bright brick-red, crystalline precipitate separated, which, after filtration and washing with alcohol, was dried in vacuo. The mol. conductivities, μ, of soln. with a mol. of the salt in 21·19, 58·31, and 94·08 litres of water at 1° were respectively μ=113, 140, and 142; and the conductivities increase with time owing to hydrolysis. G. Carobbi found that the crystals of the pentachloride are rhombic and isomorphous with the corresponding ferric salt. The sp. gr. is 2·39 at 18°. Solid soln. with up to 83 per cent. $K_2FeCl_5.H_2O$, of sp. gr. 2·22, were formed. A soln. of the mixed salts deposits the ferrous salt $K_2FeCl_4.2H_2O$, on standing for several days. This illustrates the strong reducing action of molybdenum trichloride. W. R. Bucknall and co-workers found that ammonium molybdenum pentachloride takes up ammonia to form **ammonium molybdenum amminopentachloride,** $(NH_4)_2[MoCl_5(NH_3)].H_2O$, when 2–3 grms. of the pentachloride are treated with about 15 c.c. of liquid ammonia at the temp. of a mixture of ether and solid carbon dioxide, and the product washed first with liquid ammonia and then with dry acetone. This mauve-coloured ammine is extremely hygroscopic and undergoes rapid hydrolysis, ammonium chloride being liberated whilst the substance itself turns brown. It is readily soluble in water, producing a reddish-brown soln. from which the hydroxide separates after a few minutes. It was therefore impossible to determine its molecular conductivity. On treatment with conc. hydrochloric acid, the ammine dissolved, producing a brilliant blue coloration. On dilution, the soln. turned green and finally pink, owing, in all probability, to the re-formation of the original red complex chloride, with liberation of ammonium chloride. Attempts to isolate the blue substance were not successful. W. R. Bucknall and co-workers obtained $H[Mo(O.OC.C_6H_4.OH)_2(H_2O)]$, by the action of sodium salicylate; $Mo(OH)[C_6H_4(CO.O)_2].3H_2O$, by the action of sodium phthalate; and $Mo(OH)C_2O_4.3H_2O$, by the action of ammonium oxalate. G. Carobbi found that the ammonium and potassium salts $R_2MoCl_5.H_2O$ are isomorphous with the corresponding ferric salts $R_2FeCl_5.H_2O$. A. Chilesotti, and W. R. Bucknall and co-workers also prepared **rubidium molybdenum pentachloride,** $Rb_2MoCl_5.H_2O$, in red crystals very soluble in water; and likewise also red crystals of **cæsium molybdenum pentachloride,** $Cs_2MoCl_5.H_2O$. By using more conc. acid soln. **rubidium molybdenum hexachloride,** Rb_3MoCl_6; and **cæsium molybdenum hexachloride,** Cs_3MoCl_6, were formed. The hexahalides can be represented by the formula $R_3[MoCl_6]$, and the pentahalides by $R_2[MoCl_5(H_2O)]$. W. R. Bucknall and co-workers found that the salts of potassium and ammonium are extremely soluble even in cold water and give intensely red soln. The salts of cæsium are quite insoluble and those of rubidium nearly so. In alcohol and ether hydrolysis occurs, and this is accelerated by warming and results ultimately in the precipitation of the hydroxide of molybdenum. All the salts have pronounced reducing properties. F. Förster and E. Fricke observed that only the tervalent elements of lower atomic weight (Ti, V, Cr, Mn, Fe, Co) in this horizontal row of the periodic system appear to form easily-crystallizable complex salts with bivalent anions, whereas the elements of higher atomic weight also give well-crystallized complex salts with univalent anions. As indicated above, the formation of red or green soln. of molybdic chloride by electrolysis was found by A. Chilesotti to depend on the conc. of the hydrochloric acid. F. Förster and E. Fricke stated that the existence of the red salts, $(MoCl_6)M_3$ and $[MoCl_5.H_2O]M_2$, indicates that in the reddish-brown solns. of tervalent molybdenum an equilibrium exists between the tervalent cations and the complex ions, $(MoCl_5.H_2O)''$ and $[Mo(H_2O)_6]^{\cdots}$, respectively. Considerations of static potential lead to similar conclusions. No confirmation was obtained of Chilesotti's hypothesis of an incipient reduction of tervalent to bivalent molybdenum taking place. The presence of the ions $MoCl_6'''$, $(MoCl_5,H_2O)''$, and $[Mo,(H_2O)_6]^{\cdots}$ is held to account for the increased reducing power of the green tervalent molybdenum soln. H. J. Braun prepared complex salts with aniline, quinoline, and pyridine; and A. Rosenheim and T. H. Li, with ethylenediamine.

According to L. P. Liechti and B. Kempe,[3] when molybdenum trichloride is heated to redness in a slow current of carbon dioxide, it is resolved into molybdenum dichloride and **molybdenum tetrachloride,** $MoCl_4$, which appears as a yellow vapour, and condenses to a brown, crystalline powder which is not stable in dry carbon dioxide. When heated in a sealed tube, it decomposes into molybdenum pentachloride and trichloride, and the latter decomposes into the dichloride, etc., as indicated above—this is an extraordinary cycle. It probably means that there is a state of equilibrium between the different chlorides, and that a rise of temp. favours the lower chlorides which are less volatile. The tetrachloride is therefore one of the products of the action of chlorine on heated molybdenum; and C. W. Blomstrand, and H. Debray obtained it by the action of chlorine on a heated mixture of carbon and molybdenum oxide or sulphide. A. Michael and A. Murphy prepared the tetrachloride by heating molybdenum dioxide and carbon tetrachloride in a sealed tube at 250°. Molybdenum trioxide reacts with carbon tetrachloride at 280° with the formation of the pentachloride. When the trioxide is heated with a soln. of chlorine in carbon tetrachloride at 200°, the product consists of a yellowish-green oxychloride mixed with unchanged trioxide; at 225°, a mixture of yellow and green compounds is obtained, probably consisting of the dioxydichloride and the oxytetrachloride; at 240°, the pentachloride is produced. The pentachloride is also obtained when the oxide, Mo_3O_8, is heated with carbon tetrachloride at 240°. According to L. P. Liechti and B. Kempe, molybdenum tetrachloride is a brown, partly crystalline powder. It is affected by air as in the case of the trichloride. It does not melt when heated in a sealed tube and forms brown vapour which consists of the decomposition products as indicated above; when heated in an open tube, it forms a yellowish-white sublimate, which, owing to the action of the atm. moisture, consists of the complex oxychlorides $MoO_3.2HCl$, and MoO_2Cl_2, and chlorine and hydrogen chloride are evolved. It produces a hissing noise in contact with water; there is a vigorous reaction, and most of it forms a brown aq. soln.; alcohol, and ether behave similarly. No hydrate has been prepared; J. J. Berzelius found that a soln. of molybdenum tetrahydroxide in hydrochloric acid gives, on evaporation, a dark, amorphous, soluble mass. J. N. Pring and W. Fielding observed that the vapour of the tetrachloride, in contact with carbon, forms molybdenum or the carbide at a temp. below 1300°. There is a hissing noise produced by the action of conc. hydrochloric acid, but the boiling acid dissolves only a little tetrachloride; there is also a hissing noise produced by conc. sulphuric acid, hydrogen chloride is evolved, and a bluish-green soln. is formed. Conc. nitric acid forms a yellow soln. J. J. Berzelius evaporated a hydrochloric acid soln. of molybdenum dioxide mixed with ammonium chloride, and obtained brown crystals which C. W. Blomstrand regarded as ammonium chloride stained a brown colour. W. Wardlaw and N. D. Sylvester observed no reaction between sulphur and soln. of quadrivalent molybdenum. J. J. Berzelius saturated a hydrochloric acid soln. of molybdenum dioxide with ammonia, and obtained, on evaporation, a black, crystalline mass which formed a red soln. with water. According to C. W. Blomstrand, if a soln. of ammonium chloride is saturated with molybdenum tetrachloride, and evaporated over sulphuric acid, brown crystals of impure ammonium chloride first separate, and afterwards, green, octahedral crystals of **ammonium molybdenum tetradecachloride,**

$2NH_4Cl.3MoCl_4.6H_2O$. The salt is stable in dry air; and it decomposes when heated giving off water, ammonium chloride, hydrogen chloride, as well as molybdenum dioxide, and, if air has access, molybdenum oxychloride. The salt deliquesces in moist air. This complex salt may be an oxychloride, and not really a salt of molybdenum tetrachloride.

J. J. Berzelius,[4] and C. W. Blomstrand first prepared **molybdenum pentachloride,** $MoCl_5$; but they mistook it for *Molybdäntetrachlorid.* H. Debray showed that the product must have been the pentachloride, and this was confirmed by the analyses of L. P. Liechti and B. Kempe. According to J. J. Berzelius, chlorine gas does not act on molybdenum at ordinary temp., but when gently heated, chlorine gas freed from air and oxygen produces a transient glow over the surface of the metal, and a dark red vapour of molybdenum pentachloride is formed, and this condenses to greyish-black crystals. H. Debray distilled the product in a current of carbon dioxide in order to remove the chlorine. L. P. Liechti and B. Kempe, W. Lederer, and B. Kalischer employed an analogous mode of preparation; E. F. Smith and H. C. Burr passed chlorine over a heated mixture of molybdenum and sugar-charcoal; and C. W. Blomstrand passed dry and air-free chlorine over a mixture of molybdenum dioxide or disulphide and charcoal—the by-product, sulphur monochloride, is easily removed. P. Camboulives obtained the pentachloride by passing the vapour of carbon tetrachloride over molybdenum trioxide at 510°. A. Michael and A. Murphy's observations on this subject are indicated in connection with molybdenum tetrachloride. W. Lederer observed that when the product obtained by dissolving molybdenum in aqua regia is heated, the vapour of the pentachloride is given off. A. Chilesotti observed the presence of the pentachloride in the green soln. obtained by the electrolysis of a hydrochloric acid soln. of molybdenum trioxide (*q.v.*).

The black or greyish-black crystals of molybdenum pentachloride are very like those of iodine. The greenish tinge mentioned by H. Debray is taken by L. P. Liechti and B. Kempe to show that a trace of oxychloride is present, but O. Ruff and F. Eisner added that the crystals are dark green—almost black. C. W. Blomstrand found that the acicular crystals obtained by sublimation in carbon dioxide are dark brown or brownish-black. W. Biltz and C. Fendius gave 2·928 for the sp. gr. at 25°/4°, and 93·3 for the mol. vol. H. Debray found the vap. density at 35° to be between 9·40 and 9·53 when the theoretical value for $MoCl_3$ is 9·47. J. J. Berzelius said that the salt readily fuses; H. Debray gave 194° for the m.p., and L. P. Liechti and B. Kempe added that when the molten salt is cooled, it forms a crystalline mass. A. Michael and A. Murphy gave 194° to 195° for the m.p. H. Debray gave 268° for the b.p. C. W. Blomstrand said that when strongly heated the salt is partially decomposed. According to W. Hampe, the molten salt is dark red, and in thick layers it appears black, and if the access of moisture be prevented, it does not conduct electricity either at the m.p. or at the b.p. S. J. Lloyd found that the electrical conductivity, μ, of a mol of the salt in v litres of solvent at 18° is for the green soln. in methyl acetate $\mu=5{\cdot}1$, 3·33, and 2·88 respectively for $v=2600$, 10,400, and 41,600; for the green soln. in ethyl acetate, $\mu=1{\cdot}12$, 0·91, and 0·82 respectively for $v=3200$, 6400, and 25,600; for the olive-green soln. in acetone, $\mu=2{\cdot}02$, 2·36, and 3·75 respectively for $v=2925$, 11,700, and 103,600; for the olive-green soln. in benzaldehyde, $\mu=2{\cdot}4$, 2·15, and 1·92 respectively for $v=2900$, 5800, and 23,200; for the reddish-brown soln. in pyridine, $\mu=1{\cdot}14$, 1·79, and 3·12 respectively for $v=3150$, 12,600, and 50,400; and for the reddish-brown soln. in glycerol, $\mu=0{\cdot}92$, 1·08, and 1·95 for $v=2509$, 5018, and 20,072. A. Voigt and W. Biltz found the sp. conductivity of the molten pentachloride to be $1{\cdot}8\times10^{-6}$ mho at 216°, and $7{\cdot}5\times10^{-6}$ at 258°, and W. Biltz gave for the temp. coeff. of the conductivity $0{\cdot}0_521$. The subject was discussed by W. Biltz and W. Klemm, and G. von Hevesy.

N. Parravano and C. Mazzetti observed that molybdenum pentachloride mixed with hydrogen is reduced when passed over an iron rod at 900°, forming a film of a molybdenum-iron alloy on the heated rod. J. J. Berzelius found that when the salt is kept in a vessel containing air, an oxychloride is formed, and L. P. Liechti and B. Kempe obtained a similar product by heating the pentachloride in air. The salt fumes in moist air, and, according to J. J. Berzelius, rapidly turns bluish-green, and then deliquesces to a black, bluish-green, greenish-yellow, deep red, reddish-brown, and finally yellow liquid while hydrogen chloride is evolved. The pentachloride dissolves in water vigorously giving off so much heat that the liquid boils. H. Debray said that the aq. soln. is green or brown; and L. P. Liechti and B. Kempe added that it hisses when in contact with a small proportion of water and forms a brown liquid; with a large proportion of water the soln. is colourless. M. Guichard found that in aq. soln. the pentachloride is resolved into the tetrachloride and trioxide, and the strongly acid soln. forms a blue oxide when exposed to air. J. Nordenskjöld, and B. Kalischer consider that, in all probability, the first action of water can be represented: $MoCl_5+H_2O=MoOCl_3+2HCl$. According to L. P. Liechti and B. Kempe, a little absolute alcohol dissolves the pentachloride without hissing to form a dark green soln. which becomes brown if moisture be present; absolute ether also forms a green soln. without hissing. B. Kalischer added that chloroform and carbon tetrachloride form brown soln. which become green if a little water be present—*vide supra*. According to O. Ruff and F. Eisner, at ordinary temp., hydrogen fluoride converts it into a gaseous molybdenum fluoride and hydrogen chloride; hydrogen chloride turns the pentachloride emerald-green, whilst hydrochloric acid dissolves it with the evolution of much heat; nitric acid forms a colourless soln.; conc. sulphuric acid gives a bluish-green soln. which gradually turns brown and then yellow. W. Hampe observed that the pentachloride forms a green soln. with a small proportion of conc. hydrochloric acid, and a red or reddish-brown soln. with a larger proportion of acid. On electrolysis, the soln. of the pentachloride in conc. hydrochloric acid is reduced at the cathode to the trichloride, and at the anode $MoO_3.nHCl$ is formed. A. G. Page observed that molybdenum pentachloride acts as a catalyst in chlorinations. O. C. M. Davis obtained the complex *molybdenum nitrogen tetrasulphopentachloride*, $MoCl_5.N_4S_4$, by the action of nitrogen tetrasulphide on molybdenum pentachloride. H. J. Braun studied the action of ammonia on molybdenum pentachloride—*vide* the molybdenum amides. F. W. Bergstrom represented the reactions by $MoCl_5+8NH_3=Mo(NH)_2NH_2+5NH_4Cl$, and by $MoCl_5+8NH_3=Mo(NH_2)_4Cl+4NH_4Cl$. A. Piutti obtained *molybdenum phosphoryl octochloride*, $MoCl_5.POCl_3$, by the action of 3 mols of phosphorus pentachloride on a mol of molybdenum trioxide in a sealed tube at 170°; and E. F. Smith and G. W. Sargent, *molybdenum phosphorus decachloride*, $MoCl_5.PCl_5$, by using 5 mols of phosphorus pentachloride. W. Hampe observed that absolute alcohol or ether reacts vigorously with the evolution of heat, and giving of hydrogen chloride and ethyl chloride. The grass-green soln. formed with absolute alcohol gives a reddish-brown tetroxide when treated with alkali-lye. B. Kalischer said that the alcoholic soln. contains $MoOCl_3$; and he found that the pentachloride dissolves with a hissing noise in many organic liquids—*e.g.* alcohols, ethers, ketones, aldehydes, acids, acid anhydrides, esters, and amines. W. Wardlaw and H. W. Webb also observed that molybdenum pentachloride reacts vigorously with dry methyl, ethyl and benzyl alcohols, forming molybdenyl trichloride, but it does not react with phenol. Dry ether forms $MoCl_5.2(C_2H_5)_2O$, and with moist ether there is formed $MoOCl_3.2(C_2H_5)_2O$, which with hydrogen chloride furnishes $MoOCl_3.(C_2H_5)_2O$. Pyridine forms $MoOCl_5.2C_5H_5N$, as well as $MoCl_4.3C_5H_5N$, $MoCl_4.4C_5H_5N$, and $MoClH_4.5C_5H_5N$. A. Michael and A. Murphy found that the pentachloride is soluble in carbon tetrachloride. J. J. Berzelius said that molybdenum pentachloride unites with ammonium chloride, but not with sodium or potassium chloride. B. Kalischer found that an excess of alkali hydroxide forms $Mo(OH)_4$ and K_2MoO_4; and P. Klason, that the theoretical proportion of alkali hydroxide forms $MoO(OH)_3$.

E. F. Smith and H. C. Burr [5] found that metallic molybdenum rapidly acts on ferric chloride soln. with reduction of the ferric salt, and dissolves as a hexad; and they tried to prepare **molybdenum hexachloride,** $MoCl_6$, by driving the oxygen from an oxychloride of sexivalent molybdenum. Thus, molybdenyl chloride, MoO_2Cl_2, was mixed with an equivalent quantity of phosphorus pentachloride, and heated in a sealed tube, in the presence of chlorine, at 170°. On cooling, it was found that the tube contained a mass of greenish-black crystals; these, when freed from phosphorus oxychloride by distillation in a current of chlorine, yielded a product which, on analysis, gave figures approximating more to the pentachloride than to the hexachloride. The experiment was repeated, silicon tetrachloride being substituted for the phosphorus compound. The crystalline product was quickly removed to a boat, and distilled in an atmosphere of carbonic anhydride. The brown vapours condensed in the colder portions of the tube, and on analysis gave results varying between those required by the tetrachloride and the pentachloride. O. Ruff and F. Eisner heated a mixture of molybdenum pentachloride and liquid chlorine in a sealed tube for 96 hrs. at 100°, but obtained only crystals of the pentachloride.

§ 20. Molybdenum Oxychlorides

According to W. Wardlaw and R. L. Wormell,[1] **molybdanyl chloride**, $MoOCl.4H_2O$, can be isolated from a conc. soln. of tervalent molybdenum.

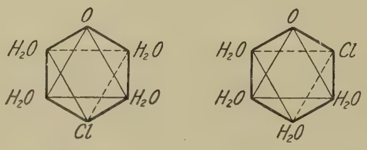
A soln. of 60 grms. of molybdenum trioxide in 390 c.c. of hydrochloric acid of sp. gr. 1·16 was heated on a water-bath for 8 hours, made up to 600 c.c., and electrolyzed, in a diaphragm cell with smooth platinum electrodes until the cathode soln. was olive-green. This soln. was then conc. at 50° under diminished press., in an air-free flask; the colour changed from green to reddish-brown at about 250 c.c. After conc. to 180–200 c.c., the soln. was transferred to a small cell and re-electrolyzed. A soln. was thus obtained having a much higher conc. of tervalent molybdenum than one prepared by direct dissolution of the trioxide in conc. hydrochloric acid. The electrolysis was continued until a sample of the cathode liquid, poured into acetone, gave an appreciable buff-coloured precipitate. The cathode soln. was now forced by the press. of carbon dioxide into air-free acetone; the oxychloride, which separated as a heavy, buff-coloured powder in almost quantitative yield, was washed with acetone, alcohol and dry ether, all these operations being performed in an atmosphere of carbon dioxide with rigid exclusion of air, and transferred to a desiccator filled with carbon dioxide, which was then evacuated. The analysis corresponds with $MoOCl.3H_2O$, but the salt was dried in a desiccator. If the oxychloride be precipitated from a soln. of about a quarter the concentration here indicated, the analysis corresponds closely with $MoOCl.4H_2O$.

It is assumed that the formation of molybdenyl chloride in aq. soln. of potassium molybdenum hexachloride is a result of a series of hydrolytic reactions $R_3[MoCl_6] + H_2O \rightleftharpoons R_2[MoCl_5(H_2O)] + RCl$; $R_2[MoCl_5(H_2O)] + H_2O \rightleftharpoons R[MoCl_4(H_2O)_2] + RCl$; $R[MoCl_4(H_2O)_2] + H_2O \rightleftharpoons MoCl_3.3H_2O + RCl$; $MoCl_3.nH_2O \rightleftharpoons MoCl_2(OH) + HCl + (n-1)H_2O$; and $MoCl_2(OH) \rightleftharpoons MoOCl + HCl$. The mol. wt. of molybdenyl chloride calculated from the f.p. of aq. soln. containing 0·1682 and 0·2531 grm. of salt in 10 grms. of water was respectively 186·1 and 191·3. The salt is thus in all probability hydrolyzed in aq. soln.; $[MoOCl.4H_2O] + H_2O \rightleftharpoons [MoO.5H_2O]^{\cdot} + Cl'$. The hydrolysis thus yields a binary electrolyte. The progressive hydrolysis is shown by the fact that aq. soln. at 1° have a mol. conductivity $\mu=33·7$ for $v=4$ after 4 min. and $\mu=50·8$ after 220 min.; and for soln. with $v=25$, $\mu=33$, after 2 min., and after 40 min., $\mu=65·2$. The dried solid is buff-coloured; and it does not deliquesce in air, although its titration value gradually falls owing to air oxidation. It is readily soluble in water and in conc. hydrochloric acid, yielding amber and reddish-brown soln. It is insoluble in acetone or ether, but dissolves slightly in cold, and readily in hot absolute alcohol. Cupric and mercuric chlorides are reduced to the " ous " condition, with further reduction to the metal by use of excess of the oxychloride. Ferric chloride also is readily reduced to the " ous " state. Sulphur, on boiling with a soln. of the solid, yields hydrogen sulphide. Sodium and ammonium hydroxides give black, flocculent precipitates, readily soluble in acids, which are probably the trihydroxides. Potassium cyanide reacts similarly. Potassium ferricyanide gives a deep red coloration. Silver nitrate is reduced to the metal, whilst lead acetate acidified with acetic acid gives no precipitate of lead chloride, indicating the absence of the chloride ion. Tungsten and uranium do not yield analogues of molybdanyl monochloride, but vanadium, which should resemble it by reason of its diagonal position in the periodic table, forms a brown, insoluble oxychloride, VOCl. An oxychloride of chromium, $CrCl(OH)_2$, has been described, but the general method of preparation of tervalent chromium oxychlorides is not satisfactory.

A green modification of molybdanyl chloride, $MoOCl.4H_2O$, has also been prepared:

A soln. of 60 grms. of molybdenum trioxide in 390 c.c. of hydrochloric acid of sp. gr. 1·16, was diluted to 500 c.c., electrolyzed for 4 hours in a diaphragm cell and concentrated at 50° under diminished press. to 250 c.c. This conc. soln., in which the molybdenum was quinquevalent, was then re-electrolyzed. On prolonged electrolysis, the soln. because green and the conc. of "free" acid diminished. At this stage, a portion of the soln., on being poured into acetone, gave a bluish-green precipitate, a typical hydrolyzed product. The cell was now cooled in ice, and the cathode liquid forced by the press. of carbon dioxide into an equal vol. of ice-cold $10N$- hydrochloric acid. The olive-green soln. thus produced was poured into air-free acetone and a green solid then separated in excellent yield. It was filtered off, washed with acetone, and dried in a vacuum desiccator. All these operations were performed in an atmosphere of carbon dioxide, air being rigidly excluded.

The mol. wts. calculated from the depression of the f.p. of water containing 0·2302 and 0·9774 grm. of the salt in 10 grms. of water were respectively 161·7 and 191·4. The mol. conductivities of a soln. with $v=5·7$ at 1° were 42·77 after the lapse of one minute, and 53·6 after the lapse of 7 min. The freshly-precipitated solid is green, but on drying it becomes greyish-green. On exposure to the air, it darkens in colour and hydrolyzes. It is more readily soluble in water and in conc. hydrochloric acid than its brown isomeride, but is insoluble in alcohol. It has similar reducing properties to the brown oxychloride, but is much more reactive. The results agree with the assumption that the two isomerides have the co-ordination formula $[MoOCl.4H_2O]$; and the reactions with sodium salicylate favour the assumption that the red and green modifications are respectively *cis-* and *trans-* isomerides:



Trans- or green form. *Cis-* or red form.

W. Wardlaw and R. L. Wormell showed that by double decomposition of the theoretical amounts of molybdanyl monochloride and the alkali salts of benzoic, tartaric, and phosphoric acids, respectively, in air-free, aq. soln., reactions occur in accordance with the equations: $MoOCl+C_6H_5.CO_2Na=C_6H_5.CO_2.MoO+NaCl$; $2MoOCl+NaKC_4H_4O_6=(MoO)_2C_4H_4O_6+NaCl+KCl$; $3MoOCl+Na_2HPO_4=(MoO)_3PO_4+2NaCl+HCl$. These insoluble molybdanyl salts are all buff-coloured and undergo gradual hydrolysis in contact with water. They are best purified by washing with dil. soln. of the corresponding acids. Soln. of sodium oxalate and normal sodium citrate also give well-defined, buff precipitates when they are added to a soln. of molybdanyl chloride. These precipitates are probably the corresponding molybdanyl salts.

W. R. Bucknall and co-workers prepared **potassium molybdenum dichloride,** $KMoOCl_2.3H_2O$, in the following manner: 350 c.c. of the green soln. containing 35 grms. of molybdenum trioxide were conc. to about 120 c.c., and re-electrolyzed for an hour to ensure the complete reduction of the molybdenum to the tervalent form. 250 c.c. of a 10 per cent. soln. of potassium chloride were added, and the whole was conc. nearly to dryness under reduced press. at 70°. The red salt formed was then removed and the filtrate treated with alcohol, whereby a bright yellow substance was precipitated. This was filtered, washed with alcohol, and dried in vacuo. It was slowly soluble in water to a reddish-brown soln., and after a time the solid turned greenish-brown. The mol. conductivity increased with time, and agreed with the assumption that the co-ordination formula is $K[MoOCl_2(H_2O)_3]$. The salt is rapidly hydrolyzed in aq. soln. By similarly treating a green soln. with ammonium chloride, an impure **ammonium molybdenum chloride,** probably $(NH_4)[Mo(OH)Cl_3(H_2O)_2]$, was formed.

It is doubtful if **molybdenyl trichloride,** $MoOCl_3$, has been prepared, although complex salts, $RCl.MoOCl_3$, are known. C. W. Blomstrand[2] obtained a product of the composition $Mo_9O_8Cl_{32}$, by the action of chlorine on an intimate mixture of molybdenum dioxide and carbon heated by an alcohol lamp; and also by passing chlorine over incompletely reduced molybdenum oxide. I. Nordenskjöld regarded the product as a mixture of MoO_2Cl_2 and $MoCl_5$; and P. Klason, as molybdenyl trichloride. C. W. Blomstrand described it as a dark green mass of tabular crystals; it melts and vaporizes below 100°. It is stable when heated in a sealed tube, and in thin layers in direct sunlight, it acquires a reddish colour. It quickly decomposes when exposed to air and becomes blue. It can be sublimed in hydrogen. The vapour is dark reddish-brown. It is vigorously attacked by water; it forms a green soln. with a small proportion of water—a single drop of water colours it blue—and with more water a blue precipitate is formed. H. Fleck and E. F. Smith found that the compound reacts with ethylamine; and I. Nordenskjöld obtained complexes by adding aliphatic amines or pyridine to the soln. in hydrochloric acid. This soln. is supposed to contain $MoOCl_3.2HCl$, or $H_2[MoOCl_5]$, for, with alkali or organic ammonium chlorides, it yields complex salts of the type $R_2[MoOCl_5)$. For a similar reason, green soln. of molybdenum pentachloride are supposed to contain molybdenyl trichloride. If the green soln. is diluted with water, it becomes brown owing to the formation of colloidal $Mo(OH)_5$, but when hydrochloric acid is added the soln. becomes green. J. J. Berzelius showed that a soln. of molybdenum trioxide is readily reduced by hydriodic acid, and F. Mauro and L. Danesi showed that the molybdenum trioxide is reduced to a quinquevalent form with the liberation of an atom of iodine per mol. of the trioxide. The reaction was utilized in the iodometric determination of molybdenum by C. Friedheim and H. von Euler-Chelpin, and F. A. Gooch and co-workers.

G. Bailhache prepared **ammonium molybdenyl pentachloride,** $2NH_4Cl.MoOCl_3$, or $(NH_4)_2[MoOCl_5]$, by crystallization from a soln. of potassium molybdenyl oxalate and ammonium chloride in hydrochloric acid; and by passing hydrogen chloride into a soln. of molybdenum trioxydisulphate, $Mo_2O_3(SO_4)_2$, and ammonium chloride. P. Klason also obtained this salt by adding a mol of ammonium iodide, and 0·1 mol ammonium chloride per gram-atom of molybdenum, to a soln. of 200 grms. of ammonium molybdate in 600 c.c. of fuming hydrochloric acid; distilling off the iodine on a sand-bath with fresh additions of hydrochloric acid; and saturating the liquid with hydrogen chloride. The green liquid was allowed to stand for crystallization. F. Förster and E. Fricke obtained the salt by electrolytically reducing a soln. of molybdenum trioxide in hydrochloric acid, and subsequently adding ammonium chloride to the liquid. R. G. James and W. Wardlaw used the following process:

> 100 grms. of molybdenum trioxide were dissolved in 500 c.c. of hot hydrochloric acid of sp. gr. 1·16, and the soln. evaporated to 250 c.c., filtered, and made up to 500 c.c. with hydrochloric acid. 150 c.c. of this liquid were placed in a diaphragm cell containing $10N$-NH_4OH and a small quantity of ammonium chloride. On electrolysis with a current density of 0·1 amp. per sq. cm., and continuous saturation of the cathode with hydrogen chloride, a good yield of the salt separated out.

The lowering of the f.p. of aq. soln. agrees with a mol. wt. of about 36 when the mol. wt. of $(NH_4)_2MoCl_5$ is 325·3. The electrical conductivities of soln. with a mol of the salt in 199·2, 796·8, 1593·6, and 3187·2 litres of water are, respectively, 755·3, 865·6, 916·8, and 948. The results are taken to agree with the assumption that the complex $MoOCl_5''$-ion is unstable and that ionization and hydrolysis occur in

accord with $R_2[MoOCl_5]+H_2O\rightleftharpoons R[MoOCl_4,H_2O]+RCl$; $R[MoOCl_4,H_2O]+H_2O \rightleftharpoons [MoOCl_3.2H_2O]+RCl$; $[MoOCl_3,2H_2O]+H_2O\rightleftharpoons[MoO(OH)Cl_2,2H_2O]+HCl$; $[MoO(OH)Cl_2.2H_2O]+H_2O=[MoO(OH)_2Cl,2H_2O]+HCl=[MoO_2Cl,3H_2O]+HCl$; $[MoO_2Cl,3H_2O]+H_2O\rightleftharpoons[MoO_2(OH),3H_2O]+HCl$. Whence at infinite dilution: $R_2[MoOCl_5]+5H_2O\rightleftharpoons[MoO_2(OH),3H_2O]+2RCl+3HCl$. This agrees with the observed fact that 10 ions per mol. are produced at infinite dilution. Additional confirmation of this scheme of ionization for the complex salts is afforded by the isolation of the intermediate products $R[MoOCl_4,H_2O]$, $R[MoO_2Cl_2,2H_2O]$, and an oxychloride, $[Mo_2O_4(OH)Cl,4H_2O]$, which may be considered as derived from the intermediate substances $[MoO_2Cl,3H_2O]$ and $[MoO_2(OH),3H_2O]$. According to P. Klason, the green, octahedral crystals are stable in air, and easily soluble in water. The salt can be reprecipitated from its aq. soln. by passing in hydrogen chloride. The salt in aq. soln. is hydrolyzed, and it may then suffer auto-reduction to form molybdenum blue. The salt is decomposed by alcohol. In addition to the green salt, H. Winkler obtained a brown form by evaporating on a water-bath the green mother-liquid from the green salt until a film of crystals appears on the surface, and cooling the liquid by ice-water. If the crystals are green, the treatment is repeated on the mother-liquid. The brown, cubic crystals are stable in air; and they are easily auto-oxidized. They form a green soln. with water—*vide infra.* A. Rosenheim and M. Koss, G. Scagliarini, R. G. James and W. Wardlaw, and J. Sand and O. K. H. Burger obtained complex salts with pyridine; and R. G. James and W. Wardlaw, salts with quinoline, and with trimethylammonium. I. Nordenskjöld prepared **potassium molybdenyl pentachloride,** $K_2MoOCl_5.2H_2O$, by adding the calculated quantity of hydriodic acid to a soln. of molybdenum trioxide in fuming hydrochloric acid, driving off the free iodine, saturating the soln. with hydrogen chloride, adding the calculated quantity of potassium chloride, and concentrating the soln. in a current of hydrogen chloride. F. Förster and E. Fricke, and R. G. James and W. Wardlaw also prepared this salt. The lowering of the f.p. of aq. soln. agrees with an apparent mol. wt. of about 40 when the theoretical value for K_2MoOCl_5 is 367·5. The electrical conductivities of soln. of a mol of the salt in 36·54, 292·3, 584·6, and 1169·3 litres of water are, respectively, 676·6, 834·3, 987·3, and 954. G. G. Henderson added potassium chloride to a conc. soln. of molybdic hydroxide in hydrochloric acid, and saturated the liquid with hydrogen chloride; and he also treated a soln. of molybdenum trioxide in hydrochloric acid with potassium amalgam. The dark green, rhombic prisms are stable in air; and when it is treated in hydrochloric acid soln. with potassium amalgam, $K_3MoOCl_6.2H_2O$ is formed. I. Nordenskjöld prepared **rubidium molybdenyl pentachloride,** Rb_2MoOCl_5, in a similar manner, and obtained green, rhombic octahedral crystals, which are less soluble than the potassium salt. This salt was also prepared by F. Förster and E. Fricke, and by R. G. James and W. Wardlaw as indicated above. The lowering of the f.p. of aq. soln. agrees with an apparent mol. wt. of about 36 when the theoretical value for Rb_2MoOCl_3 is 460·3. The electrical conductivities of soln. with a mol of the salt in 51·14, 409·1, 818·2 and 1636·4 litres of water are, respectively, 688, 849, 910, and 973. I. Nordenskjöld prepared sparingly soluble **cæsium molybdenyl pentachloride,** Cs_2MoOCl_5, which forms yellowish-green, rhombic, octahedral, sparingly-soluble crystals. The salts R_2MoOCl_5, generally crystallize in the rhombic system, and range in colour from dark green through shades of emerald-green to yellowish-green. The pyridine salt exhibits a strong pleochroism and has a very high double refraction. When exposed to a moist atm., these salts more or less rapidly turn reddish-brown, in which condition they are very susceptible to aërial oxidation, molybdenum blue being formed. The pyridinium and the ditrimethylammonium salts give a bright copper-red substance at one stage of these changes. The potassium and the substituted-ammonium salts are the most sensitive, and the quinolinium the least sensitive, to the action of moist air. All the complex salts are soluble in water, the conc. soln. being reddish-brown, passing through orange to bright yellow on dilution. On sat. with hydrogen chloride, these aq. soln. finally turn emerald-green and from sufficiently conc. soln. the complex salts separate. Alcohol dissolves all these green salts, and from the soln. of the alkali complex salts, alkali chlorides separate on heating. The pyridinium salt under these conditions yields a red precipitate, which will be referred to in detail later. The addition of pyridine or quinoline to aq. soln. of any of the complex salts gives a brown, insoluble precipitate.

R. G. James and W. Wardlaw prepared **trimethylammonium molybdenyl tetrachloride,** $R[MoOCl_4(H_2O)]$, as follows: 75 c.c. of the soln. of molybdenum oxide, indicated above, were electrolytically reduced to the quinquevalent stage, and were concentrated on a water-bath under diminished press. to 20–25 c.c. Thirty c.c. of a soln. of 11 grms. of trimethylamine hydrochloride were now admitted by releasing the vacuum, and the mixture was heated to boiling under diminished press. The soln. was then sat. with hydrogen chloride while it was being cooled, finally in a freezing-mixture, and the emerald-green crystals thus obtained were filtered, washed with conc. hydrochloric acid, and dried in a vacuum over solid potassium hydroxide and phosphoric oxide. The mol. wt. by the cryoscopic process is about 47, when the mol. wt. of $(CH_3)_3HNMoOCl_4H_2O$ is 331·8. The mol. conductivity, μ, of a soln. in v litres of water is:

v . .	35·6	71·2	142·4	284·8	569·6	1139·2	2278·4	4556·8
μ . .	580	614	657	706	773	852	849	874

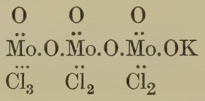
The calculated value for μ_∞ at 0° is nearly 880, on the scheme of ionization and hydrolysis indicated above, when there are 8 ions produced per mol.

According to J. Sand and O. K. Burger, when green **pyridine molybdenyl pentachloride** is boiled with alcohol and cooled there separate out copper-red crystals of pyridinium molybdenyl dichloride, $C_5H_6N.MoO_2Cl_2.2H_2O$. The salt was also prepared by R. G. James and W. Wardlaw. The mol. wt. by cryoscopic methods ranges from 61·6 to 86·06 when the value for $C_5H_6N.MoO_2Cl_2(H_2O)$ is 296·9. The mol. conductivity, μ, at 0°, of a soln. of a mol of the salt in v litres is:

v . .	20·56	41·12	164·5	329	1316
μ . .	185	210·6	275·1	312·0	336·0

These results are explained by the assumption that in aq. soln. the pyridinium salt undergoes ionization and hydrolysis in accordance with the scheme: $MoO_2Cl_2,2H_2O + C_5H_6N + H_2O \rightleftharpoons C_5H_6NCl + MoO_2Cl + 2H_2O \rightleftharpoons C_5H_6N^{\cdot} + Cl' + MoO_2Cl.3H_2O$; $MoO_2Cl.3H_2O + H_2O \rightleftharpoons MoO_2(OH),3H_2O + H^{\cdot} + Cl'$. R. G. James and W. Wardlaw prepared **molybdenum tetroxyhydroxychloride,** $Mo_2O_4(OH)Cl.4H_2O$—mol. wt. 380·5—as follows: The reddish-brown soln. of quinquevalent molybdenum, obtained by the electrolytic reduction of 150 c.c. of molybdic acid soln., was conc. on a water-bath under diminished press. until a dark, viscous mass was obtained. Pure, dry acetone was admitted in small portions with frequent shaking and warming, until the mass just dissolved, giving a deep brown soln. This was poured with constant stirring into a large volume of dry ether and a bulky reddish-brown precipitate separated, which was washed with dry ether and kept over solid potassium hydroxide in vacuo. This salt is a reddish-brown powder, readily soluble in water and in alcohol, giving deep reddish-brown soln. which on dilution become bright yellow. The aq. soln. is acid to litmus and reduces soln. of silver salts. The brown aq. or alcoholic soln. of the compound turn emerald-green on saturation with hydrogen chloride, and complex salts of the type R_2MoOCl_5 may be isolated from them. On heating, the chloride decomposes with evolution of hydrogen chloride. The mol. wt. by the cryoscopic process is 157·9 to 205·7. These results indicate that two ions are present in the more conc. soln. and three individuals in the more dil. This is satisfactorily explained by the progressive hydrolysis $Mo_2O_4(OH)Cl + H_2O \rightleftharpoons Mo_2O_4(OH),H_2O + Cl \rightleftharpoons Mo_2O_4(OH),H_2O^{\cdot} + Cl'$ or $Mo_2O_4(OH)Cl + H_2O \rightleftharpoons Mo_2O_4(OH)_2 + H^{\cdot} + Cl'$.

H. Rose,[3] and J. J. Berzelius prepared **molybdenum dioxydichloride,** MoO_2Cl_2, as a sublimate by the action of dry chlorine on heated molybdenum dioxide ; and also by heating a mixture of molybdenum trioxide, potassium hydrosulphate, and sodium chloride ; W. Püttbach, and O. Ruff and F. Eisner, by passing chlorine over a heated mixture of molybdenum trioxide and carbon ; and C. W. Blomstrand, by the action of oxygen on molybdenum chloride or oxychloride, or by exposing the substances to moist air in the cold. According to C. W. Blomstrand, the yellowish-white, scaly crystals in the presence of some of the other oxychlorides may produce a red coloration. The crystals have a bitter, and acidic taste. The salt volatilizes without melting, but it can be melted in a sealed tube. It is hydrolyzed by water, $MoO_2Cl_2+H_2O=MoO_3+2HCl$. A. W. Cronander observed that with phosphorus pentachloride, *molybdenum diphosphotetradecachloride*, $MoCl_4.2PCl_5$, is formed. The salt is soluble in water, alcohol, and ether. W. Hampe said that the soln. in alcohol is an electrical conductor, but the soln. in ether is a non-conductor unless a trace of water be present. Hydrogen reduces the salt to molybdenum dioxide. E. Weinland and W. Knöll obtained six-sided plates of **ammonium molybdenum dioxytetrachloride,** $2NH_4Cl.MoO_2Cl_2.2H_2O$, or $Mo(ONH_4)_2Cl_4.2H_2O$, or $(NH_4)_2[MoO_2Cl_4].2H_2O$, from a soln. of molybdenum trioxide in conc. hydrochloric acid, saturated with ammonium chloride ; greenish-yellow, six-sided plates of **potassium molybdenum dioxytetrachloride,** $K_2[MoO_2Cl_4].2H_2O$, were obtained in a similar way from soln. with $MoO_3 : KCl=1 : 1$; likewise with six-sided plates of **rubidium molybdenum dioxytetrachloride,** $Rb_2[MoO_2Cl_4]$, and yellowish-green, hygroscopic crystals of **cæsium molybdenum dioxytetrachloride,** $Cs_2[MoO_2Cl_4]$. The salts are hydrolyzed by water. The mother-liquor obtained in preparing the potassium salt also furnishes six-sided plates of **potassium molybdenum dioxytrichloride,** $K[MoO_2Cl_3(H_2O)]$, or $MoCl_3(OK).(OH)_2$, and the same salt is deposited by soln. with $MoO_3 : KCl=3 : 1$; and similarly with **rubidium molybdenum dioxytrichloride,** $Rb[MoO_2Cl_3(H_2O)]$, and **cæsium molybdenum dioxytrichloride,** $Cs[MoO_2Cl_3(H_2O)]$. The mother-liquor employed in the preparation of the potassium salt furnishes aggregates of prisms of **potassium trimolybdenum dioxyheptachloride,** $KCl.3MoO_2Cl_2$, or $K[Mo_3O_6Cl_7].3H_2O$; and similarly with **cæsium trimolybdenum dioxyheptachloride,** $CsCl.3MoO_2Cl_2.11H_2O$, which is also obtained from a hydrochloric acid soln. with $MoO_3 : CsCl=8$ to $12 : 1$. The prismatic crystals are very hygroscopic. The constitution of these salts can be represented by :



$$\underset{\overset{\cdot\cdot\cdot}{\mathrm{Cl_3}}}{\overset{\mathrm{O}}{\ddot{\mathrm{Mo}}}}\mathrm{.O.}\underset{\overset{\cdot\cdot}{\mathrm{Cl_2}}}{\overset{\mathrm{O}}{\ddot{\mathrm{Mo}}}}\mathrm{.O.}\underset{\overset{\cdot\cdot}{\mathrm{Cl_2}}}{\overset{\mathrm{O}}{\ddot{\mathrm{Mo}}}}\mathrm{.OK}$$

W. Püttbach [4] reported **molybdenum oxytetrachloride,** $MoOCl_4$, to be formed by the action of molybdenum pentachloride on molybdenum dichloride ; and by the action of chlorine on a mixture of molybdenum and its dioxide. The green, crystalline sublimate is hygroscopic, and on exposure to air acquires a red film. This compound was represented by C. W. Blomstrand by the formula $Mo_9O_8Cl_2$. P. Klason regarded it as containing $MoOCl_3$; but I. Nordenskjöld showed that it is probably a mixture of molybdenum pentachloride and molybdenum dichloride.

C. W. Blomstrand observed that in the preparation of molybdenyl trichloride, a much less volatile **molybdenum trioxyhexachloride,** $Mo_2O_3Cl_6$, is formed ; and W. Püttbach obtained the same product by repeatedly subliming molybdenyl tetrachloride in a current of carbon dioxide. The deep violet, or ruby-red crystals are stable in dry air, but they gradually decompose in moist air. The salt is hydrolyzed by water. W. Hampe found that it forms a yellow, non-conducting soln. with ether. When the violet salt is heated in a current of carbon dioxide, C. W. Blomstrand, and W. Püttbach found that *molybdenum pentoxyoctochloride*, $Mo_3O_5Cl_8$, is formed in radiating masses of red needles which are stable in air ; they are insoluble in hydrochloric acid, and in cold sulphuric acid ; and soluble in hot sulphuric acid, in nitric acid, and in aq. ammonia.

Some intermediate oxychlorides have been reported. Thus, W. Püttbach heated molybdenyl tetrachloride in a current of hydrogen, and obtained *molybdenum trioxyheptachloride*, $Mo_3O_3Cl_7$, as the chief product along with some molybdenum, and molybdenum dichloride. The dark violet, acicular crystals are treated with water to decompose the unchanged molybdenyl chloride. The brown, acicular crystals volatilize without melting, and are slightly soluble in hydrochloric acid ; and form a colourless soln. with nitric acid, or alkali-lye. W. Püttbach also said that *molybdenum trioxytetrachloride*, $Mo_2O_3Cl_4$, is obtained as an easily volatilized sublimate in the preparation of molybdenum tetrachloride. C. W. Blomstrand prepared molybdenum trioxypentachloride, $Mo_2O_3Cl_5$, by heating molybdenum hemitrioxide in dry chlorine, and subliming the product in hydrogen. The brown or brownish-black product easily melts, and it sublimes slowly giving dark reddish-brown vapours. It deliquesces in moist air forming a blue liquid. It is easily soluble in water—the soln. becomes green, and then blue. With an excess of water, a blue precipitate is formed.

H. Debray[5] prepared *molybdenum trioxybishydrochloride*, or **molybdenyl dihydroxydichloride,** or **molybdenum oxydihydroxydichloride,** $MoO_3.2HCl$, or $MoO(OH)_2Cl_2$, or, according to A. Werner, $H_2[MoO_3Cl_2]$, by passing hydrogen chloride over molybdenum trioxide at 150° to 200°. It collects as a sublimate beyond the heated zone. E. Péchard, and E. F. Smith and V. Oberholtzer obtained it by heating a non-volatile molybdate to 360°–400° in a current of hydrogen chloride. According to H. Debray, the compound forms white, or if slowly cooled, yellowish needles which are very easily volatilized in a current of hydrogen chloride, but are decomposed when heated in air. This volatility enables molybdenum to be separated from silica, tungsten trioxide, and other substances which do not form chlorides volatilizable at about 400°. A. Vandenberghe's observations on the vap. density show that the compound is somewhat dissociated at 160°. H. Debray said that the salt is easily soluble in water, and when the aq. soln. is evaporated, it deposits molybdenum trioxide. E. Péchard found that the salt is readily soluble in ether, so that it can be extracted by ether from a conc. hydrochloric acid soln. of a molybdate, and the ethereal soln. deposits crystals of an ethereal complex ; the salt is also soluble in alcohols, acetone, ether, and glacial acetic acid. B. Kalischer observed some reduction accompanied by the smell of aldehyde with the alcoholic soln. A. Vandenberghe found from the effect of the salt on the f.p. of glacial acetic acid that the mol. wt. is 114·4 to 123·0 ; acetic acid, 156·0 to 314·1 ; and water, 38·4 to 57·8 ; while its effect on the b.p. of ethyl ether agrees with the mol. wt. 208·6 to 229·0 ; acetone, 220·8 to 236·1 ; methyl alcohol, 101·3 to 121·6 ; and ethyl alcohol, 160·0 to 181·8. The data with ether and acetone are in agreement with the normal mol. wt. ; with alcohol, the salt is dissociated, and more so with methyl than with ethyl alcohol ; with water, the decomposition is great.

E. Weinland and W. Knöll found that when molybdenyl dihydroxydichloride is made into a mush with fuming hydrochloric acid, and the mixture warmed, the mass solidifies to form crystalline **molybdenum oxyhydroxytrichloride,** or **molybdenyl hydroxytrichloride,** $MoO(OH)Cl_3.7H_2O$, or

$$\left.\begin{matrix}O\\HO\end{matrix}\right>Mo\equiv Cl_3.7H_2O$$

The salt is also formed by saturating with hydrogen chloride a soln. of molybdenyl dihydroxydichloride in fuming hydrochloric acid, and evaporating the liquid over sulphuric acid ; and the salt has been found to separate from soln. containing magnesium or calcium molybdates. The pale green prisms or plates are very hygroscopic, and effloresce over sulphuric acid losing at the same time some hydrogen chloride. The salt dissolves in water without depositing molybdic acid.

C. W. Blomstrand obtained **molybdenum dihydroxytetrachloride,** $Mo_3(OH)_2.Cl_4.2H_2O$, by adding acetic acid to an alkaline soln. of molybdous chloride. The *dihydrate* is a pale yellow, amorphous salt insoluble in water, or alcohol ; it is freely soluble in strong acids if it is freshly precipitated and washed with cold water ; if washed with hot water, it is less soluble in acids. If the soln. in sulphuric or nitric acid is washed with water, it is precipitated as a compact, yellow powder which is not soluble in acids—conc. sulphuric acid or fuming nitric acid. C. W. Blomstrand obtained pale yellow crystals of the *octohydrate* by precipitation from an alkaline soln. of molybdous acid by carbon dioxide. W. Muthmann and W. Nagel obtained it at the cathode by the electrolysis of a soln. of molybdous chloride in 96 per cent. alcohol. K. Lindner and co-workers found that at 35° it can be represented by $[Mo_3Cl_4(H_2O)_2](OH)_2.H_2O$; at 67°–100°, by $[Mo_3Cl_4(H_2O)_2](OH)_2$; and at 200°–300°, it forms **molybdenum oxytetrachloride,** $[Mo_3Cl_4(H_2O)_2]O$. They also prepared a complex acetate, $[Mo_3Cl_4(H_2O)_2](C_2H_3O_2)_2$.

P. Didier [6] did not succeed in preparing **chloromolybdates** analogous to the chlorotungstates.

§ 21. Molybdenum Bromides and Oxybromides

C. W. Blomstrand [1] obtained **molybdenum dibromide,** or **molybdous bromide,** $MoBr_2$, or $(MoBr_2)_3$, by heating the tribromide to redness. If molybdenum is heated in the vapour of bromine, molybdous bromide will be found as a non-volatile residue in the part subjected to the strongest heat. It is purified by elutriation with water so as to leave the unchanged molybdenum behind. A. Atterberg obtained it by a similar process; and K. Lindner and H. Helwig, by passing nitrogen and bromine vapour over powdered molybdenum at 600° to 700°. The yellowish-red product is infusible. It is insoluble in water and acids, and even in boiling nitric acid. W. Muthmann and W. Nagel represent the bromide by the formula $[Mo_3Br_4]Br_2$. Molybdous bromide is completely decomposed by alkali-lye with the separation of black hydrated molybdic oxide, while it is freely soluble in dil. alkali-lye forming a yellow liquid containing alkali bromide and $Mo_3(OH)_2Br_4$; acids precipitate from this soln. various complexes $[Mo_3Br_4]X_2.nH_2O$, where X_2 denotes F_2, Cl_2, Br_2, I_2, SO_4, $(NO_3)_2$, $(H_2PO_4)_2$, CrO_4, MoO_4, C_2O_4, etc. If hydrobromic acid be added to $Mo_3(OH)_2Br_4$, or to $Mo_3Br_4I_2$, the trihydrate, $[Mo_3Br_4]Br_2.3H_2O$, is formed. K. Lindner discussed the constitution of these compounds. W. Lederer obtained a yellowish-white compound by the action of bromine or bromine water on molybdenum. F. W. Bergstrom studied the action of liquid ammonia and obtained an ammoniobasic halide. K. Lindner and H. Helwig prepared **molybdous amminobromide,** $Mo_3Br_6(NH_3)_2.C_2H_5OH$, as well as a complex with pyridine, $Mo_3Br_6.C_5H_5N$. The action of alcoholic halogen acids furnishes the pyridine salt of **hydrobromomolybdous acids,** $C_5H_5N.HMo_3Br_7$; $(C_5H_5N)_5H_5Mo_6Br_{17}.2C_2H_5OH$; and also salts of mixed hydrobromochloromolybdous acids.

C. W. Blomstrand[2] prepared **molybdenum tribromide,** or **molybdic bromide,** $MoBr_3$, by passing the vapour of bromine over molybdenum or a mixture of molybdenum dioxide and carbon heated by an alcohol lamp; and A. Rosenheim and H. J. Braun obtained it by passing dry carbon dioxide mixed with the vapour of dry bromine over warm molybdenum, and as a brownish-red soln. by the electrolytic reduction of a soln. of 37 grms. of hydrated molybdic acid in 240 c.c. of conc. hydrobromic acid by a current of 0·6 to 0·8 amp. The tribromide forms a dark green or black mass of acicular crystals. It volatilizes with difficulty, and when strongly heated yields bromine and the dibromide. It is insoluble and not decomposed by water; ammonia gas transformed it at a low temp. into molybdenum; boiling hydrochloric acid, and cold dil. nitric acid do not attack it perceptibly; dil. alkali-lye acts slowly in the cold, whilst the boiling lye transforms it into hydrated oxide. F. W. Bergstrom studied the action of liquid ammonia, and obtained a deep red soln. and an ammoniobasic bromide. When a soln. of the salt is treated with ammonium bromide, and evaporated, A. Rosenheim and H. J. Braun obtained black rhombic crystals of **ammonium molybdenum pentabromide,** $(NH_4)_2MoBr_5.H_2O$. The salt is very soluble in water, forming a blood-red soln. F. Förster and E. Fricke represented it by $(NH_4)_2[MoBr_5(H_2O)]$. W. Wardlaw and A. J. I. Harding prepared **potassium molybdenum pentabromide,** K_2MoBr_5, by adding 20 c.c. of a soln. of 1·5 grms. of potassium bromide to 100 c.c. of a soln. of tervalent molybdenum bromide, in an air-free flask, and conc. at 65°–70° under reduced press. until nearly dry. Alcohol was introduced, and the crystalline brick-red salt separated out. By a similar process an impure **rubidium molybdenum pentabromide** was obtained; and the double decomposition of the potassium salt and cæsium bromide furnishes **cæsium molybdenum pentabromide,** $Cs_2MoBr_5.H_2O$. They also prepared **potassium molybdenum hexabromide,** K_3MoBr_6, by adding 10 grms. of potassium bromide, in a sat. aq. soln., to 200 c.c. of a soln. of tervalent molybdenum bromide, and concentrating at 65°–70° under diminished press. to about 100 c.c. Air-free alcohol was then admitted to the flask, and the excess of potassium bromide precipitated. After filtration in an atmosphere of carbon dioxide, the filtrate was concentrated to 40 c.c. On addition of absolute alcohol a crystalline, light red solid was obtained which was filtered off and dried. All these soluble complex salts give deep red soln. with water, in which both potassium salts are very soluble, the rubidium salt is sparingly soluble, and the cæsium compound insoluble. The aq. soln. gradually turn brown, then turbid, and finally yield a dark brown precipitate. This decomposition is accelerated by warming. The salts reduce copper sulphate soln. to cuprous bromide, whilst silver nitrate soln. is reduced to the metal.

C. W. Blomstrand obtained a small yield of **molybdenum tetrabromide,** $MoBr_4$, as a product of the action of bromine on heated molybdenum. Molybdenyl dibromide sublimes first; green molybdenum tribromide appears near the hot zone, and most distant from the heated metal occur black needles of the tetrabromide. The exact conditions have not been established. The salt is fusible and volatile; it furnishes brownish-red vapour; it easily decomposes into the tribromide and bromine; it deliquesces rapidly in air to a black liquid; and it gives with water a yellowish-brown soln. from which alkalies precipitate hydrated molybdic oxide.

C. W. Blomstrand[3] found that a soln. of molybdous bromide in alkali-lye is gradually decomposed by air containing carbon dioxide forming golden-yellow crystals of **molybdenum dihydroxytetrabromide,** $Mo_3Br_4(OH)_2.8H_2O$; the crystals of the *octohydrate* were also produced by adding ammonium chloride to a hot, alkaline soln. of molybdous bromide; and by adding acetic acid to an alkali soln. of molybdous bromide. According to A. Atterberg, and C. W. Blomstrand, if the octohydrate be dried over sulphuric acid, it gives the dark red *dihydrate;* and if one of the hydrates be dried at 100° or in vacuo over sulphuric acid, a red powder of the anhydrous salt is formed. If it has not been heated over 90°, it dissolves completely in alkali-lye. The octohydrate forms a yellow, amorphous powder which rapidly loses water in air. If the hydrate be heated until all the water is expelled, and the residue treated with alkali-lye, a black powder—possibly molybdous oxide—remains. Hydrochloric acid dissolves the product; nitric acid attacks the salt; and, according to W. Muthmann and W. Nagel, it is decomposed by alkali hydroxide to form hydrated molybdic oxide. The alkaline soln. is precipitated by acids to form mixed salts, $[Mo_3Br_4]X_2.nH_2O$, as indicated above. Hydrogen sulphide was found by A. Atterberg to precipitate hydrated molybdic oxide; and A. Atterberg also studied the action of potassium cyanide.

According to A. Atterberg, an alkaline soln. of molybdenum dihydroxytetrabromide yields a dark reddish-yellow precipitate of **molybdenyl bromide,** $MoOBr,\frac{1}{2}H_2O$, when treated with ammonium molybdate and acetic acid; the colour becomes reddish-brown at 100°. W. Wardlaw and A. J. I. Harding prepared the bromide by precipitating a conc. soln. of a tervalent molybdenum bromide in acetone.

> 25 grms. of molybdenum trioxide and 350 c.c. of the hydrobromic acid were heated under a reflux condenser for 3 to 6 hours, when a golden-brown liquid was finally obtained. The filtered soln. was electrolyzed in a diaphragm cell with smooth platinum electrodes, a current of 3·5 amps. being used, until the cathode soln. was reddish-brown. This soln. was transferred to an air-free flask and conc. at 70° under diminished press. to 80–100 c.c. The liquid was then transferred to a small cell and re-electrolyzed to ensure that the molybdenum was tervalent. The electrolysis was continued until a sample of the liquid added to air-free acetone gave a flocculent fawn precipitate of molybdenyl bromide. (If the electrolysis is continued beyond this stage, the product is hydrolyzed and is much darker than the true compound.) The cathode soln. was now forced by press. of carbon dioxide into air-free acetone, and the solid which separated was filtered off and washed with acetone. All these operations were performed in an atm. of carbon dioxide, air being rigidly excluded. The solid was transferred to a desiccator which was then evacuated.

The composition is $MoOBr.4H_2O$. The dried solid is light fawn in colour and does not deliquesce in the air, although it gradually undergoes atm. oxidation. It is readily soluble in water or hydrobromic acid, its solubility in water being greater than that of the oxychloride. It is insoluble in acetone or dry ether, slightly soluble in cold absolute alcohol and more soluble on warming. The substance has pronounced reducing properties. Silver nitrate is reduced to the metal, whilst with lead acetate acidified with acetic acid no precipitate of lead bromide is obtained. This test seems to indicate that molybdenyl bromide is not a binary electrolyte. The mol. wts. determined by the depressions of the f.p. of soln. of 0·1235, and 0·0640 grm. in 10 grms. of air-free water are, respectively, 218·8 and 218·2. This agrees with the assumption that the salt is a co-ordination compound $[MoOBr.4H_2O]$, which undergoes gradual hydrolysis, $[MoOBr,4H_2O]+H_2O=[MoO.5H_2O]Br =[MoO.5H_2O]^{\cdot}+Br'$. This view receives support from the fact that the mol. wts. determined with soln. of the solid, after standing some hours in ice-cold water, were considerably less than those quoted above, whilst after longer periods the hydroxide of molybdenum gradually separated. The mol. conductivity of soln. of a mol of the salt in 24 litres of water at 1°, changes from 66·8 in 2 min. to 78·2 in 9 min. The rate of hydrolysis is faster in more dil. soln.

E. Weinland and W. Knöll found that when the product of the action of hydrogen bromide on heated molybdenum trioxide, is dissolved in warm, 40 per cent. hydrobromic acid until bromine is no longer evolved, and the soln. crystallized over sulphuric acid, green hygroscopic needles of **molybdenum hydroxytetrabromide,** $Mo(OH)Br_4.2H_2O$, are formed. They are rapidly decomposed in humid air. If the soln. used in the preparation of this salt be allowed to stand over soda-lime at 30°, dark brown, hygroscopic prisms of **molybdenum oxyhydroxydibromide,** or

molybdyl dibromide, $MoO(OH)Br_2.1\frac{1}{2}H_2O$, are formed. The aq. soln. is brown, and ammonia precipitates hydrated molybdenum pentoxide.

The **molybdenyl tribromide,** $MoOBr_3$, has not been isolated. A. Chilesotti observed that by the electrolytic reduction of molybdenum trioxide in hydrochloric or sulphuric acid soln. of suitable concentration, a soln. of quinquevalent molybdenum is formed if a platinized platinum cathode is employed, but with a polished platinum cathode, a tervalent salt is produced. The complex **ammonium molybdenyl pentabromide,** or **ammonium molybdenum oxypentabromide,** $2NH_4Br.MoOBr_3$, or $MoOBr_3(NH_4Br_2)(ONH_4)$, or $(NH_4)_2[MoOBr_5]$, was obtained by E. Weinland and W. Knöll, from a hydrobromic acid soln. of the components. It forms reddish-brown, octahedral crystals. F. G. Angell, R. G. James and W. Wardlaw prepared the ammonium salt by reducing electrolytically a soln. of molybdenum trioxide in hydrobromic acid to the quinquevalent state, and transferred the soln. in a current of nitrogen to an air-free flask containing a soln. of ammonium bromide. The light brown crystals were washed with hydrobromic acid of sp. gr. 1·7, drained, and dried in vacuo over potassium hydroxide and phosphorus pentoxide. The mother-liquor furnishes other crops when concentrated and seeded with crystals of the salt. According to E. Weinland and W. Knöll, an analogous process furnishes by using Mo : K in the proportions 2 : 1, **potassium molybdenyl pentabromide,** K_2MoOBr_5, in black or dark red crystals; similarly with **rubidium molybdenyl pentabromide,** Rb_2MoOBr_5, in dark red or green, rhombic pyramids; and **cæsium molybdenyl pentabromide,** Cs_2MoOBr_5, in garnet-red, octahedral crystals. F. G. Angell and co-workers obtained potassium molybdenum oxypentabromide, $K_2[MoOBr_5].2H_2O$, in dark brown needles; rubidium molybdenum oxypentabromide, $Rb_2[MoOBr_5]$, as a yellow solid; **pyridinium molybdenum oxypentabromide,** $(C_5H_6N)_2[MoOBr_5])$, in yellowish-green needles; and **quinolinium molybdenum oxypentabromide,** $(C_9H_8K_2[MoOBr_5]$, in golden-brown crystals. A. Rosenheim and M. Koss, and E. Weinland and W. Knöll also prepared the pyridine and quinoline complex salts. The calculated mol. wts., and those calculated from the depression of the f.p. of the salts, dissolved in air-free water, as well as the osmotic factor *i*, are, in aq. and alcoholic soln.,

		NH_4-	K_4-	Rb-	C_5H_6N-	C_9H_8N-salt.

Alco. Soln.	*v* . . .	29·4–19·5	—	—	28·2–19·1	27·6–16·1
	By lowering .	29·4–19·5	—	—	219–214	179–264
	i . . .	3·84–4·12	—	—	3·07–3·14	431–2·92

The mol. electrical conductivities, μ, of soln. with *v* litres per mol, were:

$(NH_4)_2[MoOBr_5$	*v* . .	14·3	28·5	57·0	114·0	228·1	456·3
	μ . .	561·0	598·8	613·0	655·0	689·3	757·0
$K_2[MoOBr_5]$	*v* . .	19·7	39·4	78·9	157·8	315·5	631·0
	μ . .	450·1	487·1	515·2	526·8	566·1	660·4

and similarly with the pyridinium and quinolinium salts. The chlorides are green, and the bromides brown to yellow when dry, but in aq. soln. these salts are extensively hydrolyzed and ionized. By treatment with thiocyanic acid, they yield black thiocyanates, $R_2[MoO(CyS)_5]$, insoluble in water but readily soluble in alcohol. The bromides are more sensitive to oxidation than the chlorides. Like the chlorides, the complex bromides in absolute alcohol give an osmotic factor approximating $i=3$, and the soln. retain the characteristic colour of the salts themselves. This is taken to mean that in alcoholic soln., the formula of the salts are of the co-ordination type $R_2[MoOX_5]$, rather than $2RX.MoOX_3$, where the osmotic factor would be nearly $i=1$. An alcoholic soln. ionization is in accord with $R_2[MoOX_5]\rightleftharpoons 2R^{\cdot}+[MoOX_5]''$; and hydrolytic decomposition does not occur as is the case in aq. soln. where the colours are quite different from those in alcoholic soln. E. Weinland and W. Knöll prepared **magnesium molybdenyl pentabromide,** $Mg(MoOBr_5).7H_2O$, in hygroscopic, olive-green, octahedral crystals or six-sided pyramids.

E. Weinland and W. Knöll prepared **potassium molybdenyl tetrabromide,** or **potassium oxytetrabromide,** $KMoOBr_4.2H_2O$, or $K[MoOBr_4H_2O].H_2O$, in olive-green columnar columns, from a hydrobromic acid soln. of the component salts with Mo : K=1 : 4. F. G. Angell and co-workers doubt if the salt is olive-green because, whilst the oxytetrachlorides are green, the oyxtetrabromides they obtained are all red. They prepared red, hygroscopic crystals of **lithium molybdenum oxytetrabromide,** $Li[MoOBr_4(H_2O)].3H_2O$, from the electrolytically reduced soln. of quinquevalent molybdenum in hydrobromic acid, by the addition of lithium bromide, cooled in ice. The product was washed with hydrobromic acid of sp. gr. 1·7, and dried over sodium hydroxide and phosphorus pentoxide. The corresponding **pyridinium molybdenum oxytetrabromide,** $(C_5H_6N)[MoOBr_4]$, was also obtained in red, hygroscopic needles, and **quinolinium molybdenum oxytetrabromide,** $(C_9H_8N)[MoOBr_4]$, in orange, hygroscopic needles, which when dried change to pink. The f.p. of the aq. soln. gives an osmotic factor $i=9{\cdot}0$ to 7·7 or a mol. wt. 56·5 to 66·5—calculated for the trihydrate 510·7. This corresponds with complete decomposition in aq. soln. In alcoholic soln., the osmotic factor i is nearly 3 indicating a dissociation $2R[MoOBr_4]\rightleftharpoons R_2[MoOBr_5]+MoOBr_3$. The lithium salt was also prepared by E. Weinland and W. Knöll; and they also reported that **calcium molybdenum oxytetrabromide,** $CaMoOBr_4.7H_2O$, or $Ca[MoOBr_4(H_2O)].6H_2O$, furnishes red, four-sided plates.

E. F. Smith and V. Oberholtzer obtained **molybdenum trioxytetrabromide,** $Mo_2O_3Br_4$, along with the trihydroxytribromide by the action of hydrogen bromide on molybdenum trioxide. The colour of the salt resembles that of potassium permanganate; the tabular crystals which are slowly acted upon by purified air, but not by carbon dioxide; they dissolve in water with the development of heat, forming a colourless soln. which becomes blue on standing. E. F. Smith and V. Oberholtzer obtained **molybdenum trihydroxytribromide,** $Mo(OH)_3Br_3$, as indicated above. The brownish-yellow volatile liquid at a low temp., and under reduced press., yields yellow needles, which liquefy as soon as air is admitted. The aq. soln. is very pale yellow, almost colourless, and becomes deep yellow on standing, and in about 24 hrs. deposits blue molybdenum oxide.

C. W. Blomstrand prepared **molybdenum dioxydibromide,** MoO_2Br_2, by heating molybdenum dioxide in bromine vapour; and by melting molybdenum trioxide with boric or phosphoric acid, and heating the cold and powdered mass with potassium bromide: $MoO_3+B_2O_3+2KBr=2KBO_2+MoO_2Br_2$. The yellowish-red, tabular crystals deliquesce in air; and they form a colourless soln. with water. F. G. Angell and co-workers obtained **lithium molybdenum dioxydibromide,** $Li[MoO_2Br_2(H_2O)_2].4H_2O$, from an electrolytically reduced soln. of quinquevalent molybdenum mixed with lithium bromide, evaporated to a small volume, and cooled in ice. The salt was washed in hydrobromic acid of sp. gr. 1·7, and dried over sodium hydroxide and phosphorus pentoxide.

§ 22. Molybdenum Iodides, and Mixed Halides

J. J. Berzelius[1] found that iodine does not act on red-hot molybdenum; and that a soln. of hydrated molybdic oxide in hydriodic acid, behaves like the soln. in hydrochloric acid. M. Guichard found that when dry molybdenum pentachloride is heated in a current of dry hydrogen iodide, iodine is liberated, and brown, amorphous **molybdenum diiodide,** or **molybdous iodide,** MoI_2, is formed. The sp. gr. is 4·3. Molybdous iodide is insoluble in water and alcohol. When heated in vacuo up to the m.p. of glass, it is not decomposed, but when heated in air, iodine is liberated and an oxide is formed which, at a higher temp., is converted into molybdenum trioxide. Hydrogen reduces the iodide at 500°, and the change is very rapid at an incipient red-heat. Chlorine decomposes it below 240°, and bromine behaves similarly. In oxygen at 350°, there is vigorous incandescence, with a liberation of iodine and formation of molybdenum trioxide. Sulphur readily converts the iodide into a black sulphide, but nitrogen is without action at the softening point of glass. Water decomposes it very slightly at the ordinary temp., and a little more rapidly at 700°, whilst in superheated steam, hydrogen is liberated as well as hydrogen iodide, probably as a result of the decomposition of the steam by an oxide, MoO, formed as the first product of the action of the steam on the iodide. Hydrogen sulphide converts the iodide into sulphide, and sulphuric and nitric acids oxidize it slowly in the cold and more rapidly on heating. Potash-lye acts on it slowly at ordinary temp.

J. J. Berzelius obtained a red soln. by dissolving molybdenum tetrahydroxide in hydriodic acid. When the soln. is evaporated in air, it forms red or brown crystals which are soluble in water, and give off hydrogen iodide when heated leaving a residue of molybdenum dioxide. M. Guichard obtained **molybdenum tetraiodide,** MoI_4, by the action of liquid hydrogen iodide, under press., on molybdenum tetrachloride. The black crystals change in air, and lose iodine at 100°. The salt cannot be obtained free from chlorides.

J. H. Gladstone[2] observed that when hydrofluoric acid is added to a green soln. of molybdous oxide in hydrochloric acid, a rich purple precipitate is produced, and this is succeeded by a white precipitate which is insoluble in an excess of hydrofluoric acid, but readily soluble in hydrochloric acid reproducing the green soln. The white substance was said to be a compound of molybdenum with both halogens. O. Ruff and F. Eisner condensed hydrogen fluoride over powdered molybdenum pentachloride cooled by a freezing mixture, and, after the mixture had stood for some time, distilled off the hydrogen fluoride. There remained **molybdenum fluochloride,** $Mo_3F_{10}Cl_5$, as a blue solid. A. Atterberg prepared **molybdenum difluotetrabromide,** $Mo_3Br_4F_2.3H_2O$, as a yellow powder, by the action of hydrofluoric acid on an alkaline soln. of molybdenum dihydroxytetrabromide.

A. Atterberg, and C. W. Blomstrand prepared **molybdenum dichlorotetrabromide,** $Mo_3Br_4Cl_2.3H_2O$, by adding an excess of hydrochloric acid to an alkaline soln. of molybdenum dihydroxytetrabromide. The yellow powder loses no water at 100°; and when treated with boiling water, forms the dihydroxytetrabromide. C. W. Blomstrand prepared **molybdenum tetrachlorodibromide,** $Mo_3Cl_4Br_2,3H_2O$, by allowing a soln. of molybdous chloride or molybdenum dihydroxytetrachloride to stand in hot hydrobromic acid for some time. The cold soln. deposits crystals of the *trihydrate* which are insoluble in water, and in dil. hydrochloric acid; with fuming nitric acid, hydrogen bromide is given off. If a warm aq. soln. is allowed to stand on a water-bath it deposits red prisms of the *hexahydrate*. It is soluble in water; and it can be recrystallized from its soln. in dil. hydrobromic acid. It is soluble in alcohol and ether. When water is added to the alcoholic soln., there is precipitated **molybdenum hydroxytetrachlorobromide,** $Mo_3(OH)BrCl_4.2H_2O$. C. W. Blomstrand also prepared **ammonium molybdenum tetrachlorotetrabromide,** $2NH_4Br.Mo_3Cl_4Br_2.2H_2O$, in yellowish-red crystals, by saturating a soln. of molybdous chloride with potassium chloride and adding ammonia and hydrobromic acid. The salt is decomposed by water; it can be recrystallized from dil. hydrobromic acid, and it dissolves without decomposition in alcohol. Similarly with the preparation of **potassium molybdenum tetrachlorotetrabromide,** $2KBr.(Mo_2Cl_4)Br_2.2H_2O$.

C. W. Blomstrand obtained **molybdenum tetrachlorodiiodide,** $Mo_3Cl_4I_2.3H_2O$, from a hot soln. of molybdous chloride or molybdenum dihydroxytetrachloride in hydriodic acid. The *trihydrate* separates as a scaly crystalline precipitate. The mother-liquor, when concentrated on a water-bath, deposits dark red prisms of the *hexahydrate.* The salt is decomposed by water; and with fuming nitric acid, iodine separates out. It behaves towards alcohol like the tetrachlorodibromide. Dark yellowish-red crystals of **ammonium molybdenum tetrachlorotetraiodide,** $2NH_4I.Mo_3Cl_4I_2.2H_2O$, are formed by a method analogous to that used for the tetrachlorotetrabromide. Similarly with the preparation of **potassium molybdenum tetrachlorotetraiodide,** $2KI.(Mo_3Cl_4)I_2.2H_2O$. A. Atterberg, and C. W. Blomstrand prepared a complex with **molybdenum tetrabromodiiodide,** namely, $Mo_3(OH)_2Br_4.2Mo_3Br_4I_2.8H_2O$, from an alkaline soln. of dihydroxytetrabromide saturated with hydriodic acid. These mixed salts were discussed by I. Koppel, and K. Lindner and co-workers. K. Lindner and H. Helwig obtained pyridine salts of some mixed acids, namely, $C_5H_5N.HMo_3Br_4Cl_3$; $C_5H_5N.HMo_3Br_4Cl_3.C_2H_5OH$; and $C_5H_5N.HMo_3Br_4Cl_3$.

§ 23. Molybdenum Sulphides

M. Guichard[1] found that when molybdenum disulphide is heated in the electric arc-furnace for 2 to 4 min., a mixture of molybdenum and **molybdenum hemitrisulphide,** or **molybdic sulphide,** Mo_2S_3, is formed. The metal can be removed by treatment with cold dil. aqua regia. W. Muthmann and co-workers heated molybdenite mixed with calcium oxide and fluoride in the arc-furnace, and obtained bluish black crystals. M. Guichard found that this sulphide forms steel-grey needles of sp. gr. 5·9 at 15°, and it is rather harder than molybdenite. If heated in the electric arc-furnace, it forms molybdenum; and when heated in sulphur vapour, molybdenum disulphide is formed. M. Picon observed that this sulphide is largely dissociated at 1100°, and volatilization occurs at 1200°. W. Muthmann and co-workers found that this sulphide is not attacked by conc. hydrochloric acid. K. von der Heide studied the action of potassium cyanide on molybdic sulphide. V. Montoro found that the X-radiogram of the supposed sesquisulphide is the same as that of molybdenite, MoS_2, superposed on that of a molybdenum hemicarbide, MoC_2, and that the latter disappears after the substance has been treated with dil. aqua regia.

The history of **molybdenum disulphide,** MoS_2, and its occurrence as **molybdenite,** has been discussed in connection with the history, and occurrence of molybdenum. F. Cornu applied the term **jordiste** to the colloidal mineral from Himmelsfürst, Freiberg, which has the same composition as molybdenite. Analyses of molybdenite were made by C. F. Bucholz, R. Brandes, P. Jannasch, A. Cossa, L. F. Svanberg and H. Struve, W. Gerrie, A. Liversidge, H. Seybert, C. M. Wetherill, J. C. Ilsemann, J. C. H. Heyer, R. Nasini and E. Baschieri, K. Nenadkewitsch, and F. Zambonini. The results agree with the formula MoS_2, and with the analyses of L. F. Svanberg and H. Struve, and M. Guichard of the artificial compound. Molybdenum disulphide was prepared by C. W. Scheele, and J. J. Berzelius by heating one of the higher sulphides in a closed vessel; and by heating molybdenum trioxide admixed with sulphur, or in a current of hydrogen sulphide. M. Guichard heated a mixture of 150 grms. of potassium carbonate, 310 grms. of sulphur, and 200 grms. of molybdenum dioxide at a high temp. for half an hour, and washed out the potassium polysulphide by means of water. A. de Schulten used a similar process. M. Guichard obtained the same compound by heating a mixture of 50 grms. of ammonium molybdate, 100 grms. of sulphur, and some lamp-black. St. Meunier used a similar process. J. Milbauer found it to be a product of the action of potassium thiocyanate on molybdenum oxide at a high temp. C. W. C. Fuchs calcined a mixture of molybdenum trioxide and cinnabar; and H. Debray heated a mixture of ammonium molybdate and an excess of lime in a current of hydrogen chloride and sulphide; E. Péchard obtained it by the action of hydrogen sulphide on an acidic soln. of molybdenum dioxide; and C. Winssinger, by the action of an excess of dil. acetic acid on potassium sulphomolybdate. C. Winssinger found that if the product so obtained be dialyzed for about 72 hrs., a brown, neutral liquid—**colloidal molybdenum disulphide**—is formed. F. V. von Hahn prepared colloidal sols by the cathodic discharge. P. Bary and J. V. Rubio, and P. Bary studied the structure of the dried gel.

J. J. Berzelius described molybdenum disulphide as a black powder; and E. Péchard, as a reddish-brown precipitate, Molybdenite occurs in lead-grey masses which may be foliated, scaly, or granular. The crystals are hexagonal in form and appear in flexible but not elastic plates resembling mica, or in short prisms which are slightly tapering. The prismatic planes are horizontally striated; and striæ sometimes occur on the base normal to the edges. A. Knop said that thin plates are green. The cleavage of the crystals resembles that of mica, and thin sheets of the mineral several square centimetres in area may be scaled off from a large crystal of molybdenite. These sheets have a metallic lustre and look not unlike sheets of lead foil. They can be readily electroplated with copper, so that connecting wires may be soldered to them. The streak, said J. L. C. Schröder van der Kolk, is greenish-grey. H. Schneiderhöhn examined polished sections of the mineral. J. B. L. Romé de l'Isle compared the crystals of molybdenite with those of mica and talc. R. J. Haüy said that the *présumée forme primitive* is a rhombic prism. J. G. Schmeisser described the crystals as hexagonal prisms; J. F. L. Hausmann, as regular six-sided plates; and F. Mohs, as rhombohoidal (trigonal). N. A. E. von Nordenskjöld doubted if the crystals are hexagonal. M. Hörnes, and N. von Kokscharoff said that the crystals are monoclinic or possibly rhombic; and P. Groth, rhombic. G. A. Kenngott, however, showed that the crystals are probably hexagonal; and A. P. Brown gave for the axial ratio of the hexagonal crystals $a:c=1:1\cdot9077$. This is in agreement with the observations of A. J. Moses, W. E. Hidden, W. C. Brögger, and O. Mügge. A. J. Moses found that the corrosion figures of molybdenite agree with those for hexagonal crystals. R. G. Dickinson and L. Pauling found that the X-radiograms agreed with a typical, hexagonal, layer lattice. Each hexagonal unit contains two molecules of the disulphide, and has an axial ratio 1·95. Each sulphur atom is equidistant from three molybdenum atoms, and each molybdenum atom is surrounded by six equidistant sulphur atoms at the corners of a small triangular prism of altitude 3·17 A., and edge 3·15 A.—Fig. 28 when the circles represent sulphur atoms, and the black spots, molybdenum atoms. There is a layer of sulphur atoms each side of a layer of molybdenum atoms; two layers of sulphur atoms are in contact. The sulphur atoms form pyramids which are 3·66 A. in length along the pyramid edges, and 3·15 A. along the basal edges. The distance of the molybdenum atom to the nearest sulphur atom is 2·41 A. The excellent basal cleavage of molybdenite is connected with the relatively great distance between the sulphur atoms. A. E. van Arkel, J. W. Gruner, V. Montoro, and E. J. Cuy made some observations on this subject. O. Hassel studied the structure of the disulphide, and H. Mark, the deformation produced by stresses. F. Mohs found the sp. gr. of molybdenite to be 4·591 ; and H. Seybert, 4·444. M. Guichard gave 4·80 for the sp. gr. at 14° of the artificial crystals, and 4·88 at 14° for the amorphous disulphide. A. de Schulten gave 5·06 for the sp. gr. of the artificial crystals. The hardness of molybdenite is 1·0 to 1·5. Observations on this subject were made by A. Reis and L. Zimmermann. E. Jannettaz found the heat conductivity from a central point of the prisms furnished an ellipse with the axes 1 : 2 or 1 : 3. F. E. Neumann gave 0·1067 for the sp. ht. ; A. de la Rive and F. Marcet, 0·1097 ; and H. V. Regnault, 0·12334. H. V. Regnault observed that the disulphide is not altered by heating it to a high temp. out of contact with air. E. D. Clark said that when heated in the oxyhydrogen blowpipe flame, molybdenite fuses at once and forms a white sublimate containing minute globules of metal, and a molten mass of metal resembling arsenical iron. J. Joly gave 450° for the temp. of sublimation. R. Cusack gave 1185° for the m.p. ; and G. Spezia added that if heated in the oxyhydrogen flame, the disulphide melts and forms a white crystalline sublimate and a yellowish-white vapour. N. Parravano and G. Malquori found that for the dissociation of the disulphide log p_{S_2} is $-11·963$ at 600° ; $-7·620$ at 805° ; $-6·463$ at 910° ; $-5·453$ at 1005° ; and $-4·629$ at 1100°. M. Picon studied the thermal decomposition of the sulphide. A. W. Meyer found the index of refraction, μ ; the absorption coeff., k ; and the reflecting power, R, for light of wave-length $\lambda = m\mu$, to be for molybdenite :

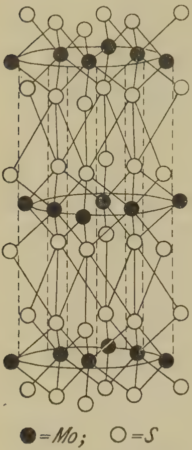

FIG. 28. — The Arrangement of Atoms in Molybdenite, MoS_2.

λ	500	450	410	370	350	330
μ	5·668	4·675	4·002	3·209	2·640	2·217
k	0·341	0·581	0·812	0·963	0·982	1·001
R	52·97	56·75	59·71	52·93	47·13	42·10

Observations on the optical constants were also made by E. P. T. Tyndall. A. de Gramont observed that the spark spectrum does not show the sulphur lines, but molybdenum lines are well-defined. A. Cossa said that the yellowish-green flame gives a continuous spectrum ; and a phosphate bead is blue in the reducing flame ; and a borax lead when heated in the oxidizing flame is yellow when hot and white when cold. W. W. Coblentz found that the ultra-red reflection spectrum of molybdenite is uniform—18 to 20 per cent.—through the spectrum up to 14μ. Molybdenite has four maxima of selective reflection in the ultra-violet at 260, 450, 610, and $690\mu\mu$ respectively. The ultra-red transmission spectrum shows that molybdenite is very opaque up to 15μ. I. B. Crandall found that molybdenite has a low transmission in the visible region followed by great transparency and high reflectivity in the ultra-red. A decrease in temp. to the b.p. of liquid air greatly increases the transparency of molybdenite. A sample transparent to $0·702\mu$ at room temp., was transparent to $0·666\mu$ at $-190°$. For incident light of wave-length 1μ, $2·2\mu$, and 4μ, W. W. Coblentz and C. W. Hughes found the percentage absorptions of the incident light in traversing 0·3 mm. layer were respectively 22·3, 18·1, and 18·1 ; the percentage light reflected at the first surface, 29·8, 27·8, and 27·8 ; the percentage sums of returning light, 39·0, 38·1, and 38·0 ; the percentage sums of the transmitted light, 40·5, 45·0, and 45·0 ; and the indices of refraction, respectively 3·40, 3·23, and 3·23. I. B. Crandall calculated the indices of refraction for light of wave-length λ to be :

λ . .	0·6757	0·6915	0·7136	0·80	3·0	5·0	7·0μ
μ . .	14·8	9·48	7·44	6·00	4·02	3·98	3·90

E. P. T. Tyndall found two maxima in the variation of the index of refraction in the visible spectrum at 600$m\mu$ and 660$\mu\mu$. There is also anomalous dispersion. O. Stelling studied the X-ray absorption spectrum.

R. G. Harvey measured the electrical conductivity. T. W. Case observed the change in the electrical resistance of molybdenite in light. S. L. Martin showed that the result is not a contact effect ; and W. W. Coblentz, that the change is more marked with natural than with artificial molybdenite ; and it is destroyed by heating to 700°. A photoelectric change occurs in the resistance of molybdenite when it is subject to an impressed e.m.f. and exposed to thermal radiation between λ=0·36μ in the ultra-violet to beyond λ=9μ in the ultra-red. W. W. Coblentz showed that the effect of increasing the intensity of the exciting radiations is to produce a more rapid response in the long wave-lengths than in the short wave-lengths, with a resultant shift of the spectral photoelectric sensitivity curve toward the long wave-lengths. There is no simple law governing the variation in the photoelectric response in molybdenite, with variation in intensity of the radiation stimulus. At room temp. there are maxima of sensitivity in the regions of λ=0·7μ, 0·85μ, 1·02μ, and 1·8μ. Beyond 2·5μ the photoelectric sensitivity is practically nil. Raising the temp. causes a rapid decrease in the spectral photoelectric sensitivity, especially in the regions of 1·02μ to 1·8μ. At 80° the spectral photoelectric sensitivity has practically disappeared—only slight indications being observed for radiations of wave-lengths λ=0·6μ to 0·8μ. The effect produced by lowering the temp. is greatly to increase the sensitivity curve throughout the whole spectrum from the ultra-violet to 2·5μ in the infra-red. This increase in sensitivity is greatest in the region of 0·8μ to 0·9μ, so that at the temp. of boiling liquid air the maximum sensitivity occurs at about 0·85μ, with a new band at 1·25μ to 1·35μ. Samples of molybdenite which are quite insensitive at room temp. become fairly sensitive, photoelectrically, at —178°. At low temp., the spectral photoelectric sensitivity curves of all samples are quite similar, with a maximum in the region of 0·8μ to 0·9μ. From this it would appear that this photoelectric property is one of degree rather than one of quality. The fact that the bands at 1·02μ and 1·8μ occur together, and that the 0·85μ band may occur alone suggests the possibility that they are characteristic bands of spectral photoelectric sensitivity of different sulphur compounds of molybdenum. Using frequency instead of wave-length to indicate the spectral position of the radiations which cause the maximum change in electrical conductivity, it is found that in some instances there is a constant difference of the wave numbers analogous to the series relations of spectral lines. The time required for recovery of equilibrium in electrical conductivity is close to twice the time of exposure. Mechanical working of the material appears to lower the photoelectric sensitivity. There appears to be no close connection between photoelectric sensitivity and current rectification in molybdenite. The greatest photoelectrical activity occurs in the region of the spectrum, where there is a rapid decrease in spectral absorption. While selenium is photopositive in that on exposure to light the electrical conductivity greatly increases, some samples of molybdenite are photonegative in that the resistance in light is greater than it is in darkness. W. W. Coblentz found that the two opposing effects may occur simultaneously. The photopositive reaction occurs quickly and prevails on low voltages. The photonegative action usually builds up more slowly and predominates on high voltage. It is selective to the wave-length of the radiation stimulus, as well as to the magnitude and direction for the electric current through the crystal. Temp. also affects the phenomenon, and under certain conditions, on exposure of the molybdenite, the photonegative reaction occurs first followed by the photopositive action. For the short wave-length region of the spectrum, extending to about 0·67μ, the photoelectric reaction in one sample of molybdenite passed from purely positive on low voltages through intermediate stages to an apparently purely negative reaction on high voltages. Furthermore, this reaction is dependent upon the direction of the current through the crystal. On high voltages a secondary negative reaction appears to be present. The recovery after exposure is also unusual. When operated on the intermediate voltages, on shutting off the radiation stimulus, the negative effect still further increases, after which the crystal gradually returns to its former dark conductivity. However, at moderately low temp., —20°, the recovery from the photonegative reaction is irregular, resulting in overshooting so that momentarily the apparent resistance is lower than the normal dark resistance. At a given temp. the region of transition in the spectrum, in which the action changes from photonegative to photopositive, is very narrow (less than 9 A.). It appears to shift slightly toward the short wave-lengths with decrease in temp. or increase in intensity of the radiation. The critical voltage is very small. Under certain temp. conditions an increase of 1 volt sufficed to change a small positive-negative galvanometer deflection of ± 1 cm. into a pure negative deflection of perhaps —25 cms. With decrease in temp. the potential must be increased in order to produce a negative reaction. S. L. Martin, and D. S. Steinberg also discussed the photoelectric effect.

Molybdenite not only shows a photoelectric change in resistance when subjected to an impressed e.m.f. and exposed to thermal radiation; but it shows an actinoelectric effect in that an e.m.f. may be manifested when it is exposed to thermal radiation without an impressed e.m.f. The actinoelectrical phenomenon is more common than is the photoelectric effect; occurring in both the high and the low resistance classes of molybdenite. The intrinsic sensitivity of the actinoelectric reaction seems to be the highest in the low-resistance class of molybdenite, which is just the opposite of the photoelectric reaction. Both effects are usually observed in small spots or loci in the lamina; and both phenomena may be found in the same lamina. The actinoelectric e.m.f. of these spots, which are sometimes separated by only 0·5 to 1·5 mm., may be positive or negative. The polarity of this e.m.f. does not appear to have any relation with the positive and negative thermal e.m.f. observed at the ends of the sample, connected with the copper electrodes. The spectral actinoelectric effect may be positive or negative, depending upon the wave-length of the thermal radiation stimulus, as is the case with the photoelectric effect. The maximum of the spectral actinoelectric reaction is produced by thermal radiation stimuli of wave-lengths between 0·65 and 0·9μ. There may be several such maxima in this spectral region. The material seems to be insensitive actinoelectrically to radiation stimuli of wave-lengths greater than about 1μ. On the other hand, the maxima of the spectral photoelectric reaction in molybdenite usually occur beyond 0·8μ; and the sensitivity extends to 2μ. Moreover, the magnitude of the photoelectrical reaction may be from 75 to 100 times greater than the actinoelectrical response. Hence, since the former is usually observed with an insensitive galvanometer the actinoelectrical reaction has no effect upon previously published data on the spectraphotoelectrical sensitivity of molybdenite. The time for attaining the maximum spectral actinoelectric response is practically instantaneous irrespective of the kind (high or low resistance) of molybdenite examined, and of the wave-length of the exciting radiation. On the other hand, in the typical, high-resistance, high-photoelectrical sensitivity class of molybdenite, for certain wave-lengths of the exciting radiation, the photoelectrical reaction requires from one to several minutes to attain a maximum, and twice that time for recovery after exposure to thermal radiation. In the typical low-resistance, low-photoelectrical sensitivity but high-actinoelectrical sensitivity class of molybdenite, the spectra-photoelectrical reaction appears to be instantaneous irrespective of the wave-length of the radiation stimulus. Lowering the temp. shifts the maximum of the actinoelectrical reaction toward the short wave-lengths; but this shift is much less than obtains in the photoelectric reaction. Lowering the temp. has no marked effect upon the intrinsic actinoelectric sensitivity, as compared with the marked increase in photoelectrical sensitivity observed under similar conditions. Increasing the intensity of the exciting radiation appears to produce a more rapid response on the short wave-length side than on the long wave-length side of the maximum of the spectral actinoelectric reaction, which is just the reverse of the previously observed, spectrophotoelectric reaction under similar conditions. A. Verneuil observed the effect of traces of molybdenite on the phosphorescence of calcium sulphide. J. O. Perrine found that the fluorescence of molybdenite is not excited by the X-rays.

H. F. Vieweg found that the frictional electricity developed by molybdenite is like that developed by sulphur. F. Beijerinck, and C. Doelter found that the electrical conductivity of molybdenite at ordinary temp. is very small. J. Königsberger and O. Reichenheim observed that as the temp. rises, the conductivity increases. The resistance taken in the direction of the *C*-axis was found to be :

	19·5°	73°	92·5°	400°	750°	1020°
R . .	29·0	17·24	15·0	3·9	1·14	0·751 ohm.

and perpendicular to *C*-axis :

	−185°	−145°	−65°	19°	64°	113°
R . .	750,000	13,000	306	29	10·5	6·18 ohm.

They found that molybdenite frequently contains inclusions of the mineral chlorite. C. Tubandt and M. Haedicke said that molybdenite conducts like a metal below 200°. M. J. Huizinga mentioned the presence of a dark blue liquid on the surface of a molybdenite detector ; W. W. Coblentz noticed that the liquid is exuded from some samples when an electric current is passed through them ; and A. T. Waterman, that oxidation is preceded by local eruptions of the dark blue liquid. W. W. Coblentz suggested that the liquid is the blue, colloidal molybdenum oxide described by M. Guichard. G. W. Pierce's values for the electrical resistance and conductivity of a sample of molybdenite are plotted in Fig. 30. J. Okubo, O. U. von Willer, G. Gottstein, and P. Collet also measured the resistance of molybdenite. F. Streintz found that the compressed powder of molybdenite is a good conductor. C. Tubandt and M. Haedicke found that compressed cylinders of molybdenum disulphide, between 200° and 300° behave like metallic conductors. A. T. Waterman showed that the resistance of molybdenite is very high with a small applied potential difference, but it diminishes rapidly with increasing potential difference. The effect is illustrated by Fig. 29. The effect is partly due to the rise in temp. caused by the electric current ; but this is probably a minor cause of the phenomenon. The diminution of resistance with increasing potential difference continues uniformly up to a certain potential difference, which varies to some extent with different specimens and according to the treatment to which they have been subjected : at this point, which will be referred to as " the break," the resistance diminishes

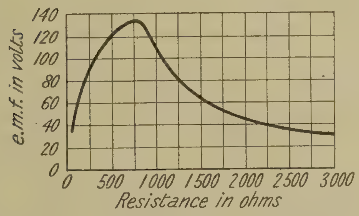

FIG. 29.—The Effect of an Applied Electromotive Force on the Resistance of Molybdenite.

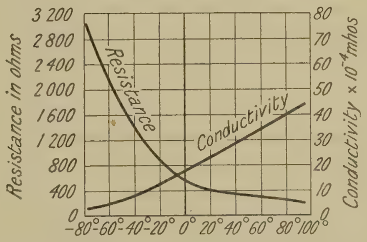

FIG. 30.—Electrical Resistance and Conductivity of Molybdenite.

suddenly and the mineral conducts, at a red-heat, with a comparatively low resistance. Before the voltage has been raised sufficiently for the break to occur the resistance diminishes, as has been noted above, with increasing voltage, whereas after the break the resistance diminishes with diminishing voltage. This difference may be regarded as characteristic of two stages, α and β, of the material which occur before and after the break. The phenomenon of the break is reversible, but the rate of change of state decreases after long heating. The substance also tends to persist in the state in which it was when the current was turned off. The light sensitivity becomes inappreciable as the conductivity of molybdenite becomes metallic. Heating the mineral to redness in a Bunsen flame for several minutes reduced the resistance to $\frac{1}{2}$ or $\frac{1}{4}$ its value, but further heating produced practically no further effect. The resistance was diminished to about half value by the momentary passage of a high voltage discharge, as from a small induction coil, but repetition caused no further decrease. The resistance is not affected by strong magnetic fields. J. Königsberger investigated the relation between the electrical conductivity and the light-absorption of the crystals; and P. H. Geiger found that if molybdenite be connected in a closed circuit with a galvanometer, and one surface of contact be illuminated, a photoelectric current is generated. J. Weiss and J. Königsberger found that the thermoelectric force of the copper-molybdenite couple is $7{\cdot}27\times10^{-4}$ volt per degree of temp. between 20° and 80°; $7{\cdot}60\times10^{-4}$ volt between 68·7° and 57·0°; and $7{\cdot}46\times10^{-4}$ volt between 57·0° and 45·8°. The current flows from the hot junction to the copper. G. W. Pierce found the thermoelectric force of different samples of molybdenite against copper at 20° varied from 110 to 175 and from —230 to —750 millivolts; and against lead, from 113 to 178 and from —227 to —717 millivolts. With the cold junction zero, the e.m.f. with a copper-molybdenite couple was —7·5 millivolts with the hot junction at 10·1°, and —130·0 millivolts at 195°. The intermediate values varied linearly with temp. O. U. von Willer observed an e.m.f. of 560 microvolts by passing a current from copper to molybdenite to copper, and the temp. of the junctions differed by one degree. In the thermoelectric couple the current flowed from copper to molybdenite at the hot junction. W. Ogawa, and M. Kimura and co-workers studied the thermoelectric properties of molybdenite.

G. Gottstein measured the Hall effect, and the Ettinghausen effect. G. Gottstein found a relatively large difference in the adiabatic and the isothermal Hall effects of molybdenite, but C. W. Heaps found the difference much smaller.

C. W. Heaps found that there is a decrease in the resistance of molybdenite in a magnetic field, and the result is little affected by the direction of the field. According to I. Bernfeld, in the electrolysis with electrodes of metallic sulphides, the following changes occur. (1) In acid soln.: at the anode, the metal is dissolved and the sulphur precipitated or oxidized; at the cathode, hydrogen sulphide is formed with separation of the metal; (2) in alkaline soln.: at the anode, the metal forms a hydroxide, and the sulphur is oxidized; at the cathode, the metal is precipitated and the sulphur passes into soln. as an ion. In electrolyzing molybdenum disulphide in fused potassium hydroxide, E. F. Smith found that the sulphur is oxidized to sulphate. W. W. Coblentz, and G. W. Pierce discussed the rectifying action of molybdenite. H. S. Roberts and L. H. Adams, M. J. Huizinga, and E. T. Wherry found molybdenite to be a fair radio-detector.

H. Rose found that the disulphide is not decomposed by hydrogen at a red-heat; but O. F. von der Pfordten observed that if strongly heated in hydrogen, the disulphide is reduced to molybdenum. N. Parravano and G. Malquori showed that in the reaction $MoS_2+2H_2\rightleftharpoons 2H_2S+Mo$, $\log K=\log (P_{H_2S}/P_{H_2})$, and

	805°	910°	1005°	1100°
$\log (P_{H_2S}/P_{H_2})$ . . .	—2·235	—2·059	—1·863	—1·319
Q	77,400	79,200	80,000	81,100 cals.

According to J. J. Berzelius, when molybdenum disulphide is heated in air, it forms molybdenum trioxide and sulphide ; and, as indicated above, A. T. Waterman found that the oxidation of molybdenite is preceded by local eruptions of a dark blue liquid. P. H. A. de Clermont and J. Frommel showed that the disulphide is not decomposed by water, but H. V. Regnault said that it is decomposed by steam at a red-heat. C. W. Blomstrand observed that molybdenite is easily attacked by chlorine, but not so readily by bromine ; and A. Cossa added that when heated in chlorine, the disulphide is completely converted into pentachloride. M. Guichard said that sulphur vapour, at ordinary press., does not transform the disulphide into trisulphide. E. F. Smith found that the vapour of sulphur monochloride at 300° partially decomposes the disulphide. Boiling sulphuric acid, said J. J. Berzelius, forms sulphur dioxide and a blue soln ; the cold acid has very little action. Warm aqua regia converts it into molybdic and sulphuric acids ; and nitric acid oxidizes it easily. According to H. B. North and C. B. Conover, molybdenite is not attacked by thionyl chloride at 150° to 175°. If mixed with potassium nitrate and detonated, potassium molybdate is formed. P. Camboulives found that the vapour of carbon tetrachloride converts any oxide in molybdenite into molybdenum chloride. E. Péchard found that the disulphide is soluble in a soln. of potassium cyanide ; and K. von der Heide studied this reaction. P. Berthier found that it is decomposed when heated to redness with lead oxide. A. Cossa found that molybdenite acquires a film of gold when immersed in a soln. of gold chloride ; and in copper sulphate soln. in contact with a strip of zinc, it slowly acquires a film of copper.

According to F. Mawroff and M. Nikoloff,[2] **molybdenum pentasulphide,** Mo_2S_5, is obtained as a *trihydrate*, $Mo_2S_5.3H_2O$, by reducing with zinc a soln. of ammonium molybdate, containing more than 20 per cent. of sulphuric acid, until the colour is dark red, and then diluting, filtering, and saturating with hydrogen sulphide. The precipitate is collected and washed with hot water and then with alcohol. It is then shaken repeatedly with carbon disulphide, washed with ether, and dried at 68°–75°. One mol. of water is lost at 135°–140°, but further heating causes decomposition. The hydrated sulphide dissolves in warm soln. of alkali sulphides to give bright red soln. depositing an orange precipitate on cooling. It dissolves with difficulty, but completely, in warm conc. hydrochloric acid. Careful heating in carbon dioxide gives the anhydrous sulphide, Mo_2S_5, which is almost black. When the hydrated compound is heated in hydrogen sulphide, an exchange of water for hydrogen sulphide takes place, and the *hemitrisulphohydrate*, $2Mo_2S_5.3H_2S$, is formed.

J. J. Berzelius[3] prepared **molybdenum trisulphide,** MoS_3, by saturating a soln. of an alkali molybdate with hydrogen sulphide, or by dissolving molybdenum trioxide in a soln. of an alkali sulphide or ammonium sulphide, and decomposing the sulphomolybdate so formed by dil. hydrochloric or sulphuric acid. The reddish-brown, gelatinous precipitate becomes dark brown when dried. The precipitate may contain some admixed sulphur or molybdic acid. A. Atterberg said that when precipitated from cold soln., the precipitate is more slimy, more easily oxidized, and less easily washed than when obtained from hot soln. R. F. Weinland and F. Sommer found that in order to get a trisulphide of a high degree of purity it is necessary to start from a pure sulphomolybdate. The precipitation of molybdenum as trisulphide, by passing hydrogen sulphide into a cold, acid soln. of molybdic acid, is incomplete, heat is necessary ; and if the soln., sat. with hydrogen sulphide, is heated in a closed vessel for a long time at 100°, the molybdenum is precipitated quantitatively as trisulphide provided the right proportion of acid be present in the soln. This subject was discussed above in connection with the analytical reactions of molybdenum. J. Milbauer found that the trisulphide is the one produced by the action of potassium thiocyanate on molybdenum oxide at a high temp. L. Moser and M. Behr, E. Wendehorst, and by L. Dede and T. Becker obtained the compound in this manner. J. J. Berzelius observed that the molybdenum trisulphide may appear as a colloidal soln., for he said that the sulphide is somewhat soluble in water, particularly hot water, forming a dark yellow soln., and this is probably the peptized trisulphide. C. Winssinger studied the properties of colloidal molybdenum trisulphide. J. J. Berzelius showed that when heated to a high temp., the trisulphide passes into the disulphide. G. Preuner and I. Brockmöller measured the vap. press. of sulphur, p mm., from the trisulphide for temp. between 450° and 500°, and N. Parravano and G. Malquori, between 390° and 450° :

	355°	390°	418°	450°	475°	480°	500°
p . . .	40	28·8	178·6	(80)	250	313	980

M. Wasjuchnowa gave 34 mm. at 450° ; 195 mm. at 475° ; 255 mm. at 480° ; and 560 mm. at 500° ; while E. T. Allen and R. H. Lombard gave 31 mm. at 450° and 170 mm. at 475°. According to O. F. von der Pfordten, the trisulphide is reduced to metal when heated to a high temp. in hydrogen. As shown by E. Collett and M. Eckardt, when the sulphide is roasted to transform it into trioxide, there is a tendency for small particles to be projected violently from the crucible, and also a tendency for some of the oxide to be lost by volatilization. The trisulphide, said J. J. Berzelius, dissolves in conc. soln. of potassium hydroxide partially as oxysulphomolybdate. F. Feigl, and O. Ruff and B. Hirsch discussed the association of sulphur with the trisulphide, $MoS_3.S_n$, where the sulphur is not removed by camphor bromide. Molybdenum trisulphide unites with basic metal sulphides to form sulphomolybdates, $R_2'MoS_4$—*vide infra.*

J. J. Berzelius[4] stated that molybdenum forms not only di- and tri-sulphides, but also **molybdenum tetrasulphide,** MoS_4, which he prepared as follows :

A soln. of potassium paramolybdate is sat. with hydrogen sulphide and the nearly black liquid is boiled for some hours in a retort to drive off hydrogen sulphide. The cold soln. is filtered, and the black powder of molybdenum disulphide is separated from the heavier scaly crystals of a compound of the tetrasulphide and potassium sulphide, as well as possible, by levigation. The salt of the tetrasulphide is collected on a filter, and washed with cold water until the washings no longer give a blackish-brown, but rather a red, precipitate with hydrochloric acid. The red scaly crystals on the filter are treated with boiling water which leaves insoluble red molybdenum disulphide, and a dark red soln. The soln. is treated with an excess of hydrochloric acid, and the precipitated molybdenum tetrasulphide washed with water.

G. Krüss prepared the tetrasulphide by melting molybdic acid with potassium carbonate, extracting the melt with water, and passing hydrogen sulphide into the soln. when heated to the b.p. A black powder together with a crystalline substance separates out. This mixed material is washed first with cold water, then with hot water to dissolve out the molybdenum di- and tri-sulphides, and the resultant chocolate-brown powder is heated in a current of hydrogen sulphide until its weight is constant. J. J. Berzelius said that the tetrasulphide, when freshly prepared, is dark red, and translucent; it shrinks considerably when dried, forming a grey, granular mass which is cinnamon-brown when ground up to powder with water. G. Krüss said that the powder is very hygroscopic ; J. J. Berzelius added that it is not decomposed by water or by acids. According to G. Krüss, when the tetrasulphide is oxidized by chlorine or bromine in alkaline soln., alkali sulphate and molybdate are formed. Boiling sulphuric acid forms a reddish-yellow liquid which deposits sulphur and emits sulphur dioxide. For the observation of F. Feigl, and of O. Ruff and B. Hirsch, *vide supra.* Soln. of alkali sulphides dissolve the tetrasulphide, forming sulphomolybdates, $R_2'MoS_5$.

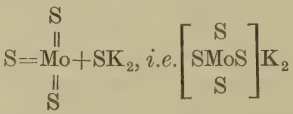
§ 24. Sulphomolybdates and Oxysulphomolybdates

As indicated in connection with molybdenum trisulphide, J. J. Berzelius[1] prepared a series of sulphomolybdates, $R_2'MoS_4$, by the union of a mol of a basic metal sulphide with a mol of molybdenum trisulphide. A mol of the basic sulphide may also unite with two or three mols of molybdenum sulphide forming respectively $R_2'Mo_2S_7$, and $R_2'Mo_3S_{10}$. The soluble sulphomolybdates are prepared by the action of hydrogen sulphide on soln. of the molybdates; or by the action of the soluble sulphides on molybdenum trisulphide. The insoluble sulphomolybdates are formed by adding a soln. of the alkali or alkaline earth sulphomolybdate to a soln. of the metal salt. A. Werner represented the formation of the sulphomolybdate, $K_2[MoS_4]$, by the equation:



$$\mathrm{S{=}}\overset{\overset{\textstyle \mathrm{S}}{\|}}{\underset{\underset{\textstyle \mathrm{S}}{\|}}{\mathrm{Mo}}}+\mathrm{SK_2},\ i.e.\left[\begin{matrix}\mathrm{S}\\ \mathrm{SMoS}\\ \mathrm{S}\end{matrix}\right]\mathrm{K_2}$$

J. J. Berzelius prepared **ammonium sulphomolybdate,** $(NH_4)_2MoS_4$, by evaporating a soln. of ammonium molybdate sat. with hydrogen sulphide; by evaporating a soln. of molybdic acid in ammonium sulphide; by dissolving freshly precipitated molybdenum trisulphide in ammonium sulphide, and adding alcohol, or evaporating the liquid. G. Krüss dissolved 5 grms. of ammonium paramolybdate in 15 c.c. of water, added 50 c.c. of aq. ammonia of sp. gr. 0·94, passed hydrogen sulphide into the liquid which became yellow, and then deep red, and, in about half an hour, the liquid deposited blood-red, tabular crystals with a green shimmer. According to C. von Haushofer, the rhombic bipyramids have the axial ratio $a : b : c = 0{\cdot}7846 : 1 : 0{\cdot}5692$. From J. W. Retgers', and H. Vater's observations, the sulphomolybdates and sulphotungstates are isomorphous. G. Krüss said that the crystals become matt and dark violet in air; and J. J. Berzelius said dark brown. They decompose at 100° losing some ammonium sulphide. The crystals are freely soluble in water, and sparingly soluble in alcohol. There is a loss of ammonium sulphide when the aq. soln. is evaporated. According to R. Fernandes, ammonium sulphomolybdate is stable in an atm. of ammonia; but

when it is exposed to air, it gives off ammonia and becomes dark green, dark violet, and finally black; and it absorbs water. If washed at this stage, it forms a dark red, microcrystalline **ammonium parasulphomolybdate,** $(NH_4)_5H_5[H_2(MoS_4)_6].10H_2O$, which is stable in air, and in a soln. of ammonium sulphomolybdate, but is decomposed by boiling water into ammonia, hydrogen sulphide, and molybdenum trisulphide. The formation of the parasulphomolybdate is represented by the equation: $6(NH_4)_2MoS_4=7NH_3+(NH_4)_5H_5[H_2(MoS_4)_6]$. It is also formed by saturating with hydrogen sulphide an ice-cold, conc. soln. of ammonium sulphomolybdate, or by keeping a warm aq. soln. of ammonium sulphomolybdate for several days. When a conc. soln. of ammonium sulphomolybdate is heated for 4 to 5 hrs. on a water-bath, a maroon-coloured, microcrystalline precipitate of **ammonium trisulphomolybdate,** $(NH_4)_4H_6[H_2(MoS_4)_6].16H_2O$, separates. The *guanidine sulphomolybdate*, Gu_2MoS_4, was obtained in dark red crystals; and also *guanidine parasulphomolybdate*, $Gu_5H_5[H_2(MoS_4)_6].8H_2O$, in dark red crystals. These sulphomolybdates are relatively stable; are not very soluble in water; and are decomposed when boiled with water. Hydrogen sulphide is evolved when the salts are treated with acids. It is supposed that these salts are derivatives of a hypothetical acid, $6H_2S=H_{10}[H_2S_6]$.

J. J. Berzelius prepared **lithium sulphomolybdate,** $Li_2MoS_4.nH_2O$, as an amorphous dark red mass by evaporating an aq. soln. of the components. It also forms a complex with more than one mol. of molybdenum trisulphide. Dark red crystals of **sodium sulphomolybdate,** Na_2MoS_4, were similarly prepared, as well as of **sodium sulphodimolybdate,** $Na_2Mo_2S_7.nH_2O$. R. Fernandes could not prepare *sodium trisulphomolybdate*, $Na_4H_6[H_2(MoS_4)_6]$, analogous to the ammonium salt. J. J. Berzelius prepared **potassium sulphomolybdate,** K_2MoS_4, by heating to bright redness a mixture of molybdenum disulphide, potassium carbonate, sulphur, and a little powdered charcoal; extracting the cold mass with water; evaporating the aq. soln.; and purifying the product by adding alcohol to the aq. soln. The salt is also formed by digesting molybdenite with a soln. of potassium pentasulphide; and by evaporating a soln. of potassium molybdate, saturated with hydrogen sulphide. G. Krüss obtained it by saturating with hydrogen sulphide a soln. of 5 grms. of potassium molybdate in 10 c.c. of water and 50 c.c. of potash-lye of sp. gr. 1·44 to 1·48, and allowing the soln. to stand some time for crystallization. C. F. Rammelsberg said that the rhombic bipyramids have the axial ratios $a:b:c=0·7651:1:0·5721$. C. von Haushofer said that the dark red crystals are isomorphous with those of the ammonium salt. According to J. J. Berzelius, when heated out of contact with air the salt becomes grey; about one-third remains undecomposed at a white-heat, and the remainder forms a mixture of potassium sulphide and molybdenum disulphide. G. Krüss and H. Solereder found that hydrogen reduces the salt to a mixture of potassium sulphide and molybdenum. J. J. Berzelius found that the salt is soluble in water forming a yellowish-red soln. from which alcohol precipitates the salt as a cinnabar red powder which then forms scaly crystals. If the aq. soln. of the sulphomolybdates are boiled in closed vessels, they deposit molybdenum disulphide and a complex with the tetrasulphide (*q.v.*) giving off at the same time hydrogen sulphide. The conc. aq. soln. are fairly stable in air, provided an excess of molybdenum trisulphide is present; but if the alkali sulphide predominates, or if free alkali be present, or if the soln. is dil., the soln. gradually darkens forming a compound with an excess of molybdenum trisulphide. This compound slowly decomposes with the separation of molybdenum trisulphide, and the supernatant liquor contains compounds of the alkali with sulphur acids, with molybdic acid, and with the blue oxide of molybdenum. Acids added to the aq. soln. precipitate molybdenum trisulphide with the liberation of hydrogen sulphide. Metal oxides which readily part with their oxygen form in the aq. soln. an alkali molybdate and a metal sulphide which enters into combination with the undecomposed molybdenum trisulphide. J. J. Berzelius prepared **potassium sulphodimolybdate,** $K_2Mo_2S_7$, as a dark grey substance, on adding a mineral acid, or preferably acetic acid, to an aq. soln. of the normal sulphomolybdate, and evaporating the brown liquid. The brown powder dissolves slowly in cold water, and rapidly in boiling water. The aq. soln. with an aluminium salt liberates hydrogen sulphide and precipitates molybdenum trisulphide and aluminium hydroxide; and similarly also with titanium salts. R. Fernandes prepared **potassium parasulphomolybdate,** $K_5H_5[H_2(MoS_4)_6].16H_2O$; but he could not obtain *potassium trisulphomolybdate,* $K_4H_6[H_2(MoS_4)_6]$, analogous to the corresponding ammonium salt. G. Krüss obtained crystals of **potassium orthosulphodimolybdate,** $3K_2S.2MoS_3$,

$$\begin{matrix}(KS)_3\\ S\end{matrix}\!>\!Mo.S.Mo\!<\!\begin{matrix}(KS)_3\\ S\end{matrix}$$

from a soln. of 5 grms. of potassium molybdate in 10 c.c. of water and 60 c.c. of potash-lye, of sp. gr. 1·53–1·56, sat. with hydrogen sulphide, by allowing it to stand for crystallization. The orange-red plates were thought by C. von Haushofer to be rhombic. They decompose after some time to form the normal sulphomolybdate. The salt is freely soluble in water, but insoluble in alcohol and ether. The aq. soln. decomposes slowly in air, and it gives a pale lemon-yellow precipitate with a barium salt; brownish-yellow with a manganous salt; olive-green with a cadmium salt; and dark brown with a uranyl salt. G. Krüss prepared **cæsium sulphomolybdate,** Cs_2MoS_4, in red needles.

J. J. Berzelius obtained **cupric sulphomolybdate,** $CuMoS_4$, as a dark brown precipitate; **silver sulphomolybdate,** Ag_2MoS_4, as a black precipitate; and **gold sulphomolybdate,** $Au_2(MoS_4)_3$, as a black powder. By boiling barium disulphide with water and an excess of molybdenum trisulphide, and cooling the filtered soln., J. J. Berzelius obtained **barium sulphotrimolybdate,** $BaS.3MoS_3$, in brownish-red crystals. The salt is easily attacked by dil. hydrochloric acid, but not by the conc. acid, precipitating molybdenum trisulphide. The evaporation of the mother-liquor gives **barium sulphomolybdate,** $BaMoS_4$. G. Krüss obtained **barium orthosulphodimolybdate,** $3BaS.2MoS_3$, from the potassium salt as indicated above. J. J. Berzelius obtained, as in the case of the corresponding barium salts, **strontium sulphotrimolybdate,** $SrS.3MoS_3$; **strontium sulphomolybdate,** $SrMoS_4$; **calcium sulphotrimolybdate,** $CaS.3MoS_3$; **calcium sulphomolybdate,** $CaMoS_4$; **beryllium sulphomolybdate,** $BeS.3MoS_3$; and **magnesium sulphotrimolybdate,** $MgS.3MoS_3$. F. Rodolico obtained a complex with hexamethylene tetramine, X, $MgMoS_4(X).10H_2O$. J. J. Berzelius prepared **zinc sulphomolybdate,** $ZnMoS_4$; and **cadmium sulphomolybdate,** $CdMoS_4$. G. Krüss also obtained **cadmium orthodisulphomolybdate,** $3CdS.2MoS_3$, from the potassium salt as indicated above. J. J. Berzelius prepared **mercurous sulphomolybdate,** Hg_2MoS_4, as a brownish-black precipitate; and **mercuric sulphomolybdate,** $HgMoS_4$, as a pale brown precipitate. J. J. Berzelius did not obtain **aluminium sulphomolybdate,** because the precipitate was hydrolyzed to aluminium hydroxide; but he obtained a soln. of **yttrium sulphomolybdate,** which precipitated yttrium hydroxide in a few hours. A black precipitate of **stannous sulphomolybdate,** and a brown precipitate of **stannic sulphomolybdate** were obtained; likewise also with **lead sulphomolybdate.**

For the **arsenic sulphomolybdates,** *vide* the sulpharsenates. J. J. Berzelius obtained **bismuth sulphomolybdate,** $Bi_2(MoS_4)_3$, as a dark brown precipitate.

L. Fernandes prepared some complex **sulphomolybdatovanadates** or **sulphovanadatomolybdates** with guanidine, Gu, thallium, and ammonium. Thus, **ammonium sulphovanadatomolybdate,** $(NH_4)_3H_5[H_2(MoS_4)_4(VS_3)_2].10H_2O$; $(NH_4)_5H_2[H_2(MoS_4)_3(VS_3)_3].12H_2O$; $(NH_4)_5H[H_2(MoS_4)_2(VS_3)_2].25H_2O$; **thallium sulphovanadatomolybdate,** $Tl_5H[H_2(MoS_4)_2(VS_3)_4].60H_2O$; and also **guanidine sulphovanadatomolybdate,** $Gu_5H_3[H_2(MoS_4)_4(VS_3)_2].15H_2O$; $Tl_5H_2[H_2(MoS_4)_3(VS_3)_3].22H_2O$; and $Tl_5H[H_2(MoS_4)_2(VS_3)_2].15H_2O$. J. J. Berzelius prepared **chromic sulphomolybdate,** as a dark brown precipitate; **uranyl sulphomolybdate,** as a dark brown precipitate; and G. Krüss obtained a dark brown uranyl salt corresponding with $3K_2S.2MoS_3$. J. J. Berzelius obtained **manganous sulphomolybdate** as a brownish-yellow precipitate, and a polysulphomolybdate as a dark red powder; and G. Krüss obtained a brownish-yellow magnanese salt corresponding with $3K_2S.2MoS_3$. J. J. Berzelius prepared **ferrous sulphomolybdate** as a rust-yellow powder; **ferric sulphomolybdate,** as a dark brown powder; **cobalt sulphomolybdate,** as a brownish-black precipitate; **nickel sulphomolybdate,** as a dark brown precipitate; and **platinum sulphomolybdate,** as a brownish-black precipitate.

In the course of the preparation of molybdenum tetrasulphide, G. Krüss obtained a blood-red liquid which furnished crystals of the composition $KHMoS_5$. When a soln. of this salt is treated with dil. hydrochloric or, better, acetic acid, **permonosulphomolybdic acid**, H_2MoS_5, is precipitated. This is washed successively with cold air-free water, alcohol, ether, carbon disulphide, and water-free ether, and dried in vacuo over sulphuric acid. The product loses hydrogen sulphide when warmed in a closed vessel, and at 140°, it passes into molybdenum tetrasulphide. It is insoluble in water, alcohol, ether, and acetic acid; with boiling conc. hydrochloric acid, hydrogen sulphide is evolved; hot, conc. sulphuric acid forms a reddish-yellow liquid which deposits sulphur and gives off sulphur dioxide; it forms a yellow liquid with warm alkali-lye; potassium hydrosulphide forms $KHMoS_5$; and potassium sulphide, K_2MoS_5. Many of the **permonosulphomolybdates,** $R_2'MoS_5$, reported by J. J. Berzelius may be oxysulphomolybdates.

J. J. Berzelius prepared **ammonium permonosulphomolybdate,** $(NH_4)_2MoS_5$, by digesting moist molybdenum tetrasulphide in a soln. of ammonium sulphide containing an excess of ammonia which lowers the solubility of the salt. The yellow powder becomes dark red when dried in air presumably owing to the loss of ammonium sulphide. The salt is sparingly soluble in cold water; freely soluble in hot water; and insoluble in aq. ammonia. J. J. Berzelius obtained **lithium permonosulphomolybdate,** Li_2MoS_5, as a pale yellow crystalline powder; **sodium permonosulphomolybdate,** Na_2MoS_5, as a reddish-yellow powder; and **potassium permonosulphomolybdate,** K_2MoS_5, by the method indicated in connection with molybdenum tetrasulphide, and also by the action of a soln. of potassium sulphide on moist molybdenum tetrasulphide. The ruby-red plates or powder decrepitate when heated; and they are decomposed into potassium trisulphide and molybdenum disulphide. The salt is sparingly soluble in cold water, but more soluble in boiling water. The hot soln. is red and does not give a precipitate on cooling; with hydrochloric acid, the aq. soln. gives a precipitate of molybdenum tetrasulphide. The salt is insoluble in cold potash-lye. According to G. Krüss, the salt obtained in the preparation of molybdenum tetrasulphide (*q.v.*), and considered by J. J. Berzelius to be K_2MoS_5, is really **potassium hydropermonosulphomolybdate,** $KHMoS_5$. It is also formed by the action of a soln. of potassium hydrosulphide on molybdenum tetrasulphide. The blood-red, rhombic prisms are quickly decomposed by moist air. Most metal salt soln. give red precipitates with the soln. of the potassium salt. K. A. Hofmann's analysis of a salt made by mixing NH_4MoS_3 with a soln. of potassium hydrosulphide agreed with the formula $KMoS_5$.

J. J. Berzelius prepared **copper permonosulphomolybdate,** $CuMoS_5$, as a dark red precipitate; dark brown **silver permonosulphomolybdate,** Ag_2MoS_5; dark brown **gold permonosulphomolybdate,** $Au_2(MoS_5)_3$; yellowish-red **barium permonosulphomolybdate,** $BaMoS_5$; scarlet-red **calcium permonosulphomolybdate,** $CaMoS_5$; red **magnesium permonosulphomolybdate,** $MgMoS_5$; red **zinc permonosulphomolybdate,** $ZnMoS_5$; red **cadmium permonosulphomolybdate,** $CdMoS_5$; reddish-brown **mercurous permonosulphomolybdate,** Hg_2MoS_5; red **mercuric permonosulphomolybdate,** $HgMoS_5$; dark brown **stannous permonosulphomolybdate;** red **stannic permonosulphomolybdate;** dark red **lead permonosulphomolybdate;** reddish-brown **bismuth permonosulphomolybdate;** dark red **chromic permonosulphomolybdate;** dark red **uranyl permonosulphomolybdate;**

red **manganese permonosulphomolybdate**; red **ferrous permonosulphomolybdate**; red **ferric permonosulphomolybdate**; reddish-brown **cobalt permonosulphomolybdate**; dark brown **nickel permonosulphomolybdate**; and dark red **platinum permonosulphomolybdate.**

According to K. A. Hofmann, when a soln. of ammonium sulphomolybdate is mixed with ammonium polysulphide, and allowed to remain 24 hrs., black needles of **ammonium perdisulphomolybdate,** $NH_4MoS_6.H_2O$, are formed, and more of the salt is precipitated by adding alcohol to the mother-liquor. The salt is purified by washing it successively with water, alcohol, ether, and carbon disulphide, and drying it over potassium hydroxide. It is sparingly soluble in water, and in alcohol. When treated with cold, 10 per cent. hydrochloric acid, **perdisulphomolybdic acid,** $HMoS_6$, is deposited. It is washed with carbon disulphide. If the ammonium salt is treated with a 10 per cent. soln. of potassium hydroxide for 24 hrs. at ordinary temp., dark brown leaflets of **potassium perdisulphomolybdate,** $KMoS_6$, are formed. The potassium salt is more soluble than the ammonium salt. Black insoluble prisms of **cæsium perdisulphomolybdate,** $CsMoS_6$, are similarly obtained; and likewise black, insoluble prisms of **thallium perdisulphomolybdate,** $TlMoS_6$.

F. Rodolico[2] prepared **magnesium oxytrisulphomolybdate** in association with hexamethylenetetramine, $MgMoS_3O.2X.10H_2O$. According to H. ter Meulen, if sodium sulphide acts on molybdenum oxychloride in absolute alcohol **molybdenum dioxysulphide,** MoO_2S, is formed. H. Debray prepared golden-yellow needles of **ammonium dioxydisulphomolybdate,** $(NH_4)_2MoO_2S_2$, by treating a conc. soln. of ammonium molybdate with ammonium sulphide at a low temp. L. Bodenstab obtained it by saturating with hydrogen sulphide a strong ammoniacal soln. of ammonium molybdate containing much ammonium chloride. The red prisms were washed with aq. ammonia and dried over sulphuric acid. G. Krüss obtained golden-yellow, monoclinic needles of the salt by passing hydrogen sulphide into a soln. of 5 grms. of ammonium paramolybdate in 15 c.c. of water and 25 c.c. of ammonia of sp. gr. 0·96, at 6°. The crystals which separate in about a quarter of an hour are washed with cold water, then with alcohol, and dried in vacuo. The yellow crystals redden on exposure to air. G. Krüss and H. Solereder reduced the salt to molybdenum by heating it in hydrogen. G. Krüss found that the salt is soluble in water; sparingly soluble in alcohol; and insoluble in ether and carbon disulphide. L. Bodenstab added that the crystals are sparingly soluble in cold water, and freely soluble in boiling water; insoluble in alcohol, and in a sat. soln. of ammonium chloride. The aq. soln. decomposes when boiled. Dil. hydrochloric acid precipitates molybdenum trisulphide from the aq. soln. without giving off hydrogen sulphide: $3(NH_4)_2MoO_2S_2+6HCl=2MoS_3+MoO_3+6NH_4Cl+3H_2O$. According to H. ter Meulen, if acetic acid is used in place of hydrochloric to decompose the dithiomolybdate, stable colloidal soln. of the trisulphide are obtained. The fusion of sodium carbonate and the trisulphide or tetrathiomolybdate also yields the dithiocompounds, $MoS_3+2Na_2CO_3=Na_2MoO_2S_2+Na_2S+2CO_2$. Cold, conc. sulphuric acid dissolves the salt, the soln. gradually darkens in colour, and the brownish-yellow soln. becomes green. Precipitates are produced by salts of the elements of the ammonium sulphide or hydrogen sulphide groups. L. Fernandes and F. Palazzo prepared polyphenolic, and pyridine complexes. G. Krüss prepared **potassium dioxydisulphomolybdate,** $K_2MoO_2S_2$, in reddish-yellow needles. F. Rodolico prepared **magnesium dioxydisulphomolybdate** in association with hexamethylenetetramine, $MgMoS_2O_2.2X.10H_2O$.

L. Fernandes and F. Palazzo regarded the oxysulphides of molybdenum as isopolyacids in which oxygen is partly replaced by sulphur. They prepared **sulphotrimolybdates** containing four substituted hydrogen atoms by strong acidification; and **oxysulphoparamolybdates** with five substituted hydrogen atoms by weak acidification. Ammonium salts with five substituted hydrogen atoms, and containing the group MoS_2O_2 could not be prepared, because, with the smallest addition of acid, tri-salts with four ammonium radicles were formed. Salts were prepared by adding increasing proportions of ammonium sulphomolybdate, $(NH_4)_2MoS_4$, to ammonium dioxydisulphomolybdate, $(NH_4)_2MoS_2O_2$, so as to obtain soln. with progressively increasing proportions of sulphur. Thus, $(NH_4)_4H_6[H_2(MoS_2O_2)_6].5H_2O$ was obtained as an orange-yellow powder, stable in air, by adding 1 to 15 c.c. of *N*-acetic acid to 10 grms. of ammonium dioxydisulphomolybdate dissolved in the smallest proportion of water, and washing the precipitate with alcohol and ether. If *N*-acetic acid be added to a soln. of equal parts of ammonium sulphomolybdate and dioxydisulphomolybdate, $(NH_4)_5H_5[H_2(MoS_3O)_3(MoS_2O_2)_3].16H_2O$ is formed as a maroon-red powder. The addition of *N*-acetic acid to soln. with proportions of ammonium sulphomolybdate, and dioxydisulphomolybdate in proportions up to 9 : 1, furnishes $(NH_4)_5H_5[H_2(MoS_3O)_6].27H_2O$.

By adding a soln. of guanidine acetate to a hot, dil. soln. of ammonium dioxydisulphomolybdate, and cooling, $Gu_4H_6[H_2(MoS_2O_2)_6].8H_2O$ is formed as an orange-yellow powder; if relatively dil. soln. be allowed to stand for some days, fire-red crystals of $Gu_5H_5[H_2(MoS_2O_2)_6].9H_2O$ appear; if acetic acid be added to soln. of guanidine acetate, and ammonium sulphomolybdate and dioxydisulphomolybdate, a maroon-red powder of $Gu_4H_6[H_2(MoS_2O_2)_3(MoS_3O)_3].10H_2O$ is formed; if only a very small proportion of acetic acid is used, red crystals of $Gu_5O_5[H_2(MoS_2O_2)_3(MoS_3O)_3].9H_2O$ are formed; and if the proportion of sulphomolybdate to dioxydisulphomolybdate is greater, dark red crystals of $Gu_5H_5[H_2(MoS_2O_2)_2(MoS_3O)_4].7H_2O$ are formed.

G. Krüss obtained **sodium trioxysulphomolybdate,** Na_2MoO_3S, by treating sodium trimolybdate with freshly prepared sodium hydrosulphide at 20°–30°, adding alcohol, and allowing the reddish-yellow oily precipitate to crystallize. The golden-yellow crystals are washed successively with alcohol, ether, carbon disulphide, ether, and alcohol, and dried in an air-bath at 100°. The hygroscopic crystals are freely soluble in water; acetic acid forms a green soln.; conc. sulphuric acid a deep blue soln. which becomes green. Ammonium sulphide transforms the salt into sodium sulphomolybdate. The soln. gives a yellowish-green precipitate with copper salts; a yellowish-white precipitate with zinc salts; and a yellow precipitate with barium salts. F. Rodolico prepared **magnesium trioxybisulphomolybdate** in association with hexamethylenetetramine, $MgMoSO_3.2X.10H_2O$.

G. Krüss prepared **ammonium hydrotetroxytrisulphodimolybdate,** $(NH_4)HMo_2O_4S_3$, by treating a soln. of ammonium paramolybdate, at about 90°, with ammonium hydrosulphide; and adding ammonium chloride to the cold soln. The reddish-yellow precipitate thus coagulates and it can be washed successively with water, alcohol, and carbon disulphide, and dried at 40°. It is also formed when a soln. of ammonium molybdate is sat. with hydrogen sulphide. The brownish-yellow product decomposes when heated in air; it develops hydrogen sulphide when boiled with water; it is soluble in water, but insoluble in alcohol, ether, and carbon disulphide. Hot, dil. soda-lye forms a reddish-yellow soln. which on cooling gives a precipitate of the sodium salt; potash-lye gives only a trace of the potassium salt. Hot, conc. alkali-lye precipitates sulphur, and olive-green molybdenum dioxide; with ammonia: $(NH_4)HMoO_4S_3+NH_3=(NH_4)_2MoO_2S_2+MoO_2S$; and with an excess of ammonium sulphide: $(NH_4)HMo_2O_4S_3+5(NH_4)_2S=2(NH_4)_2MoS_4+7NH_3+4H_2O$. Conc. nitric acid oxidizes the salt vigorously; and hot, conc. sulphuric acid forms a yellow liquid which gives off sulphur dioxide. G. Krüss prepared pale yellow, amorphous **sodium hydrotetroxytrisulphodimolybdate,** $NaHMo_2O_4S_3$, and lemon-yellow **potassium hydrotetroxytrisulphodimolybdate,** $KHMo_2O_4S_3$, in a similar manner. These salts can be regarded as derivatives of $2H_2Mo_2O_2S_2$ less a mol. of H_2S. Soln. of the alkali salts give brown or reddish-brown precipitates with soln. of salts of aluminium, chromium, manganese, copper, lead, silver, and uranium; and yellow precipitates with mercury, platinum, lanthanum, and cæsium salts.

G. Krüss found that if potassium trimolybdate be dissolved in a soln. of potassium hydrosulphide, and alcohol be added, a red oil is precipitated from which golden-yellow, monoclinic prisms of **potassium heptoxyenneasulphotetramolybdate,**

$K_8Mo_4O_7S_9$, can be separated. They are washed successively with alcohol, ether, and carbon disulphide, and dried at 100°. The golden-yellow, aq. soln. reddens when treated with acetic acid; and when the aq. soln. is heated to boiling molybdenum trisulphide is precipitated. When treated with a barium salt a yellow precipitate is formed at once, while with the normal sulphomolybdate the precipitate forms in 12 hrs., and with the sulphodiamolybdate, in a few minutes. Copper and lead salts give reddish-brown precipitates.

For **molybdenum enneachloroctosulphide,** $Mo_5S_8Cl_9$, *vide supra,* action of sulphur monochloride on molybdenum; and for $MoCl_5.N_4S_4$, *vide supra,* molybdenum pentachloride.

§ 25. Molybdenum Sulphates

According to J. J. Berzelius,[1] when dry hydrated molybdic oxide, $Mo(OH)_3$, is rubbed in a mortar with an eq. amount of sulphuric acid, a black mass of normal **molybdic sulphate** is formed. It is decomposed by water into a soluble acidic and an insoluble basic salt. A basic salt is also formed by rubbing an excess of molybdic oxide with sulphuric acid; and if the acid is in excess, an acidic salt is formed. These products represent more or less hydrolyzed and oxidized derivatives of the compound sought. W. Wardlaw and co-workers prepared molybdic oxydisulphate, $Mo_2O(SO_4)_2.5(\text{or } 6)H_2O$, from a soln. of 40 grms. of molybdenum trioxide in 81 c.c. of boiling sulphuric acid of sp. gr. 1·84, mixed with a little nitric acid made up to a litre with water, and electrolyzed in a diaphragm cell with smooth platinum electrodes. The electrolysis is conducted with the soln. in an atm. of carbon dioxide. The green soln. is concentrated between 55° and 70°. If the temp. is too high, the soln. becomes brown, and if the soln. be too much concentrated, red. The green, conc. soln. is poured into acetone. The freshly precipitated salt is intensely green, but when dried over phosphoric oxide, it becomes grey, with the loss of sulphate. When heated, it decomposes: $Mo_2O(SO_4)_2.nH_2O = Mo_2O_5 + 2SO_2 + nH_2O$. The substance is very hygroscopic and readily hydrolyzable. It is insoluble in alcohol, ether, or acetone, but dissolves readily in water; the soln. loses its green colour immediately on exposure to air, and a rusty-brown precipitate, readily soluble in acids, gradually forms. The oxydisulphate immediately precipitates the metals from soln. of copper sulphate and silver nitrate at the ordinary temp., and reduces mercuric and ferric salts to the "ous" state. On warming with sulphur or sodium sulphite, a soln. of the oxydisulphate, acidified with dil. sulphuric acid, evolves hydrogen sulphide. Barium chloride produces no precipitate in a freshly prepared soln. of the oxydisulphate, but barium sulphate is thrown down on warming. Lead acetate with acetic acid gives similar results. Sodium and potassium hydroxides give green deposits. Ammonia is without action in the cold, but produces a black precipitate on warming. Potassium ferricyanide gives a deep red coloration; a similar coloration is slowly produced by potassium ferrocyanide. F. Förster and E. Fricke, and A. Chilesotti did not succeed in preparing alums of tervalent molybdenum.

According to J. J. Berzelius, if molybdenum is dissolved in hot, conc. sulphuric acid; or in dil. sulphuric acid mixed with a little nitric acid; or if hydrated molybdenum dioxide is dissolved in dil. sulphuric acid, black **molybdenum disulphate** is formed. It forms a red soln. with water. J. Meyer and V. Stateczny prepared **sulphatomolybdic acid,** $H_2[MoO(SO_4)_2(MoO_4)]$, by cooling a soln. of molybdenum trioxide in hot, conc. sulphuric acid. It is not considered to be a pyrosulphatomolybdic acid, H_2MoSO_7. L. Forsén also prepared potassium sulphatomolybdate, $K_2H_2[SO_2(Mo_3O_{12})].3H_2O$.

G. Bailhache [2] found that when a rapid current of hydrogen sulphide is passed into a boiling soln. of molybdenum trioxide in six times its weight of sulphuric acid, **molybdenum trioxydisulphate,** $Mo_2O_3(SO_4)_2$, or $Mo_2O_5.2SO_3$, is obtained as a mass of black, olive prisms, slowly but completely soluble in water, and yielding a deep brown soln. if kept out of contact with air. When exposed to air, the compound deliquesces and its aq. soln. becomes green and then blue. The brown soln. is readily oxidized to molybdic acid; when mixed with an alkali molybdate, it yields the blue molybdenum oxide, and when mixed with an alkali it yields a soluble molybdate and a precipitate of hydrated molybdenum dioxide. When heated alone, the compound yields molybdic, sulphuric, and sulphurous oxides; hot sulphuric acid converts it into the compound $MoO_3.SO_3$; hydrogen at a red-heat converts it into molybdenum dioxide and sulphuric acid, and dry ammonia also reduces it at a dull red-heat. When heated with an intimate mixture of sodium chloride or bromide, it yields molybdenum oxychloride, MoO_2Cl_2, or the oxybromide, together with molybdenum dioxide, sodium sulphate, and sodium molybdate, the proportions of the two latter depending on the duration of the operation. A. Kurtenacker and F. Werner studied the catalytic decomposition of hydroxylamine by quinquevalent molybdenum sulphate.

According to E. Péchard,[3] when alcohol is gradually added to a soln. of molybdic acid in sulphuric acid and the liquid warmed on the water-bath for a short time, diluted, and neutralized with ammonia, a crystalline precipitate is produced which consists of a mixture of two **ammonium molybdosic sulphates,** one of the composition $5NH_3.MoO_2SO_3.7MoO_3.8H_2O$, crystallizing in blue, hexagonal plates, and the other, $3NH_3.MoO_2SO_3.7MoO_3.10H_2O$, in dark blue prisms; the latter is converted into the former by the further action of ammonia. Both these compounds are very soluble in water, but insoluble in soln. of ammonium salts; they are only very slowly decomposed by alkales or nitric acid at the ordinary temp., and are therefore more stable than the other blue compounds of molybdenum which have been described. Analogous compounds containing potassium, and both potassium and ammonium, have also been obtained, but the corresponding sodium salt is too soluble to admit of isolation. The prolonged reduction of molybdic acid by alcohol in the presence of sulphuric acid at the ordinary temp. results in the formation of **molybdosic sulphate,** $7MoO_3.2MoO_2.7SO_3.nH_2O$, crystallizing in slender, black needles; while if the operation is conducted at 100°, soln. are formed which are immediately decomposed by ammonia. M. K. Hoffmann repeated E. Péchard's observations. He also reported products with $(NH_4)_2O : MoO_2 : MoO_3 : SO_3 : H_2O$ in the proportions $1:1:7:1:n$; $1:5:1:7:1:15$; and $2:1:7:1:14$. He also obtained in a similar way **potassium molybdosic sulphate,** $K_2O.MoO_2.7MoO_3.SO_3.8H_2O$.

According to J. J. Berzelius,[4] if an excess of molybdenum trioxide be boiled with sulphuric acid, a turbid liquid is obtained which gelatinizes on cooling and deposits flakes of a basic sulphate which are sparingly soluble in water, but insoluble in alcohol. A soln. of molybdenum trioxide in an excess of dil. sulphuric acid is pale yellow, and dries to a lemon-yellow, crystalline mass, which deliquesces in air, and is only partially soluble in water. M. Ruegerberg and E. F. Smith said that precipitated molybdenum trioxide is easily soluble in sulphuric acid of sp. gr.

1·378. According to T. Anderson, if barium molybdate be decomposed by an excess of dil. sulphuric acid, and the soln. evaporated, crystals of **molybdenum trisulphate,** $Mo(SO_4)_3.2H_2O$, are formed. A. C. Schultz-Sellak, however, could not obtain this product. There is no satisfactory evidence that the normal salt has been obtained. M. K. Hoffmann, M. Ruegerberg and E. F. Smith, and A. Mazzucchelli and G. Zangrilli studied the properties of soln. of molybdenum trioxide in sulphuric acid. If hydrogen dioxide be added to the soln., the results are complicated by the decomposition of the complex **molybdenum persulphates,** and do not admit of any simple interpretation. A. Mazzucchelli and C. Barbero measured the potentials of the soln.—*vide supra,* permolybdates.

A. C. Schultz-Sellak evaporated a soln. of molybdenum trioxide in conc. sulphuric acid and obtained crystals of what he regarded as **molybdenum dioxysulphate,** or **molybdenyl sulphate,** $MoO_2(SO_4)$, but T. Anderson could not obtain crystals. W. Muthmann cooled a sat. soln. of molybdenum trioxide in boiling, conc. sulphuric acid, and washed with alcohol and ether the crystals of the salt which separated in six-sided prisms. When the salt is heated it decomposes with the expulsion of sulphur trioxide. The salt deliquesces in air, and becomes blue owing to the reducing action of dust. The aq. soln. becomes blue when warmed with molybdenum. R. Reichwald found that fumarine is coloured violet and then dark green by this salt. W. T. Schaller found that the mineral **ilsemannite,** previously assumed to be $MoO_2.4MoO_3$, or Mo_3O_{14}, found at Ouray, Utah, is rather a sulphate of the composition $MoO_2(SO_4).5H_2O$.

R. F. Weinland and H. Kühl added 5 to 8 mols of sulphuric acid to a mol of ammonium molybdate, and evaporated the mixture over sulphuric acid. He thus obtained **ammonium molybdatotrisulphate,** $(NH_4)_2O.2MoO_3.3SO_3.10H_2O$. By dissolving molybdenyl sulphate in conc. soln. of ammonium sulphate, the **ammonium molybdatosulphate,** $(NH_4)_2O.2MoO_3.SO_3.nH_2O$, is tetrahydrated or enneahydrated. If potassium sulphate be employed, the **potassium molybdatosulphate,** $K_2O.2MoO_3.SO_3.nH_2O$, is dihydrated or hexahydrated. A soln. of a mol of potassium molybdate in 5 to 8 mols of sulphuric acid furnishes **potassium molybdatotrisulphate,** $K_2O.2MoO_3.3SO_3.6H_2O$. The salts all form slender needles, which are decomposed by water with the precipitation of molybdic acid.

C. W. Blomstrand,[5] and A. Atterberg prepared **molybdous tetrabromosulphate,** $[Mo_3Br_4]SO_4.3H_2O$, by the action of sulphuric acid on an alkaline soln. of molybdous dihydroxytetrabromide.

§ 26. Molybdenum Carbonates and Nitrates

No **molybdenum carbonate** has been reported. J. J. Berzelius[1] dissolved hydrated molybdic oxide in dil. nitric acid and obtained a soln. of **molybdenum nitrate** which soon became purple-red. The soln. when concentrated becomes blue, then colourless, gives off nitric oxide, and deposits molybdenum trioxide. If molybdenum or the hydrated dioxide be digested in nitric acid, a reddish-brown soln. is obtained which gives off nitrous fumes when evaporated. C. F. Bucholz obtained a yellow residue—presumably molybdenum trioxide contaminated with iron—on evaporating the soln. K. Lindner and co-workers treated an alcoholic soln. of molybdous chloride with an alcoholic soln. of silver nitrate, and obtained on evaporation **molybdenum alcoholotetrachlorodinitrate,** $Mo_3Cl_4(NO_3)_2.C_2H_5OH$; and by adding ether to the alcoholic soln., **molybdenum tetrachlorodinitrate,** $Mo_3Cl_4(NO_3)_2$, was obtained as an amorphous, yellow powder. S. M. Tanatar and E. K. Kurowsky prepared **beryllium oxynitratomolybdate,** $Be(NO_3)_2.mBe_3(MoO_4)_2.nBeO$.

§ 27. Molybdenum Phosphates, and Phosphato- or Phospho-Molybdic Acids

As previously indicated, W. Wardlaw and R. L. Wormell[1] found that when molybdenyl monochloride is treated with an alkali phosphate, **molybdenyl phosphate,** $(MoO)_3PO_4.12H_2O$, is formed. A. Colani observed that when molybdenum trioxide is heated with metaphosphoric acid to a dull red-heat, it undergoes a very slight reduction, the loss in oxygen corresponding with the formation of the hypothetical oxide Mo_6O_{17}. When molybdenum dioxide is similarly heated, it yields the lower oxide Mo_2O_3, which gives **molybdic metaphosphate,** $Mo_2O_3.3P_2O_5$, and a higher oxide, which under the experimental conditions remains dissolved in the metaphosphoric acid. G. Saring prepared a complex potassium calcium phosphatomolybdate, $Ca_3(PO_4)_2.2CaO.2K_2O.MoO_3$, by fusing together the component residues. G. Denigès reported **phosphatomolybdosic acid,** $[(MoO_3)_4MoO_2]_2H_3PO_4.4H_2O$, to be obtained by treating sodium molybdate with crystalline sodium hydrophosphate in aq. soln. containing sulphuric acid and finely divided aluminium. The soln. was extracted with ether; the ether soln. extracted with water; and the aq. soln. evaporated under reduced press. The product forms sapphire-blue, rhombohedral crystals. The compound was examined by A. Verda. F. de Carli found that only an insignificant reduction of molybdenum trioxide occurs when it is fused with sodium metaphosphate, and even this is prevented with fusing the mixture in oxygen. Small proportions lower the m.p. of molybdenum trioxide (790°) down to the eutectic at 540° with 25 per cent. of the metaphosphate; the m.p. then rises to a maximum at 600° corresponding with **sodium molybdatometaphosphate,** $NaPO_3.MoO_3$, it then decreases to a second minimum at 320°, and then rises to 600°, the m.p. of the metaphosphate. The compound dissolves easily and completely in hot water; and its constitution is thought to be $Na.O.MoO_2.O.PO_2$. A. S. Schachoff discussed the preparation of sodium phosphomolybdate.

The complex **phosphatomolybdic acids** were discovered by J. J. Berzelius.[1] He found that when freshly precipitated and moist hydrated molybdenum trioxide is digested with a small proportion of phosphoric acid, a lemon-yellow, insoluble, complex acid is formed. This product dissolves in an excess of hot phosphoric acid forming a colourless liquid which on evaporation yields a tenacious, amorphous, transparent mass which is soluble in water and alcohol. The alcoholic soln. is yellow, but it turns blue on evaporation and leaves a brown residue which forms a blue soln. with water. The product was also examined by L. F. Svanberg and H. Struve, and E. Drechsel. F. Elias found that a soln. containing $P_2O_5 : MoO_3$=1 : 21·74 gives with a 10 per cent. soln. of ammonium nitrate a precipitate with the mol. proportions 1 : 22·28 ; using a cold, sat. soln. of potassium chloride as precipitate, the product has 1 : 22·71. The mother-liquors when evaporated give products with the respective ratios 1 : 18·44, and 1 : 20·3. It is therefore inferred that the soln. of molybdenum trioxide in phosphoric acid contains two or more phosphomolybdic acids. A. Miolati and R. Pizzigheli measured the sp. electrical conductivity of mixed soln. of phosphoric and molybdic acids when 1 c.c. of phosphoric acid soln. has 0·01961 grm. H_3PO_4, and 1 c.c. of molybdic acid soln. has 0·0288 grm. MoO_3 ; and when 1 c.c. of the molybdic acid soln. has 0·666 mol MoO_3 per mol of H_3PO_4. The curve shown in Fig. 31 has one break corresponding with $P_2O_5 : MoO_3$=1 : 20. A. Miolati and R. Pizzigheli also measured the sp. electrical conductivities of mixed soln. of molybdic acid and sodium hydrophosphate when 1 c.c. of the phosphate soln. has 0·02082 grm. Na_2HPO_4, and 1 c.c. of the molybdic acid has 0·01805 grm. MoO_3, or 0·5 c.c. has a mol of MoO_3 per mol of Na_2HPO_4. The curve shown in Fig. 32 has a break corresponding with $P_2O_5.MoO_3$=1 : 5 and 1 : 16 respectively. According to L. Malaprade, when phosphomolybdic acid, $P_2O_5.24MoO_3.3H_2O$, is neutralized with alkali, the electrometric curve shows no point of inflexion corresponding with the formation of the normal salt, but there is a point of inflexion corresponding with the formation of a salt of $P_2O_5.22MoO_3.7H_2O$; and a second one corresponding with the decomposition of the phosphomolybdic acid into phosphate and molybdate.

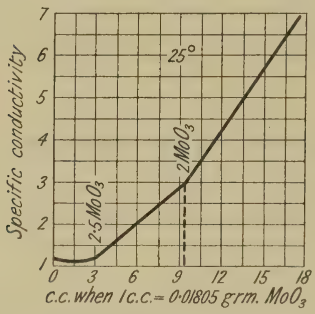

FIG. 31.—Electrical Conductivities of Mixed Solutions of Molybdic and Phosphoric Acids.

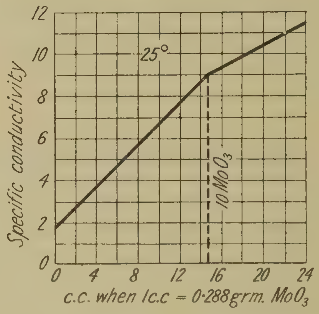

FIG. 32.—Electrical Conductivities of Mixed Solutions of Molybdic Acid and Sodium Hydrophospate.

According to A. Verda, when the ordinary phosphatomolybdic reagent (5 parts of phosphatomolybdic acid, 7 parts of nitric acid, 100 parts of water) is shaken with excess of ether, it is decolorized, the colour becoming conc. in a small quantity of dense liquid which separates at the bottom of the vessel. This proved to be a soln. of phosphatomolybdic acid in ether, for on evaporation of the ether there remained pure phosphatomolybdic acid as an amorphous yellow powder, more readily reducible than the ordinary phosphatomolybdic acid. Pure water dissolves out the phosphatomolybdic acid from the yellow liquid, but water sat. with ether is without action on it. Ether forms with solid phosphatomolybdic acid this yellow liquid, which, however, does not mix with the excess of ether. Soln. of phosphatomolybdates, acidified and treated with ether, can in this way be made to yield pure phosphatomolybdic acid. E. Péchard prepared the phosphatomolybdic acids as compounds of phosphoric acid with metamolybdic acid. A large number of salts has been reported, but, as in the case of the molybdate, there are doubts about the chemical individuality of many of them. The phosphatomolybdic acids with a high proportion of molybdate—say P : Mo=1 : 9 to 1 : 12—are yellow, whereas those with a lower proportion are white or colourless. According to A. Rosenheim, the yellow compounds can be regarded as derivatives of the septivalent PO_6-anion—or the H_7PO_6 acid—with the bivalent Mo_2O_7-radicle in place of oxygen; while the colourless series are derivatives of the tervalent PO_4-anion—or the H_3PO_4 acid—with the bivalent MoO_4-radicle.

Phosphatododecamolybdic acid	$H_7[P(Mo_2O_7)_6]$	$P_2O_5.24MoO_3.nH_2O$.

Phosphatohemipentamolybdic acid	$H_8[P_2O_4(MoO_4)_5]$	$P_2O_5.5MoO_3.nH_2O$.
Phosphatodimolybdic acid	$H_3[PO_2(MoO_4)_2]$	$P_2O_5.4MoO_3.nH_2O$.
Phosphatomolybdic acid	$H_3[PO_3(MoO_4)]$	$P_2O_5.2MoO_3.nH_2O$.

R. Finkener, and F. Kehrmann and E. Böhm obtained **phosphatododecamolybdic acid,** $P_2O_5.24MoO_3.nH_2O$, by adding yellow molybdenum trioxide to a boiling aq. soln. of phosphoric acid; evaporating, and cooling the soln. A. Miolati, and H. Debray, and M. G. Levi and E. Spelta obtained it by treating the ammonium salt with aqua regia, and repeatedly crystallizing the product from water acidulated with nitric acid. F. Hundershagen studied the conditions for its formation and separation as the ammonium salt in analytical work. According to E. Drechsel, and A. Rosenheim and J. Pinsker, phosphatododecamolybdic acid is also obtained by extracting with ether a soln. of molybdenum trioxide in phosphoric acid, or a soln. of a salt of the acid mixed with hydrochloric or nitric acid; and evaporating the ethereal layer. F. Kehrmann and E. Böhm used the following process:

Dissolve 50 grms. of sodium phosphate in water, and pour into the cold liquid, a cold, sat., aq. soln. of 200 grms. of ammonium paramolybdate in a thin stream with constant stirring. Wash the precipitate by repeated decantation with hot water acidulated with nitric acid. Dissolve it in hot aqua regia, and remove the volatile acids by repeated evaporation with water on a water-bath. Dissolve the dry residue in a little water, evaporate the filtered soln. on a water-bath. Filter by suction, wash the product with ice-cold water, and recrystallize twice from water acidulated with nitric acid.

R. Finkener, and F. Elias said that the soln. of phosphatododecamolybdic acid in a large proportion of nitric acid furnishes doubly refracting crystals of $P_2O_5.24MoO_3.32H_2O$, or the *dodecahydrate*, $H_7[P(Mo_2O_7)_6].12H_2O$. O. W. Gibbs, and G. Pohl said that if the conc. aq. soln. is allowed to stand it furnishes yellow octahedra of $P_2O_5.24MoO_3.62H_2O$—R. Finkener, and F. Elias gave $P_2O_5.24MoO_3.63H_2O$—or the *octocosihydrate*, $H_7[P(Mo_2O_7)_6].28H_2O$. A. Rosenheim and J. Pinsker also represented what they regarded as $P_2O_5.24MoO_3.63H_2O$; and G. Pohl, $P_2O_5.24MoO_3.64H_2O$. R. Finkener, and F. Elias represented the acid by the formula $H_3PO_4.12MoO_3.29H_2O$; and F. Kehrmann, by $PO(O.MoO_2.O.MoO_2.O.MoO_2.OH)_3$; A. Rosenheim gave $H_7[P(Mo_2O_7)_6]$. A. Miolati and R. Pizzighelli assume that the basicity of the acid is the difference between the negative valency of the acid groups and the positive valency of the central atom. This makes phosphatododecamolybdic acid septivalent. The septivalency of this acid is supported by the silver salt, $7Ag_2O.P_2O_5.24MoO_3$. According to the electrical conductivity rule—**1.** 15, 13—the guanidium salt behaves like a heptabasic acid. A. Miolati, and A. Rosenheim and J. Jaenicke found that the neutralization curve for the aq. soln. of the acid and a soln. of sodium hydroxide indicated that the acid is at least sexivalent and octocosihydrated. Phosphatododecamolybdic acid forms dark yellow, cubic octahedra. R. Finkener found that the salt loses all but 3 mols. of water at 140°, and A. Miolati added that no other chemical change occurs. The crystals begin to melt at 78°, and at 98° form a clear liquid from which, at 90°, crystals of the *dodecahydrate,* $H_7P(Mo_2O_7)_6.12H_2O$, are formed. The octocosihydrate is readily soluble in water and the same hydrate is deposited when the aq. soln. is crystallized. The soln. in conc. nitric acid deposits rhombic plates of the *docosihydrate,* $H_7P(Mo_2O_7)_6.22H_2O$. A. Rosenheim and J. Jaenicke gave for the eq. conductivity, λ mhos, of one-seventh a mol of the acid in v litres of water at 25°,

v . .	32	64	128	256	512	1024
λ . .	190·6	211·3	229·1	248·5	249·5	258·1

A. Rosenheim and A. Bertheim found that the dodeca-acid is gradually hydrolyzed in aq. soln. to form the ennea-acid—*vide infra*—and this explains the break in the conductivity curve, observed by A. Miolati and R. Pizzighelli—*vide supra,* when molybdic acid is successively added to phosphoric acid. T. G. y Arnal studied the reactions of nitrophosphomolybdic acid with various salts. A. Rosenheim and E. Brauer found the $H^{\cdot}$-ion conc. of the acid to be $5{\cdot}8\times10^{-3}$ for a $0{\cdot}005N$-soln. at 25°. The acid does not dissolve in *water.* The following reactions of a soln. of the acid with metallic salts, etc. were recorded by F. Kehrmann and E. Böhm : With *sodium chloride* no precipitation occurs since the sodium salt is very soluble ; *potassium and ammonium chlorides* give a yellow, very sparingly soluble, pulverulent precipitate ; *barium chloride* gives no precipitation since the barium salt is very soluble ; but it can be salted out by barium chloride ; *silver nitrate* gives a yellow, pulverulent, sparingly soluble precipitate ; *lead nitrate, mercuric chloride,* and the *sulphates of copper, zinc, cadmium, cobalt,* and *nickel* give no precipitate because the resulting salts are very soluble ; *methylamine, dimethylamine, pyridine,* and *quinoline* give yellow, pulverulent or flocculent precipitates almost insoluble ; *aniline* and *p-toluidine* give no precipitate in dil. soln., but with conc. soln. a yellow oil separates which soon crystallizes and becomes blue by reduction ; and β-napthylamine gives an oily precipitate which rapidly forms yellow, sparingly soluble crystals. F. Parmentier found that the sat. ethereal soln. has a sp. gr. of 1·3, and he measured the solubility in *ether* of what he regarded as phosphatodecamolybdic acid, but which was probably phosphatododecamolybdic acid ; and found that 100 grms. of ether dissolved S grms. of the acid :

	0°	8·1°	19·3°	27·4°	32·9°
S	80·6	84·7	96·7	103·9	107·9

According to R. Finkener, **ammonium phosphatododecamolybdate,** $m(NH_4)_2O.P_2O_5.24MoO_3.nH_2O$, is obtaine dfrom acid soln. when ammonia is added to a soln. of phosphatododecamolybdic acid. The composition of the precipitate was discussed by A. König, F. Elias, T. Salzer, H. Debray, C. Friedheim, H. von Jüptner, F. Feigl, A. von Lipowitz, V. Eggertz, E. Spiess, F. Hundeshagen, and C. F. Rammelsberg ; A. Villiers and F. Borg gave $3(NH_4)_2O.P_2O_5.24MoO_3.3H_2O$; H. C. Babbitt gave $3(NH_4)_2O.P_2O_5.24MoO_3.nH_2O$; and O. W. Gibbs, $2\frac{1}{2}(NH_4)_2O.P_2O_5.24MoO_3.8\frac{1}{2}H_2O$. According to S. Posternak, ammonium phosphatomolybdate precipitated from phosphate soln. in the absence of ammonium salts always contains phosphorus and molybdic oxide in a constant ratio. It consists of a variable mixture of di- and tri-ammonium phosphatomolybdates, varying according to the composition of the ammonium molybdate soln. used. In the presence of 5 per cent. or more of ammonium nitrate or sulphate the phosphatomolybdate precipitate obtained is a complex mixture of the types $16(NH_4)_3(MoO_3)_{12}PO_4.NH_4(MoO_3)_4NO_3$ and $8(NH_4)_3(MoO_4)_{12}PO_4.(NH_4)_2(MoO_3)_8SO_4$, respectively. In all cases the molybdic acid behaves as though, in acid medium, it existed in the tetramolybdic state, and in this form combined with the hydroxyl groups of all the mineral acids present.

A. von Endredy represented the formula $(NH_4)_3H_4[P(Mo_2O_7)_6].4H_2O$, and found that the precipitate is very prone to adsorb molybdenum trioxide. C. Friedheim, A. S. Schachoff, and G. Wirtz prepared rhombohedral crystals of **sodium phosphatododecamolybdate,** $5Na_2O(P_2O_5.24MoO_3)_2.100$ or $101H_2O$, by evaporating over sulphuric acid a soln. of a mol of sodium hydrophosphate and 10 mols of molybdic acid. M. Seligsohn obtained an *ammonium sodium phosphatomolybdate* approximating $6(NH_4)_2O.15Na_2O.P_2O_5.60MoO_3.18H_2O$. A. Miolati, and A. Rosenheim and J. Pinsker represented the sodium salt by the formula $Na_3H_4[P(Mo_2O_7)_6].19H_2O$, and the electrical conductivities of the soln. for one-third a mol of the salt in v litres of water at 25° were :

	v	32	64	128	256	512	1024
λ	A.M.	244·2	270·4	298	321·8	344·2	370·8
	A.R. and J.P.	250	275·2	301·4	325·2	350·6	380·0

O. W. Gibbs obtained yellow **potassium phosphatododecamolybdate,** $2K_2O.P_2O_5.24MoO_3.4H_2O$, by boiling for a long time a mixture of potassium molybdate and hydrosphosphate with an excess of nitric acid. F. Kehrmann and E. Böhm observed that what is presumably **copper phosphatododecamolybdate** is precipitated by copper sulphate from a soln. of the acid. The precipitate is soluble in water. A. Miolati and R. Pizzighelli obtained **silver phosphatododecamolybdate,** $7Ag_2O.P_2O_5.24MoO_3$, from a soln. of silver nitrate and phosphatododecamolybdic acid, or the ammonium salt. F. Kehrmann and E. Böhm reported **barium phosphatododecamolybdate,** $3BaO.P_2O_5.24MoO_3.nH_2O$, to be formed by treating the phosphatododecamolybdic acid with an excess of barium chloride. The pale yellow octahedra lose water of crystallization when exposed to air ; and they lose all their water at dull redness, without melting. The salt is soluble in water. M. Seligsohn obtained **ammonium barium phosphatomolybdate,** $3(NH_4)_2O.30BaO.P_2O_5.30MoO_3.nH_2O$, from a soln. of ammonium phosphatododecamolybdate and barium chloride. F. Parmentier, and A. Miolati and R. Pizzighelli obtained what was probably **mercurous phosphatododecamolybdate** by adding phosphatododecamolybdic acid to a soln. of a mercurous salt; and C. Kehrmann and E. Böhm, by using a mercuric salt soln. obtained **mercuric phosphatododecamolybdate,** $3HgO.P_2O_5.24MoO_3$, as a precipitate soluble in water. H. Beuf found that a boiling, neutral soln of a lead salt furnishes a precipitate of what is nearly **lead phosphatododecamolybdate,** namely, $25PbO.P_2O_5.24MoO_3.7H_2O$, when treated with an aq. soln. of phosphatomolybdic acid. The washed precipitate dried at 90° to 100° forms a dense white powder which is insoluble in water (1 in 500,000) and aq. ammonia, but dissolves in nitric and in acetic acids; and at a high temp., it loses 7 mols of H_2O. The **vanadium phosphatomolybdates** are discussed in connection with vanadium.

A. Arnfeld reported **manganese phosphatododecamolybdate,** $3MnO.P_2O_5.24MoO_3.58$ or $60H_2O$, to be formed by boiling a soln. of 40 grms. of manganese hydrophosphate with molybdenum trioxide, and allowing the filtered soln. to evaporate over sulphuric acid. The yellow octahedra effloresce in air. They dissolve in water ; and at 90° lose 16·8 per cent. of water, and at 140°, all the water is expelled. By boiling freshly-precipitated ferric phosphate, molybdenum trioxide, and water, and evaporating the filtered soln., a yellow powder was deposited ; the filtered liquid, when concentrated, deposits octahedral crystals of **ferric phosphatododecamolybdate,** $Fe_2O_3.P_2O_5.24MoO_3.58H_2O$. Water decomposes the salt. Instead of evaporating the soln., ether can be added, and the precipitated oil allowed to crystallize. A. Arnfeld prepared **cobalt phosphatododecamolybdate,** $3CoO.P_2O_5.24MoO_3.58$ to $60H_2O$, by the saturating with molybdenum trioxide 40 grms. of cobalt phosphate in boiling water ; and concentrating the brown soln. over sulphuric acid. The yellowish-brown, pyramidal crystals effloresce in air. The yellow aq. soln. becomes red when treated with acids. A. Arnfeld prepared green crystals of **nickel phosphatododecamolybdate,** $3NiO.P_2O_5.24MoO_3.58$ to

$60H_2O$, in an analogous way. The salt effloresces in air; loses all its water at 150°; and is soluble in water.

G. Pohl reported that if commercial phosphatomolybdic acid be recrystallized, the compound $P_2O_5.23MoO_3.nH_2O$ can be obtained from the mother-liquors; and similarly also **phosphatohenamolybdic acid,** $P_2O_5.22MoO_3.58H_2O$. C. F. Rammelsberg obtained **ammonium phosphatohenamolybdate,** $3(NH_4)_2O.P_2O_5.22MoO_3.12H_2O$, by precipitation from a nitric acid soln. of ammonium molybdate on the addition of phosphoric acid. According to A. E. Nordenskjöld, the axial ratios of the monoclinic prisms are $a : b : c = 0{\cdot}5092 : 1 : 0{\cdot}8466$, and $\beta = 90° \ 59'$. The yellow, air-dried salt loses all its water over sulphuric acid, and it is then stable at 100°, but gives off ammonia at 120°. O. W. Gibbs reported yellow crystals of **potassium phosphatohenamolybdate,** $5K_2O(P_2O_5.22MoO_3)_2.22H_2O$, to be formed by boiling for a short time a mixture of potassium molybdate and hydrophosphate with an excess of nitric acid; and C. F. Rammelsberg, $3K_2O.P_2O_5.22MoO_3.12H_2O$, by adding phosphoric acid to a nitric acid soln. of potassium molybdate. The crystals resemble those of the ammonium salt. They lose their water completely at 120°–140°, and suffer no further loss in weight at a red-heat. F. Ephraim and H. Herschfinkel obtained **rubidium phosphatohenamolybdate,** $7Rb_2O.22MoO_3.P_2O_5.12H_2O$, by gradually adding 2·5 grms. of molybdic acid to a soln. of 30 c.c. of rubidium carbonate (containing 5·5 grms. Rb_2O per litre) and 12 c.c. of 3·3 per cent. phosphoric acid. O. W. Gibbs obtained small tabular crystals of **silver phosphatohenamolybdate,** $7Ag_2O.P_2O_5.22MoO_3.14H_2O$, from a soln. of silver nitrate and the corresponding phosphatomolybdic acid. The salt is soluble in hot water.

H. Debray obtained *doublement obliques* (triclinic) prisms of what was regarded as **phosphatodecamolybdic acid,** $P_2O_5.20MoO_3.24$, 41, 51, or $52H_2O$, or $H_6[P(OH)(Mo_2O_7)_5].nH_2O$, by the action of aqua regia on ammonium phosphate. G. Pohl, and F. Parmentier also prepared this product. These phosphatomolybdic acids, as well as the salts which have been reported, are probably impure phosphatododecamolybdic acid or phosphatododecamolybdates, or else the formulæ are based on unsatisfactory analyses. A. Rosenheim and A. Bertheim, and A. Miolati considered phosphatodecamolybdic acid to be a mixture of phosphatododecamolybdic and phosphatoenneamolybdic acids. O. W. Gibbs described **ammonium phosphatodecamolybdate,** $8(NH_4)_2O.(P_2O_5.20MoO_3)_3.12H_2O$, as a yellow salt; and the salt $(NH_4)_3H_3[P(OH)(Mo_2O_7)_5]$ was described by L. F. Svanberg and H. Struve, F. L. Sonnenschein, M. Seligsohn, M. Nutzinger, and A. von Lipowitz. H. Rose prepared it from a soln. of molybdic acid, ammonia, orthophosphoric acid not in excess in an acid soln.—preferably nitric acid. Pyrophosphates and metaphosphates do not give the yellow, pulverulent precipitate, unless, added H. Struve, they are first transformed into orthophosphates. According to H. Debray, if the transformation is slow, the precipitate may be crystalline. A. von Lipowitz found that the precipitate can be obtained free from an excess of molybdic acid by dissolving 2 parts of molybdic acid, and one part of tartaric acid in 15 parts of warm water, adding 10 parts of aq. ammonia of sp. gr. 0·97, and then 15 parts of nitric acid; heating the soln. to its b.p. when some molybdic acid is precipitated; again heating the filtered soln. to its b.p.; and adding one part of phosphoric acid to 100 parts of the filtrate. The precipitate is washed with 2 per cent. nitric acid, and dried over sulphuric acid. H. Debray obtained the salt by adding phosphatodecamolybdic acid to a strongly acid soln. of an ammonium salt. The canary-yellow precipitate, said L. F. Svanberg and H. Struve, is an amorphous powder. When heated to redness, ammonia and water are given off, and the brown or green residue forms with nitric acid a soln. which is yellow when hot, and colourless when cold; and which, on evaporation, furnishes yellow rhombohedra of phosphatodecamolybdic acid. Ammonium phosphatodecamolybdate is sparingly soluble in water or acids; and it is easily soluble in aq. ammonia, and alkali-lye. If an excess of ammonium molybdate be present, E. Richter said that the precipitate is nearly insoluble in aq. ammonia, and it is also insoluble in a feebly acid soln. of ammonium nitrate. H. Struve said that acetic acid favours the precipitation; while C. R. Fresenius found that in the presence of ammonium molybdate and free nitric acid, the precipitation is retarded by hydrochloric acid, ammonium and metal chlorides, tartaric acid, ammonium tartrate or citrate, and an excess of phosphoric acid. According to F. L. Sonnenschein, the following favour the dissolution of the precipitate: a large excess of water, or alcohol; alkali hydroxides, carbonates, or ortho-, meta-, or pyrophosphates; barium borate; sodium dithionate, thiosulphate, acetate, arsenite, or arsenate; potassium sodium tartrate; ammonium oxalate; phosphoric acid, or conc. sulphuric acid; while ammonium molybdate or sulphate; potassium sulphate; tartrate, oxalate, nitrate, chlorate, chloride, bromide, or iodide; sodium bromide, or nitrate; or nitric, hydrochloric, boric, tartaric, oxalic, or dil. sulphuric acid, do not have a solvent action. F. L. Sonnenschein also described a **sodium phosphatodecamolybdate.** A. S. Schachoff recommended the following mode of preparation:

Ammonium molybdate was prepared direct from 600 grms. of commercial molybdic acid, and an aq. soln. was treated with 100 grms. of sodium phosphate, and subsequently with 400 c.c. of hydrochloric acid. The precipitated ammonium phosphatomolybdate, washed free from chloride, was dissolved in a soln. of 200 grms. of sodium hydroxide in a small quantity of water, the liquid evaporated to dryness, and the residue heated to expel the residual ammonia. The salt was then crystallized from water, the final yield being 115–120 per cent. of the molybdic acid taken. The proportions of water of crystallization and of sodium present vary in different preparations.

L. F. Svanberg and H. Struve reported **potassium phosphatodecamolybdate,** $3K_2O.P_2O_5.20MoO_3.3H_2O$, to be formed by boiling the ammonium salt with potassium hydroxide so long as ammonia is given off, mixing the colourless soln. with nitric acid, and washing the precipitate with water acidulated with nitric acid. H. Debray obtained it by adding phosphatodecamolybdic acid to a soln. of a potassium salt—a precipitate is formed if only 0·002 part of potassium be present. The yellow, four-sided prisms lose water when heated, and melt at dull redness. L. F. Svanberg and H. Struve said that the salt is insoluble in water, and H. Debray added that it is easily soluble in alkali-lye. F. Ephraim and H. Herschfinkel prepared **rubidium phosphatodecamolybdate,** $3Rb_2O.P_2O_5.20MoO_3.12H_2O$, as a yellow crystalline powder, from a soln. of 200 c.c. of rubidium carbonate (with 10·94 grms. Rb_2O) and 8·46 grms. of molybdenum trioxide, and 0845 grm. of P_2O_5 in 25 c.c. of water, and dropping in 50 c.c. of nitric acid of sp. gr. 1·20. H. Debray said that microscopic crystals of **silver phosphatodecamolybdate,** $7Ag_2O.P_2O_5.20MoO_3.24H_2O$, are precipitated by the phosphatodecamolybdic acid from a soln. of silver nitrate; and if a nitric acid soln. of this salt be evaporated, yellow crystals of $2Ag_2O.P_2O_5.20MoO_3.7H_2O$ are formed. Similarly, he obtained **thallous phosphatodecamolybdate,** by adding an acid soln. of a thallous salt to the phosphatodecamolybdic acid.

F. Kehrmann prepared **phosphatoenneamolybdic acid,** $P_2O_5.18MoO_3.nH_2O$, or $H_{12}[P_2O_2(Mo_2O_7)_9].nH_2O$, by treating a warm soln. of the potassium salt, in a small proportion of water and sulphuric acid, with five times its vol. of alcohol. An equal vol. of ether was then added to the soln., and after allowing the liquid to stand in a freezing mixture for some time, evaporating it over sulphuric acid. It was also obtained by treating yellow hydrated molybdenum trioxide with boiling phosphoric acid, when the dodeca-acid first precipitates; after the product has stood some weeks it becomes liquid, and when this is allowed to crystallize, the ennea-acid separates out. The acid was also prepared by G. Pohl, and F. Elias. The ennea-acid appears to be a hydrolysis product of the dodeca-acid, for A. Rosenheim, and A. Miolati found that if an aq. soln. of the dodeca-acid is allowed to stand for some weeks, it gradually loses its power to give a precipitate with ammonium chloride and it has then passed into the ennea-acid. The change is accelerated by adding a small proportion of phosphoric acid to the soln. E. Drechsel obtained it by extracting the soln. in dil. hydrochloric acid by means of ether, and the aq. ethereal soln. evaporated. Phosphatoenneamolybdic acid furnishes orange-red, hygroscopic prisms, and, in allusion to the colour—*luteus*, yellow—it is also called *luteophosphomolybdic acid.* The acid is freely soluble in water in any proportions. It effloresces over sulphuric acid, and it then rapidly dissolves in water without undergoing any chemical change. The acid is quantitatively precipitated as the potassium salt by the addition of potassium chloride. The orange-yellow crystals are probably those of the *tetracosi-hydrate*, although the analyses show between 24 and $30H_2O$. If the orange-yellow prisms be kept under the mother-liquid at 0° for some time, yellow crystals of the *tetratriconti-hydrate* are formed. According to A. Rosenheim and A. Traube, the progressive neutralization of the ennea-acid by alkali shows that its basicity is more than six. The electrical conductivity of the sodium salt, and the composition of the phosphato-enneamolybdates agree with the assumption that the anion is either decabasic, $[P(OH)(Mo_2O_7)_4–Mo_2O_7–P(OH)(Mo_2O_7)_4]$, or else dodecabasic: $[PO(Mo_2O_7)_4–Mo_2O_7–PO(Mo_2O_7)_4]$ or $[P(OH)_2(Mo_2O_7)_4–Mo_2O_7–P(OH)_2(Mo_2O_7)_4]$. A. Rosenheim and A. Traube found the eq. conductivity, λ mhos, of a soln. of one-twelfth of a mol of the acid in v litres at 25°, to be:

v	32	64	128	256	512	1024
λ	197·9	210·0	218·0	226·6	236·9	248·8

The following are some reactions of soln. of the ennea-acid with soln. of metallic salts, etc. recorded by F. Kehrmann and E. Böhm: There is no precipitation with *sodium chloride* owing to the solubility of the sodium salt; similarly also with *ammonium chloride*, but the ammonium salt can be salted out from the soln. by ammonium chloride; *potassium chloride* gives no precipitate, but the soluble potassium salt can be salted out by potassium chloride; *barium chloride* gives no precipitate since the barium salt is so soluble; similar remarks apply to *mercuric chloride*, the *sulphates of copper, zinc, and cadmium,* and to *lead nitrate*—the soln. with the latter salt soon decomposes with the separation of a white powder; *silver nitrate* gives a yellow, flocculent precipitate soluble in water, but insoluble in a dil. soln. of silver nitrate; mercurous nitrate gives a yellow, pulverulent precipitate very sparingly soluble in cold water but rather more soluble in hot water; *thallous sulphate* gives a dark yellow, crystalline precipitate, appreciably soluble in hot water; *stannous chloride* gives no precipitate but a blue reduction product is formed in soln.; similarly with *antimonous chloride; stannic chloride* gives no perceptible change; *methylamine,* and *dimethylamine* give no precipitates; *pyridine,* and *quinoline* give yellow flocculent precipitates almost insoluble in cold or boiling water; *aniline,* and *p-toluidine* give yellow oily drops with fairly conc. soln., and these soon form scaly crystals, and a blue reduction product; and *β-naphthylamine* gives a yellow, oily precipitate which, when warm, soon forms a crystalline powder.

F. Kehrmann and E. Böhm treated barium phosphatododecamolybdate with dil. sulphuric acid, and saturated the filtered soln. with solid ammonium chloride; orange, prismatic crystals of **ammonium phosphatoenneamolybdate,** $(NH_4)_6H_6[P_2O_2(Mo_2O_7)_9].11H_2O$, were formed. The aq. soln. can be kept days in the cold, but when heated, ammonium phosphatodecamolybdate is precipitated. E. Ephraim and M. Brand obtained orange pyramidal crystals of **lithium phosphatoenneamolybdate,** $Li_6H_6[P_2O_2(Mo_2O_7)_9].24H_2O$, which lose 18 mols. of water at 100°, and the remainder at a red-heat; the salt is soluble in cold water. F. Elias also obtained a similar salt from a soln. of lithium carbonate and molybdic acid mixed with phosphoric acid. C. Friedheim reported prismatic crystals of **sodium phosphatoenneamolybdate,** $3Na_2O.P_2O_5.18MoO_3.25$ or $26H_2O$, from a soln. of sodium phosphate and molybdic acid. F. Kehrmann and E. Böhm prepared **potassium phosphatoenneamolybdate,** $3K_2O.P_2O_5.18MoO_3.14H_2O$, by adding potassium chloride to the corresponding ammonium salt. The orange-red, prismatic crystals are more stable than the ammonium salt. The salt is sparingly soluble in cold water, but more soluble in hot water. L. Duparc and F. Pearce gave for the axial ratios of the triclinic crystals $a:b:c=0·5938:1:0·6479$, and $\alpha=60°\ 50'$, $\beta=114°\ 22'$, and $\gamma=115°\ 26'$. F. Elias represented the salt as containing $11H_2O$ and also $15H_2O$. F. Ephraim and H. Herschfinkel boiled a soln.

of rubidium phosphatodecamolybdate with rubidium carbonate, evaporated the filtered soln., and obtained **rubidium phosphatoenneamolybdate,** $6Rb_2O.P_2O_5.18MoO_3.10H_2O$. F. Kehrmann and E. Böhm observed that presumably **copper phosphatoenneamolybdate** is precipitated by copper sulphate from a soln. of the acid. The precipitate is soluble in water: by using mercurous nitrate, they obtained **mercurous phosphatoenneamolybdate;** and with mercuric chloride, **mercuric phosphatoenneamolybdate,** $3HgO.P_2O_5.18MoO_3$.

A. Arnfeld treated the mother-liquor obtained in the preparation of manganous phosphatododecamolybdate with potassium chloride, and allowed the filtered liquid to crystallize. Prismatic crystals of **manganese phosphatoenneamolybdate,** $3MnO.P_2O_5.18MoO_3.38H_2O$, were obtained. The crystals lose 19 mols. of water at 90°; 33 mols. at 100°; 35 mols. at 120°; and all the water is expelled at 150°. The salt forms a yellow soln. with water. Attempts to prepare **ferric phosphatoenneamolybdate** were not successful. A. Arnfeld obtained **cobalt phosphatoenneamolybdate,** $3CoO.P_2O_5.18MoO_3.38H_2O$, by allowing the mother-liquor from the preparation of the phosphatododecamolybdate to stand over sulphuric acid. He also obtained **nickel phosphatoenneamolybdate,** $3NiO.P_2O_5.18MoO_3.34H_2O$, in green, triclinic crystals in an analogous manner. The salt loses 30 mols. of water at 90°; and 34 mols. at 140°. The crystals effloresce in air, and form a green soln. with water.

F. Kehrmann and E. Böhm found that the hydrolysis of a soln. of a phosphatoenneamolybdate furnishes unstable salts of **phosphatohemiheptadecamolybdic acid,** $2P_2O_5.34MoO_3.nH_2O$, or $H_{22}[P_4O_4(Mo_2O_7)_{17}].nH_2O$. If a cold, sat. soln. of potassium hexahydrophosphatoenneamolybdate is mixed with a soln. of potassium hydrocarbonate, lemon-yellow scales of **potassium phosphatohemiheptadecamolybdate,** $5K_2O.P_2O_5.17MoO_3.26H_2O$, or $K_{20}H_2[P_4O_4(Mo_2O_7)_{17}].51H_2O$, are formed. The salt slowly decomposes at ordinary temp., and immediately on boiling. F. Elias also prepared $3K_2O.P_2O_5.17MoO_3.12H_2O$. F. Kehrmann and E. Böhm also prepared **ammonium phosphatohemiheptadecamolybdate,** $5(NH_4)_2O.P_2O_5.17MoO_3.nH_2O$, in bright yellow nodules by the action of ammonium hydrocarbonate on the ammonium phosphatoenneamolybdate; and similarly with **sodium phosphatohemiheptadecamolybdate,** $5Na_2O.P_2O_5.17MoO_3.nH_2O$. By treating sodium phosphatoenneamolybdate with ammonium chloride and ammonium hydrocarbonate, **ammonium sodium phosphatohemiheptadecamolybdate,** $(NH_4)_{16}Na_6[P_4O_4(Mo_2O_7)_{17}].33H_2O$, is formed; and similarly with **potassium sodium phosphatohemiheptamolybdate,** $K_{16}Na_6[P_4O_4(Mo_2O_7)_{17}].36H_2O$. By double decomposition with silver nitrate, **silver phosphatohemiheptadecamolybdate,** $Ag_{22}[P_4O_4(Mo_2O_7)_{17}].40H_2O$, is formed, and similarly with the *guanidinium salt*, $(CN_3H_6)_{22}[P_4O_4(Mo_2O_7)_{17}].40H_2O$.

O. W. Gibbs reported *ammonium phosphatoctomolybdate*, $3(NH_4)_2O.P_2O_5.16MoO_3$ $14H_2O$, as a white precipitate, by a process like that used for the phosphatohemipentamolybdate; and J. Meschoirer, $5(NH_4)_2O.P_2O_5.16MoO_3$, by the action of 25 grms. of ammonium dihydrophosphate on a cold, conc. soln. of 105 grms. of ammonium molybdate.

J. Meschoirer reported white crystals of *ammonium phosphatoheptamolybdate*, $9(NH_4)_2O.2P_2O_5.28MoO_3.8H_2O$, by the action of 25 grms. of ammonium dihydrophosphate on a hot, conc soln. of 105 grms. of ammonium molybdate. F. Ephraim and H. Herschfinkel reported *cæsium phosphatoheptadecamolybdate*, $2Cs_2O.P_2O_5.17MoO_3.3H_2O$, as a yellow, microcrystalline powder to be formed by the method employed for rubidium phosphatodecamolybdate.

F. Ephraim and M. Brand reported *lithium phosphatohexamolybdate*, $3Li_2O.P_2O_5.12MoO_3.18H_2O$, to be formed as a lemon-yellow microcrystalline powder by treating a conc. soln. of the phosphatohemipentamolybdate with dil. nitric acid. O. W. Gibbs found that soln. of what he regarded as *ammonium phosphatohexamolybdate*, $2(NH_4)_2O.2P_2O_5.12MoO_3.3H_2O$, is dissolved by a soln. of copper sulphate.

O. W. Gibbs found that what he regarded as *ammonium phosphatotetramolybdate*, $2(NH_4)_2O.P_2O_5.8MoO_3.5H_2O$, gave no precipitate with a soln. of copper sulphate, nor is it reduced by boiling with or without hydrochloric acid. Ammonia gives a green, flocculent precipitate.

F. Ephraim and H. Herschfinkel obtained *cæsium phosphatotrimolybdate*, $3Cs_2O.P_2O_5.$

$6MoO_3.8H_2O$, as a white micro-crystalline powder, by the method used for rubidium phosphatotetritaenneamolybdate excepting that cæsium hydroxide is mixed first with the phosphoric acid, and the soln. then sat. with molybdenum trioxide. H. Perlberger obtained *ammonium cadmium phosphatotrimolybdate*, $2(NH_4)_2O.CdO.P_2O_5.6MoO_3.8H_2O$, by the action of ammonium phosphatohemipentamolybdate on cadmium chloride.

N. Seligson prepared a complex of molybdic acid with inositol phosphate, $C_6H_6(NH_4HPO_4)_6.6MoO_3.15H_2O$.

H. Debray prepared salts of **phosphatohemipentamolybdic acid,** $P_2O_5.5MoO_3.nH_2O$, but added that the free acid cannot be obtained from the salts because it is decomposed into phosphoric acid and presumably phosphatododecamolybdic acid. If a yellow soln. of a phosphatomolybdate be treated with conc. aq. ammonia, hydrolysis occurs, the soln. becomes colourless, and a white phosphatohemipentamolybdate is formed. A. Miolati and R. Pizzighelli, and C. Friedheim showed that the anion is probably octobasic, and, in the language of the co-ordination theory, can be represented $[PO_2(MoO_4)_2–MoO_4–PO_2(MoO_4)_2]$, or $[P_2O_4(MoO_4)_5]$. According to C. Friedheim, when less than two mols of molybdenum trioxide react with one of potassium hydrophosphate there are formed **potassium dihydrophosphatohemipentamolybdate,** $K_6H_2[P_2O_4(MoO_4)_5].6H_2O$, and **potassium trihydrophosphatohemipentamolybdate,** $K_5H_3[P_2O_4(MoO_4)_5].4H_2O$. C. F. Rammelsberg obtained *white* prisms of the trihydrophosphatohemipentamolybdate by adding phosphoric acid to a soln. of potassium trimolybdate in as small a quantity as practicable of potassium hydroxide soln. The rhombic bipyramids had the axial ratios $a:b:c=0·9833:1:0·8209$. The salt loses water at 120°. F. A. Zenker obtained the dihydrophosphohemipentamolybdate by evaporating a soln. of phosphoric acid and molybdenum trioxide in hydrochloric acid, and saturating the syrupy liquid with potassium hydroxide; H. Debray, by melting the ammonium salt with potassium nitrate, and crystallizing from aq. soln.; and C. F. Rammelsberg, by melting a mol of potassium carbonate, 2 mols of molybdenum trioxide, and mixing a soln. of the product with phosphoric acid. The colourless, rhombic bipyramids have the axial ratios $a:b:c=0·7199:1:0·7151$. The aq. soln. has an acid reaction, and gives a precipitate with nitric or hydrochloric acid. C. Friedheim observed that if two mols of molybdenum trioxide are mixed with a mol of potassium hydrophosphate, the hemiheptadecamolybdate is formed, as well as **potassium tetrahydrophosphatohemipentamolybdate,** $K_4H_4[P_2O_4(MoO_4)_5].4H_2O$—some phosphatodimolybdate is formed. F. A. Zenker reported **ammonium dihydrophosphatohemipentamolybdate,** $(NH_4)_6H_2[P_2O_4(MoO_4)_5].6H_2O$, to be formed by the spontaneous evaporation of an ammonia soln. of ammonium phosphatodecamolybdate. The first crop of crystals is ammonium paramolybdate. The next crop of crystals can be purified by crystallization from hot water and a little ammonia. O. W. Gibbs, H. Debray, and A. Werncke prepared it from a soln. of ammonium molybdate and ammonium phosphate. H. Perlberger, and J. Meschoirer also prepared the hexahydrate; and H. Perlberger reported a *heptahydrate;* A. Mazzucchelli and G. Zangrilli obtained the *heptadecahydrate* by concentrating a soln. of ammonium hydrophosphate in a little water, mixed with ammonium molybdate, and hydrogen dioxide. F. A. Zenker, and O. W. Gibbs said that the crystals are triclinic prisms which are stable in dry air, but become opaque in moist air. The salt is then no longer soluble in water. The salt is freely soluble in hot water, but less soluble in cold water. The aq. soln. has an acid reaction, and when the aq. soln. is boiled or allowed to stand exposed to air, ammonia is given off, and a white precipitate is formed. O. W. Gibbs reported white or colourless crystals of **ammonium trihydrophosphatohemipentamolybdate,** $(NH_4)_5H_3[P_2O_4(MoO_4)_5].2H_2O$, to be formed by cooling a hot soln. of molybdenum trioxide in one of ammonium phosphate; and also the *tetrahydrate* by neutralizing phosphoric acid with ammonia, adding ammonium paramolybdate; on evaporation, there is formed a gum-like mass which yields white or colourless plates easily soluble in water. H. Perlberger also prepared the *hexahydrate.* J. Meschoirer also prepared the dihydrate; and H. Perlberger, A. Arnfeld, and J. Meschoirer reported a *hemitridecahydrate*, and H. Perlberger, a *hexahydrate*. F. Ephraim and M. Brand prepared a complex of a mol of **lithium dihydrophosphatohemipentamolybdate,** $Li_6H_2[P_2O_4(MoO_4)_5]$, and 6 mols of lithium phosphate from a soln. of 3 mols of lithium molybdate, 2 mols of molybdenum trioxide, and a mol of phosphorus pentoxide in water. They also obtained the salt $3Li_2O.P_2O_5.5MoO_3$, with 16 and $17H_2O$. H. Debray prepared **sodium dihydrophosphatohemipentamolybdate,** $Na_6H_2[P_2O_4(MoO_4)_5].13H_2O$, as in the case of the potassium salt. H. Dufet said that the crystals are rhombic bipyramids with the axial ratios $a:b:c$ $=0·7966:1:1·0726$; the (102)-cleavage is complete; the optical character is negative. For Li-, Na-, and Tl-light, at 20°, the optic axial angle, $2V$, is respectively 51° 16′, 51° 18·5′, and 51° 16′; and $2E$, respectively, 90° 2′, 90° 35′, and 90° 58′, while the indices of refraction are, respectively, $\alpha=1·5906$, 1·5962, and 1·6017; $\beta=1·6328$, 1·6411, and 1·6494; and $\gamma=1·6420$, 1·6520, and 1·6610. A rise of temp. of 1° makes the angle $2E$ about 10′ smaller. F. Ephraim and H. Herschfinkel could not prepare **rubidium phosphatohemipentamolybdate.** O. W. Gibbs found that copper sulphate gave no precipitate with a soln. of ammonium phosphatohemipentamolybdate; H. Perlberger obtained **copper phosphatohemipentamolybdate,** $3CuO.P_2O_5.5MoO_3$, by the method used by A. Arnfeld for the manganese and cobalt salts. He also obtained **ammonium copper phosphatohemipentamolybdate,** $3\{(NH_4)_2.Cu\}O_2.P_2O_5.5MoO_3.3H_2O$, by mixing aq. soln. of ammonium and copper phosphatomolybdates; likewise also by the addition of potassium chloride, **potassium copper phosphatohemipentamolybdate,** $3K_2O.CuO.2P_2O_5.10MoO_3.18H_2O$, was obtained. H. Debray reported **silver phosphatohemipentamolybdate,** $3Ag_2O.P_2O_5.5MoO_3.5H_2O$, to be formed by the action of alkali hydroxide or carbonate on silver phosphatodecamolybdate. The colourless crystals are soluble in water. C. Friedheim prepared crystals of **potassium calcium phosphatohemipentamolybdate,** $3K_2O.2CaO.2P_2O_5.10MoO_3.22H_2O$, from soln. of calcium chloride and potassium phosphatohemidecamolybdate. H. Perlberger prepared **cadmium phosphatohemipentamolybdate,** $3CdO.P_2O_5.5MoO_3.5H_2O$, as in the case of the copper salt. O. W. Gibbs obtained **mercurous phosphatohemipentamolybdate** by the action of mercurous nitrate on the ammonium salt.

A. Arnfeld prepared **manganese phosphatohemipentamolybdate,** $3MnO.P_2O_5.5MoO_3.20H_2O$, or $Mn_3H_2[P_2O_4(MoO_4)_5].19H_2O$, by allowing 9 grms. of freshly precipitated manganese hydrophosphate and 18 grms. of molybdenum trioxide to stand in cold water for 14 days. The filtered liquid is evaporated to a syrupy consistency, and treated with alcohol. The yellow, microcrystalline powder, loses 16 mols of water at 90°, and another mol at 100°; all the water is expelled at 150°. The salt is easily soluble in water, and sparingly soluble in alcohol. The aq. soln. gives a precipitate with ammonium or potassium chloride. If a soln. of a mol of ammonium phosphatohemipentamolybdate is treated with 10 mols of manganous chloride, and evaporated over sulphuric acid, crystals of **ammonium manganous phosphatohemipentamolybdate,** $(NH_4)_8MnH_2[P_2O_4(MoO_4)_5]_2.12H_2O$, are formed. A cold soln. of a mol of ammonium phosphatohemipentamolybdate and a mol of manganous chloride gives microscopic needles of **ammonium manganous dihydrophosphatohemipentamolybdate,** $(NH_4)_2Mn_2H_2[P_2O_4(MoO_4)_5].19H_2O$. A soln. of a mol of potassium phosphatohemipentamolybdate and 10 mols of manganous chloride gives **potassium manganous phosphatohemipentamolybdate,** $K_6Mn_2H_2[P_2O_4(MoO_4)_5]_2.29H_2O$, as a yellow, microcrystalline powder, Attempts to prepare **ferric phosphatohemipentamolybdate,** $Fe_2O_3.P_2O_5.5MoO_3.nH_2O$, gave a product of variable composition. The group $[P_2O_4(MoO_4)_5]$ has a basicity of 8, and $[P_2O_4(MoO_4)_5]_2$ has a basicity of 12.

A. Arnfeld obtained **cobaltous phosphatohemipentamolybdate,** $Co_3H_2[P_2O_4(MoO_4)_5].15\frac{1}{2}$ or $16\frac{1}{2}H_2O$, as in the case of the manganese salt; or by evaporating a dil. soln. of a mol of phosphoric acid, 5 mols of molybdenum trioxide, and the theoretical quantity of cobalt carbonate; or by the action of a mol of cobaltous phosphate on 10 mols of molybdenum trioxide suspended in water. The brownish-red crystalline mass is extremely soluble in water, and the soln. with alcohol precipitates an oily liquid which soon crystallizes. If a mol of ammonium phosphatohemipentamolybdate be treated with a soln. of 3 mols of cobaltous chloride in hot water, **ammonium cobaltous dihydrophosphatohemipentamolybdate,** $(NH_4)_2Co_2H_2[P_2O_4(MoO_4)_5].9H_2O$, separates out on cooling as a brick-red, microcrystalline precipitate which is decomposed by water. A soln. containing a mol of ammonium phosphatohemipentamolybdate and 10 mols of cobaltous chloride furnishes rose-coloured crystals of **ammonium cobaltous phosphatohemipentamolybdate,** $(NH_4)_8CoH_2[P_2O_4(MoO_4)_5]_2.11H_2O$, when evaporated over sulphuric acid. The salt is sparingly soluble in cold water. The corresponding potassium salts —**potassium cobaltous dihydrophosphatohemipentamolybdate,** $K_2Co_2H_2[P_2O_4(MoO_4)_5].14H_2O$, and **potassium cobaltous phosphatohemipentamolybdate,** $K_8CoH_2[P_2O_4(MoO_4)_5]_2.11H_2O$—were obtained by analogous processes.

A. Arnfeld prepared **nickel phosphatohemipentamolybdate,** $Ni_3H_2[P_2O_4(MoO_4)_5].19H_2O$, by boiling a mol of freshly-prepared nickel phosphate, and 5 mols of molybdenum trioxide with water, evaporating the green soln. to a syrupy consistency, and adding alcohol. The oily liquid crystallizes over phosphorus pentoxide. The green needles are decomposed by cold water. Green crystals of **ammonium nickel dihydrophosphatohemipentamolybdate,** $(NH_4)_6Ni_2H_2[P_2O_4(MoO_4)_5].9H_2O$, and of **ammonium nickel phosphatohemipentamolybdate,** $(NH_4)_8NiH_2[P_2O_4(MoO_4)_5]_2.11H_2O$, as well as of **potassium nickel dihydrophosphatohemipentamolybdate,** $K_2Ni_2H_2[P_2O_4(MoO_4)_5].12H_2O$, and **potassium nickel phosphatohemipentamolybdate,** $K_8NiH_2[P_2O_4(MoO_4)_5]_2.11H_2O$, were obtained as in the case of the corresponding cobaltous salts.

F. Ephraim and H. Herschfinkel reported *rubidium phosphatotetritaenneamolybdate,* $5Rb_2O.2P_2O_5.9MoO_3.13H_2O$, as a white, crystalline powder, from a soln. of a mol of rubidium carbonate and 0·5 mol of phosphorus pentoxide boiled with a mol of molybdenum trioxide. The filtered soln. is concentrated by evaporation and allowed to stand for crystallization. H. Perlberger prepared *ammonium cadmium phosphatotetritaenneamolybdate,* $3(NH_4)_2O.2CdO.2P_2O_5.9MoO_3.14H_2O$, by the action of cadmium chloride on a soln. of the pentammonium phosphatohemipentamolybdate.

O. W. Gibbs reported *barium phosphatohexitatetradecamolybdate,* $4BaO.3P_2O_5.14MoO_3.55H_2O$, from a soln. of barium hexametaphosphate in ammonium heptamolybdate. If the soln. be treated with mercurous nitrate, a mercury salt is obtained.

O. W. Gibbs also reported *ammonium stannic phosphatohexitetradecamolybdate,* $3(NH_4)_2O.4SnO_2.3P_2O_5.14MoO_3.28H_2O$, to be obtained as a yellow, crystalline precipitate by the action of ammonium chlorostannate on a soln. of an alkali phosphatomolybdate. The product is almost insoluble in boiling water.

C. Friedheim prepared the potassium salt of **phosphatodimolybdic acid,** $H_3[PO_2(MoO_4)_2].nH_2O$. By the interaction of a mol of potassium hydrophosphate and 2 mols of molybdenum trioxide, there are formed hemipentamolybdates and **potassium hydrophosphatodimolybdate,** $K_2H[PO_2(MoO_4)_2].3\frac{1}{2}H_2O$. C. Friedheim, and A. Mazzucchelli and G. Zangrilli also prepared **ammonium hydrophosphatodimolybdate,** $(NH_4)_2H[PO_2(MoO_4)_2].2H_2O$, and the *hemipentahydrate.* F. Ephraim and M. Brand reported lithium **phosphatodimolybdate,** $5Li_2O(P_2O_5.4MoO_3)_2.28H_2O$, to be formed in white needles, from a boiling soln. of 25 grms. of lithium phosphate and 77 grms. of molybdic acid. The salt loses 16 mols. of water at 100°, 18 mols. at 120°, 23 mols. at 145°, and the remainder at a red-heat. H. Perlberger obtained **copper phosphatodimolybdate,** $2CuO.P_2O_5.4MoO_3.19$ or $20H_2O$, by the action of a soln. of molybdic acid and copper oxide on phosphoric acid. A. Arnfeld prepared **cobalt hydrophosphatodimolybdate,** $CoH[PO_2(MoO_4)_2].nH_2O$, as a brown amorphous precipitate, by heating in a sealed tube a mixture of a mol of ammonium phosphatohemipentamolybdate, 3 mols of cobaltous chloride and 25 c.c. of water, and likewise also a green precipitate of **nickel hydrophosphatodimolybdate,** $NiH[PO_2(MoO_4)_2].nH_2O$.

C. Friedheim obtained the potassium salt of **phosphatomolybdic acid,** $H_3[PO_3(MoO_4)].nH_2O$, namely potassium phosphatomolybdate, $KH_2[PO_3(MoO_4)].11H_2O$, from a soln. of a mol of **potassium dihydrophosphatomolybdate,** and a mol of molybdenum trioxide. The salt may be constituted $(HO)_2$–PO–$KMoO_4$. J. Meschoirer also obtained **ammonium dihydrophosphatomolybdate,** $(NH_4)H_2[PO_3(MoO_4)]$.

F. Ephraim and H. Herschfinkel found that the evaporation of the mother-liquid obtained in the preparation of rubidium phosphatotetritaenneamolybdate furnishes *rubidium phosphatohexitadecamolybdate,* $7Rb_2O.3P_2O_5.10MoO_3.15\frac{1}{2}H_2O$.

M. Seligsohn reported *ammonium lead phosphatopentadecamolybdate,* $3(NH_4)_2O.30PbO.P_2O_5.30MoO_3$, to be formed by boiling the lead phosphate with an excess of a soln. of lead acetate. It is a white powder. W. Bodenbinder reported a *calcium lead phosphatomolybdate* to occur in plates, resembling wulfenite, in the plumbocalcite of San Luis, Argentine. Its sp. gr. is over 7.

O. W. Gibbs obtained orange-yellow crystals of *platinum phosphatomolybdate* by dissolving platinic hydroxide in a boiling soln. of sodium phosphatododecamolybdate and evaporating the filtered liquid.

Owing to the ready hydrolysis of pyrophosphoric acid in aq. soln. to form orthophosphoric acid, it is not possible to obtain ammonium and potassium pyrophosphates of a high degree of purity in aq. soln. A. Rosenheim and T. Triantaphyllides prepared **sodium molybdic pyrophosphate,** $Na(MoP_2O_7).12H_2O$, in brown prisms, by adding a soln. of tripotassium molybdic hexachloride to a soln. of sodium pyrophosphate at 80° to 90°. A. Rosenheim and M. Schapiro tried to prepare potassium and ammonium pyrophosphatomolybdates by the use of pyrophosphates instead of the orthophosphates, but the results were unsatisfactory. The products were probably mixtures of ordinary phosphatododecamolybdates with the pyrophosphatomolybdates. By heating a soln. of 12 mols of lithium molybdate, and adding a mol of lithium pyrophosphate, a pale yellow, microcrystalline precipitate of **lithium pyrophosphatododecamolybdate,** $2Li_2O.P_2O_5.12MoO_3.17H_2O$, is produced. The salt forms a yellow soln. with water, and the soln. is decolorized by mineral acids owing to the hydrolysis of the pyrophosphate. A. Rosenheim and M. Schapiro added that *es ist nicht unwahrscheinlich* that the compound is the same as F. Ephraim and M. Brand's $3Li_2O.P_2O_5.12MoO_3.18H_2O$. A boiling soln. of 12 mols of normal sodium molybdate and a mol of sodium pyrophosphate with 24 mols of hydrochloric acid, when cooled deposits pale yellow, microscopic plates of **sodium pyrophosphatododecamolybdate,** $2Na_2O.P_2O_5.12MoO_3.26H_2O$. The yellow, aq. soln. becomes colourless in the presence of hydrochloric acid owing to the hydrolysis of the pyrophosphate to orthophosphate.

According to O. W. Gibbs, if the orange precipitate which ammonia produces in a soln. of sodium gold pyrophosphate be boiled with a soln. of ammonium molybdate, pale yellow *ammonium gold amminophosphatomolybdate,* $24NH_3.12Au_2O_3.7P_2O_5.3MoO_3.21H_2O$, is formed. It explodes when heated. A dark orange-red, crystalline precipitate is produced when a soln. of sodium gold chloride is treated with sodium pyrophosphatomolybdate; and if the precipitate be boiled with a soln. of ammonium molybdate, orange-red crystals of *sodium gold amminophosphatomolybdate,* $Na_2O.5Au_2O_3.15NH_3.2P_2O_5.11MoO_3.10H_2O$, are formed. The salt explodes when heated; it forms a turbid liquid with hot water; and dissolves in hot hydrochloric acid. A soln. of sodium gold pyrophosphate, $AuNaP_2O_7$, boiled with ammonium molybdate gave a buff precipitate of *ammonium sodium gold pyrophosphatohemihenamolybdate,* $15(NH_4)_2O.Na_2O.6Au_2O_3.4P_2O_5.22MoO_3.5H_2O$. It does not explode when heated.

O. W. Gibbs described *ammonium manganous pyrophosphatomolybdate,* $5(NH_4)_2O.10MnO.2P_2O_5.20MoO_3.10H_2O$, as a reddish-yellow, sparingly soluble precipitate, formed by digesting manganous pyrophosphate for some time with a conc. soln. of ammonium paramolybdate. Likewise also *sodium manganous pyrophosphatomolybdate,* $9Na_2O.7MnO.2P_2O_5.22MoO_3.57H_2O$, by the action of manganous chloride on a boiling soln. of sodium pyrophosphate and molybdenum trioxide. The pale red, amorphous precipitate becomes crystalline when allowed to stand under its mother-liquor. When crystallized from hot water, it forms sulphur-yellow crystals. It is sparingly soluble in cold water, and fairly soluble in hot water.

G. Denigès [3] obtained sapphire-blue, hexagonal plates of a **molybdosic phosphate,** $[4MoO_3.MoO_2]_2H_3PO_4.4H_2O$, from a soln. of sodium molybdate and sodium hydrophosphate. A. Verda said that the product is obtained only when tin or aluminium is present, and that the blue product is soluble in ether.

CHAPTER LXII

TUNGSTEN

§ 1. The History of Tungsten

THE history of tungsten is closely associated with a mineral which was thought to contain tin, presumably because of its density. Thus, J. G. Wallerius [1] called the mineral from Bohemia *lapides stanniferi spathacei;* C. von Linnæus, *stannum spathosum subdiaphanum album;* and A. F. Cronstedt, *ferrum calciforme, terra quadam incognita intime mixtum.* In Sweden, the mineral was called tungsten—from the Swedish *tung*, heavy or ponderous; and *sten*, stone—and A. G. Werner called it *Schwerstein.*

G. Agricola also referred to another brownish-black mineral which he called *lupi spuma*, or *lapis niger ex quo conflatur candidum plumbum* (tin); J. G. Wallerius called it *volfram*, and regarded it as *ferrum arsenico mineralisatum;* while A. F. Cronstedt called it *wolfram*, and added that it contains *magnesia* (*i.e.* Mn) *parva cum portione martis et jovis mixta.* It was also called *lupis jovis* in allusion to its weight. R. J. Haüy called the mineral *scheelin ferruginê;* and A. Breithaupt, **wolframite,** the name which it now bears. This mineral was described by L. Ercker, P. Albinus, A. von Schönberg, B. Rossler, J. A. Cramer, J. F. Henckel, S. Rinman, etc. G. Agricola suggested that the term wolfram comes from the German word " wolf," and " *ram* " or *rahm*, froth; hence his Latin term *lupi spuma* for wolfram. Others deny this derivation and say that the term is of unknown origin. According to A. Gurlt, and W. Pryce, the tin miners of Saxony and Bohemia called it *wolf, wolfart, wolfort, wolfrig*, and *wolffert* (A. von Schönberg), *i.e.* the *wolfish* or *devouring ore*, in allusion—as stated by A. Rössing, and others—to the low yield of tin obtained from tin ores associated with this mineral. The ore was also called *woolfram* (J. A. Cramer), and *wolferam* (L. Ercker). *Lupus*, or *wolf*, was one of the alchemist's terms for antimony (*q.v.*); and G. Agricola's term *lupus spuma* is now understood to mean that the mineral was mistaken for an antimony ore. The *spuma* is probably an allusion to the scum formed when, say, gold is purified by melting it with antimony. According to T. Blair, the termination *ram* has a similar signification to that of *spuma*—a term applied by the Germans to substances with a laminated structure. I. Koppel discussed the history of tungsten. The tin miners of Cornwall regarded it as an obnoxious ore because " it eats up tin as a wolf eats up sheep," and they named it *cal* or *call* or *mock-lead.* W. Pryce said:

> In Cornwall, after the tin is separated from all other impurities, there remains a quantity of this mineral substance, *cal*, which, being of equal gravity, cannot be separated from the tin ore by water; therefore this reduces its value down to eight or nine parts of metal for twenty of mineral.

J. F. Henckel said that wolfram is an arsenical and ferruginous ore of tin. J. G. Wallerius, and A. Cronstedt regarded it as a kind of manganese ore containing tin and iron; J. H. G. von Justi, an ore containing iron, arsenic, tin, and an earth which is not metallic—and, added J. W. Baumer, sulphur and calcareous earth; G. A. Scopoli, an ore of tin yielding 28 lbs. per hundredweight; B. G. Sage, a combination of iron and basalt; and J. G. Lehmann, a vitrifiable or glassy earth containing iron and a small proportion of tin. J. G. Kaim supposed wolfram to contain a semi-metal; but the regulus he described is unlike that which is now known to be derived from that ore.

In 1781, C. W. Scheele, in his memoir: *Tungstens beständs-delar*, showed that tungsten ore (scheelite) is a compound of lime with a peculiar acid. He fused the ore with potassium carbonate, dissolved the mass in water, and added nitric acid. The white precipitate was washed and dried. He then showed that the product is the acid of tungsten—a metallic acid in which the metal is reduced by phlogiston to a metallic calx. He demonstrated the other component of the ore to be lime. Hence, the mineral is a calcium tungstate. D. L. G. Karsten then called the mineral *scheelerz;* R. J. Haüy, *scheelin calcaire;* A. Breithaupt, *scheelspath;* and C. C. Leonhard, **scheelite,** the name which the mineral now bears.

T. Bergman said that the acid of tungsten in *lapis ponderosus* is the calx of a metal which has a high sp. gr.; it is precipitated by potassium ferrocyanide, and colours glass. J. J. and F. de Elhuyar, in their *Análisis quimico del volfram y exámen de un nuovo metal que entra en su composicion* (Bascongada, 1783), showed that the mineral wolfram contains the same acid as tungsten ore, but in wolfram, the acid is associated with iron and manganese instead of lime. These chemists obtained the metal by reducing the oxide with carbon; and they described alloys of tungsten with gold, silver, lead, and iron. The question has been raised: Were the Spanish chemists the first to isolate the metal? Actually one at least of the brothers de Elhuyar worked under the direction of C. W. Scheele, and T. Bergman for some years, and, in their memoir, the two brothers—perhaps modestly—made no claim to having been the discoverers of the metal—because, according to J. J. Runner and M. L. Hartmann, C. W. Scheele had probably already prepared the metal. S. Rinman definitely ascribed the discovery of the metal to C. W. Scheele, and stated that its alloy with iron was prepared by J. J. and F. de Elhuyar. In spite of these and similar statements, the fact remains that the first published account of the isolation of the element is that of the Spaniards, J. J. and F. de Elhuyar. In 1785, R. E. Raspe referred to a Cornish mineral, which, when treated with a soln. of stannous chloride gave a blue coloration; and he added that he succeeded in obtaining from it a regulus in the proportion of 36·5 to 37·3 per cent. This regulus was said "to contain very little iron; to be most refractory in the fire; and to cut glass like the most highly tempered steel. It will therefore perhaps be useful in hardening iron and steel for some classes of work." The name J. J. and F. de Elhuyar, by the way, appears in literature spelt in many ways. According to R. A. Hadfield, on the authority of the Royal Library, Madrid, the spelling is "de Elhuyar," not d'Elhujar, etc. J. J. and F. de Elhuyar called the elemental metal *wolfram* or tungsten. The metal came to be called *scheelium,* and J. J. Berzelius suggested *wolframium* because "C. W. Scheele had already immortalized his name by other great discoveries to such an extent as to preclude the necessity of its being handed down to posterity by the denomination of a substance." The term *wolfram* is used for the metal in Germany; *tungsten* in England; and *tungstène* in France. The symbol W is in fairly general use, although in France and Italy Tu is sometimes employed. E. Moles [2] argued in favour of the term wolfram. The metal was also prepared by reducing the oxide by carbon by A. Ruprecht, L. N. Vauquelin and L. Hecht, W. Allen and A. Aiken, C. F. Bucholz, and J. J. Berzelius.

M. Gerber [3] stated that tungsten is not a simple substance but is accompanied by another element to which he gave the name *neotungsten,* and the latter is estimated to have the at. wt. 188. He said that soluble metatungstic acid furnishes ammonium isotungstate, described by A. Laurent. In the isotungstic acid prepared from this salt, the metal had an at. wt. ranging from 186·5 to 187—ordinary tungsten has the at. wt. 184. It is assumed that the isotungstic acid contained neotungsten. These statements have not been confirmed—*vide* neomolybdenum—P. Barbe could find no evidence of the existence of isotungstates, and never obtained a specimen with a mol. wt. higher than usual. He said that the ammonium isotungstate of M. Gerber was ammonium sodium tungstate.

There are a few books, monographs, and memoirs on the general properties, etc., of tungsten—*e.g.*

§ 2. The Occurrence of Tungsten

Tungsten does not occur in the elemental form in nature. Its compounds are among the scarcer constituents of the earth's crust. According to F. W. Clarke and H. S. Washington,[1] the average proportion of tungsten in the igneous rocks of the earth's crust is 5×10^{-5} per cent. J. H. L. Vogt estimated $n \times 10^{-8}$ per cent. W. Vernadsky gave 0·000048 for the percentage amount, and 0·0005 for the atomic proportion. W. and J. Noddack and O. Berg gave 5×10^7 for the absolute abundance of molybdenum in the earth. The general subject was discussed by H. S. Washington, G. Tammann, V. M. Goldschmidt, E. Herlinger, A. von Antropoff, O. Hahn, R. A. Sonder, and J. Joly. H. A. Rowland,[2] and M. N. Saha classed tungsten with the elements whose presence in the sun is doubtful.

The more important tungsten minerals are the wolfram group consisting of iron and manganese tungstates, and the scheelite group consisting of calcium tungstate. They occur irregularly and the lodes are more or less sporadic. The genesis of the ores has been discussed by R. H. Rastall.[3] The ores can be divided into primary and secondary. The primary group includes occurrences in lodes, veins, dykes, and contact deposits; while the secondary group includes alluvial and residual deposits. The primary ores are generally associated with granites, and are often accompanied by tin. The tungsten appears to have been concentrated in the later stages of the solidification of the granite magma to the margin of the intrusion. The wolfram is normally disseminated in the granite, or concentrated in pegmatites, dykes, and quartz veins of direct igneous origin. It also occurs in the country rock adjoining the veins; and some lodes are zones of rock impregnated with ores derived from vapours or solutions passing through cracks due to contraction or faulting. The tungsten in this respect resembles tin, but the tungsten zone has been carried further than the tin. Vapours escaping from the hot interior coming in contact with calcareous rocks formed contact deposits of scheelite. The secondary deposits of tungsten show that in some cases the ore has decomposed, while in other cases the tungsten has resisted weathering influences and accumulated in detrital deposits like tinstone, gold, and platinum.

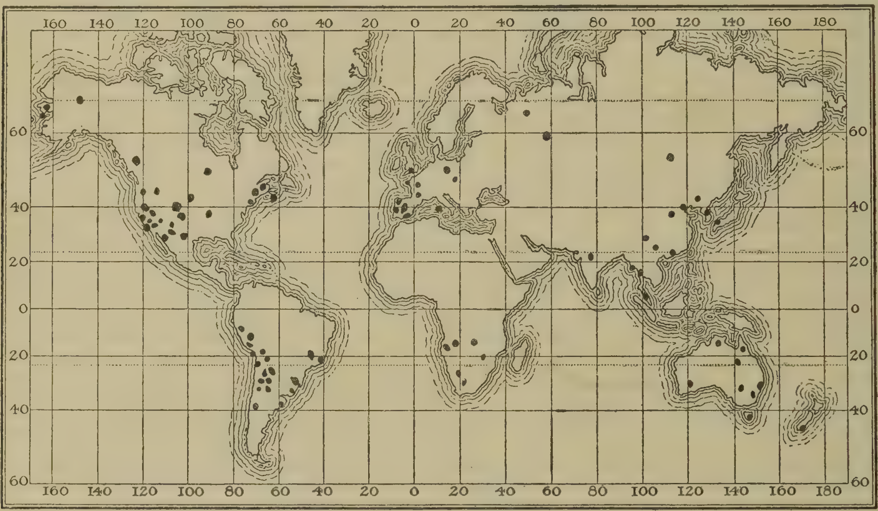

Fig. 1.—The Geographical Distribution of Tungsten Ores.

The geographical distribution of tungsten ores is illustrated by Fig. 1. The main localities are as follow:

Europe.—Nearly all the tungsten ores of the **British Isles**[4] are obtained from Cornwall and the neighbouring parts of Devonshire. The districts are Land's End; Camborne and Redruth; St. Austell; Bodmin Moor; and Callington and Tavistock. The tungsten ore occurring at Carrock Fell, Cumberland, was described by A. M. Finlayson. In **France,**[5] tungsten ores are found in Brittany—at Montbelleux, and Villeray; at Puy-les-Vignes, Haute Vienne; near Chanteloube, Mazataud, and Chabanne; at Meymac; Charente, Saône et Loir, Nievre, and Allier; Framont, Vosges; and St. Lary, Hautes Pyrénées. In **Spain,**[6] there are deposits near Lousame and Cabana, Corunna, Carbia, Pontevedra; Silleda; Zamora; Barrvecotardo, Salamanca; Caceres; Badajos near Jerez de los

Caballeros; Valle de la Serrana; Cordoba and Jaen—Conquista, Malaga, and Paterna. Most of the Spanish output comes from Badajos. In **Portugal,**[7] the northern half of the country is the largest producer of wolfram ores in Europe. There are deposits at Borralha, Serra das Alturas; Braganca, Iffanes, Para, Paradinha, Válle de Seixo, Coelhoso, Mirandella, Miranda do Douro, Sierra da Estrella, Serra de las Mesas; Panasqueira, Silvares; Fundas, Sabugal, Matta da Reinha, Pinhel, Sac Cosmado, Moirmenta, Paredes, Arouca, Capela do Senhor dos Alfitos; Vizeu, and Serra da Estralla. In **Italy,**[8] scheelite occurs in Cagliari, Sardinia, and at Suergiu, and Genna-Gureu. In **Switzerland,**[9] it occurs at Etzlithal. In **Austria-Hungary,** and **Bohemia,**[10] deposits occur near Graupen, Bohemia, and this is a continuation of the Zinnwald-Altenberg field. Deposits also occur at Felsöbanya. In **Russia,**[11] a few deposits of tungsten ore are known—*e.g.* at Baevka, Perm; Nerchinsk, Siberia; and at Pitkäranta, Finland. In **Germany,**[12] wolfram occurs in the tin district of the Erzgebirge, Saxony; Altenberg, and Zinnwald, Saxony; Annaberg, Johanngeorgenstadt, Eibenstock, Neudorf, Tirpersdorf, and Schmiedelfeld. In **Sweden,**[13] a few deposits have been reported, and so also in **Greenland.**[14]

Asia.—In **India,**[15] wolfram occurs at Argagon, Nagpur; Hazaribagh, Bengal; and Degana, Marwar. In **Burma,**[16] a considerable amount of ore is produced in the Tavoy district, Tenasserim; and there are deposits in the Southern Shan States; and in the Thaton district, Lower Burma. In the **Malay States,**[17] and the Straits Settlements extending into the Dutch territory Banka and Billiton, the chief producing states are Perak, Selangor, Negri Sembilan, Pahang, Kedah, and Trengganu. In **Siam,**[18] ore is mined in Nakawn Sritamarat, Trang, and Lacon; and also at Tonkin.

In **Japan,**[19] there are mines in Yamaguchi Ken, Ibaraki Ken, Corea, and Chin Chow, Manchuria. In **China,**[20] tungsten is obtained from the alluvial deposits in the districts of Kwantung, Hunan, and Hong Kong—Haifeng, Lufeng, Puning, Kityang, Wuhua, and Waichow.

Africa.—Tungsten minerals have been reported from the **Union of South Africa**[21]—*e.g.* at Knils River, Cape Province; the tin fields of Waterberg, and Stavoren, and near Leydsdorp. In **South-West Africa,**[22] there are deposits near Little Karas; Ubib, and Goages in Swakopmund; and in the Erongo Mountains. In **Rhodesia,** there are deposits in numerous localities from Wankie to Umtali, and from Lomagundi to the Limpopo river, Lusoakas, Northern Rhodesia; and at Essexvale, Umzingwane.

Northern America.—In **Canada,**[23] there are tungsten ores in Nova Scotia—Stillwater Brook, Halifax; in New Brunswick—Burnt Hill Brook; in Manitoba—Falcon Lake district in British Columbia—Black Prince Group; near Barkerville and in the Kootenay; and near Mayo, Yukon Territory. In the **United States,** the tungsten ores are mainly confined to the Cordilleran region in the west; and in all the Western States with the exception of Wyoming, but more particularly in the Atolia-Randsburg district of California, and about Bouder in Colorado. There are deposits in Alaska,[24] Arizona,[25] California,[26] Colorado,[27] Connecticut,[28] Idaho,[29] Missouri,[30] Montana,[31] Nevada,[32] New Mexico,[33] North Carolina,[34] Oregon,[35] Pennsylvania,[36] South Dakota,[37] Texas,[38] Utah,[39] and Washington.[40] Tungsten has been reported in **Mexico**[41] near Sonora and Durango.

South America.—In **Argentina,**[42] tungsten deposits are mainly confined to the Pampa range—Cajon, Gualapaji, Amboti, Incasti, Colorados, Mazan, Guasapampa, Quines, San Ramon, Pantana, San Ignacio, El Morro, Los Condores, Pisco Yacu, and Cumbre. In **Peru,**[43] the deposits are mainly situated in the department of Ancachs and Libertad on the Pelagatos and Tamboras Mountains. There are deposits in the department of Tayabama; and near Lircay, Huancavelica. In **Chile,**[44] there are deposits in Tacna. In **Bolivia,**[45] there are deposits on the Cordillera Real, and Eastern Cordillera. In **Brazil**[46] deposits occur at Encruzilhada, Rio Grande do Sal; and also in the States of Espirito, Santo, and Minas Geraes.

Australasia.—There are deposits in **Queensland**[47] at Mount Carbine, Wolfram and Bamford. In **New South Wales** they occur in the north-eastern portion and in the west near Broken Hill. There are also the Hill Grove scheelite deposits. In **Victoria,** tungsten is found near Benambra, and near Baragwanatti; at Maldon, and Koetong; in **Tasmania,** near Constable's Creek, Upper Scamander, Gipp's Creek, Storey's Creek, and Moina. Scheelite also occurs on King Island. In **South Australia,** tungsten occurs near Normanville; in **Northern Territory,** in the Pine Creek district, Brock's Wolfram Mine, and Hatches Creek; in **Western Australia,** in the Yalgoo and Murchison fields; and in **New Zealand,**[48] scheelite occurs in the Otago gold-fields, Glenorchy, and Macrae's Flat. Wolfram is reported from Stewart's Island, and the western parts of Nelson.

The valuation of tungsten ores is based on the percentage amount of tungsten trioxide in the conc. ore—65 per cent. is adopted as a standard in Great Britain, while 60 per cent. is preferred in the United States. If the percentage is below the standard, the selling price is penalized. An excessive proportion of phosphorus or arsenic reduces the value of the ore. Before the war, the price was 25*s.* to 35*s.* per unit. In 1915, it was 55*s.* per unit; and in 1918, the price was raised to 60*s.*

with special allowances for losses on high freights and on exchange. The price of chromite ore in 1924 ranged from 86*s*. 3*d*. to 90*s*. 0*d*. per ton. R. H. Rastall and W. H Wilcockson[49] estimated for 1910–1917 the proportion of metal in metric tons in the concentrates produced by different countries to be approximately as follows:

	1910	1913	1917	1924	1929
United Kingdom	278	785	245	2	135
Burma	402	1715	4553	813	2200
Malay States	—	324	1200	430	175
New South Wales	321	173	249	3	68
Queensland	908	549	502	1	45
Tasmania	68	69	245	60	380
New Zealand	145	225	164	3	25
Germany, Austria	60	150	250	83	120
France	30	245	225	—	14
Spain	153	150	800	200	350
Portugal	948	800	1596	400	700
Japan	250	297	1500	10	283
China	—	—	1200	3500	6500
French Indo-China	—	—	—	494	238
Siam	—	281	634	10	35
United States	1652	1395	5006	512	2300
Argentina	1912	539	1000	132	120
Bolivia	207	569	1650	18	585
Peru	12	300	1000	—	100
Mexico	—	—	—	25	45

The tungsten minerals include the wolframite series which, according to F. L. Hess,[50] comprises **ferberite** containing 80 to 100 per cent. $FeWO_4$, and 0 to 20 per cent. $MnWO_4$; **wolframite** with 20 to 80 per cent. $FeWO_4$ and 20 to 80 per cent. of $MnWO_4$; and **hübnerite** with 0 to 20 per cent. $FeWO_4$ and 80 to 100 per cent. $MnWo_4$; **reinite,** $FeWO_4$; there are also **scheelite,** $CaWO_4$; **powellite,** $Ca(Mo,W)O_4$; **stolzite**—tetragonal $PbWO_4$, and **raspite**—monoclinic $PbWO_4$; **chillagite,** a mixture of lead tungstate and molybdate; **cuproscheelite,** or **cuprotungstite,** $CuWO_4.2H_2O$; **tungstite,** or **tungsten ochre,** $WO_3.H_2O$; **ferritungstite,** $Fe_2O_3.WO_3.6H_2O$; and **tungstenite,** WS_2.

H. St. C. Deville[51] found small quantities associated with tantalic acid. F. Zambonini found it in vesbine in crevices in the Vesuvian lava of 1631. M. Mazade detected its presence in the mineral waters of Nérac.

§ 3. The Extraction of Tungsten Trioxide

The products usually obtained from tungsten ores are (i) compounds, like tungsten trioxide or tungstates, employed in the arts as pigments, mordants, etc. ; (ii) crude tungsten, usually pulverulent, employed for making ferrotungsten, and other alloys ; and (iii) purified metal in the form of sheet, rod, or wire, for use in lamps, X-ray tubes, thermionic valves, etc. The mining of tungsten ores does not present any peculiarities different from those used in mining other ores of a similar nature. The ore as mined is commonly associated with tinstone. The milling and concentration [1] of wolfram ore may involve the use of a magnetic separator since wolfram is fairly magnetic in virtue of the contained iron, while tinstone is virtually non-magnetic. A separation with less than one per cent. of tin oxide with the wolframite is rarely possible. Scheelite is not usually magnetic, but it is not commonly found associated with tinstone. When tinstone is present, a chemical process is required for the separation. The average amount of tungsten trioxide in the concentrate is about 65 per cent.

Scheelite is easily decomposed by heating it with conc. hydrochloric or nitric acid whereby calcium chloride or nitrate is formed, and hydrated tungsten trioxide. The latter can be purified by dissolving the hydrate in a soln. of ammonium carbonate and ammonia, as indicated below. This process was used by A. E. Nordenskjöld.[2] According to G. Gin, scheelite may be fused in a reverberatory furnace with potassium fluoride so as to form soluble potassium tungstate and insoluble calcium fluoride. The soln. of the tungstate is then decomposed by acid in the usual manner. P. Schwarzkopf heated the ore in air to form tungsten trioxide, and when oxidation was complete, he sublimed the trioxide in a current of air.

The extraction of tungsten trioxide by treating wolframite with acids.[3]—The finely-powdered mineral is digested with conc. hydrochloric acid, renewing the acid from time to time, and adding a little nitric acid towards the end of the operation, so as to oxidize and dissolve the iron as a ferric salt. The operation is continued until the ferric and manganic oxides have passed into soln., and the brown residue is changed to a yellow colour. The undissolved residue consists of hydrated tungsten trioxide, undissolved wolframite, and silica; it is then well-washed, and shaken up with aq. ammonia. The hydrated tungsten trioxide passes into soln.; and on evaporating the filtered soln., crystals of ammonium tungstate are formed. The ammonium salt is then ignited in air to form tungsten trioxide. Modifications of the process were described by J. B. von Borck, J. B. A. Dumas, B. Franz, W. Lotz, J. C. G. de Marignac, J. Persoz, J. Philipp, A. Riche, E. R. Schneider, and E. Zettnow. The product is of inferior purity. If desired, the small proportion of columbium and tantalum can be removed by treating the product with ammonium sulphide which dissolves only the tungsten trioxide. The soln. is acidified with hydrochloric acid to precipitate hydrated tungsten trioxide. This is washed, dried, and ignited. In another process, the finely-divided ore is digested with 50 per cent. sulphuric acid, heated by superheated steam in lead pipes immersed in the liquid. In 3 hrs. the liquid containing iron and manganese is decanted off, and the extraction repeated 2 or 3 times with 30 per cent. sulphuric acid. The residue is mixed with 20 per cent. sodium chloride and half this weight of sodium nitrate, and enough sulphuric acid added to evolve hydrogen chloride and nitrous fumes. This is repeated 2 or 3 times to oxidize the remaining iron and manganese. The hydrated tungsten trioxide mixed with any insoluble matter, like silica, remains as a sludge. It is washed and dried. The iron and manganese sulphates are recovered by evaporating the acid liquors. L. Weiss discussed the opening of wolframite by treatment with conc. hydrochloric, hydrofluoric, sulphuric or nitric acid, or with aqua regia. K. Anjow used dil. sulphuric acid at 180° under press. for opening up the finely-divided ore.

The extraction of tungsten trioxide by heating wolframite with fluxes.—J. B. Richter,[4] and J. B. von Borck fused the wolframite with four times its weight of potassium nitrate—or a mixture of sodium carbonate and potassium nitrate, or a mixture of sodium and potassium carbonates—extracted the cold product with water; precipitated calcium tungstate from the filtrate by the addition of calcium chloride; decomposed the washed calcium salt with nitric acid; and washed the hydrated tungsten trioxide with water. E. F. Anthon boiled the soln. of potassium tungstate for a quarter of an hour with an excess of hydrochloric acid, dissolved the washed hydrated tungsten trioxide in aq. ammonia; and evaporated the soln. for ammonium tungstate. C. F. Bucholz, and J. J. Berzelius fused the wolframite with twice its weight of potassium carbonate; B. Franz, and J. Philipp used 150 parts of ore, 100 parts of sodium carbonate, and 15 parts of potassium nitrate; L. Mayer, and G. C. Wittstein used one part of wolframite, one of potassium nitrate, and 2 parts of potassium carbonate; C. Scheibler, and E. Zettnow used 33 to 50 per cent. of sodium carbonate; W. B. Stoddard and I. Hochstadter used a mixture of ore, charcoal, and sodium nitrate; R. W. Stimson, alkali nitrate; and A. Riche used 17 parts of sodium carbonate with 10 parts of wolframite. The processes in use are more or less modified forms of R. Oxland's process in which the ore is first fused with sodium carbonate, and the sodium tungstate extracted by leaching with water. Modifications were described by F. A. Bernoulli, K. Christl, G. Bessa, A. K. Huntington, R. Derenbach, etc.

C. H. Jones, describing the process in use in North Chicago, said that the hand-picked ore is crushed and ground to a coarse powder; and mixed with soda-ash in a ball-mill so as to pass 100's lawn—one part each of tungsten trioxide and sodium carbonate plus a 15 per cent. excess of the latter. About 150 kgrms. of the mixture are charged into a reverberatory furnace and raked by hand for a couple of hours while the temp. is kept at about 800°. This allows a free access of air to oxidize the iron and manganese respectively to Fe_2O_3 and Mn_3O_4. The product is removed from the furnace, cooled, and crushed; and the sodium tungstate extracted by leaching with water. The clear liquor is heated by a jet of live steam, and a soln. of calcium chloride is added to precipitate calcium tungstate. This is washed by decantation, and then treated with hydrochloric acid. The yellow precipitate is washed by means of a suction pump; and dried. Its composition approximates: H_2WO_4, 99·53; FeO, 0·02; Al_2O_3, 0·05; CaO, 0·20; and SiO_2, 0·20 per cent. J. B. Ekeley and W. B. Stoddard added sodium chloride to the fusion mixture to hasten the reaction. It is then necessary to add a little sodium nitrate or chlorate as oxidizing agent. The General Electric Co., and N. T. Gordon and A. F. Spring used a continuous process.

F. Wöhler melted one part of wolframite with 2 parts of calcium chloride for an hour, and extracted the cold, powdered mass with boiling water; the chlorides of calcium, manganese, and iron passed into soln. The residual calcium tungstate was treated with conc. hydrochloric acid; the washed residue was dissolved in aq. ammonia, and the soln. evaporated for ammonium tungstate; the product was heated to redness for tungsten trioxide. F. Jean mixed powdered wolframite with 3 per cent. of calcium carbonate and 20 to 30 per cent. of sodium chloride, and heated the mixture for half an hour to dull redness. When the mixture is cold, it is pulverized, and then boiled for a quarter of an hour with hydrochloric acid, which dissolves the lime, and the oxides of iron and manganese, with the disengagement of chlorine, leaving the whole of the tungstic acid in the insoluble state as a lemon-yellow crystalline powder, which is purified by washing with acid. With calcium carbonate, without sodium chloride, it was found impossible to decompose the wolframite completely; but with about 20 per cent. of pure lime, the decomposition was easily effected at a dull red-heat. Sulphates, alkaline carbonates, or calcium chloride may replace the sodium chloride. L. Weiss compared the result obtained by opening up the wolframite by heating it with ammonium fluoride; sodium hydroxide; calcium carbonate—alone or mixed with calcium or sodium chloride; with calcium chloride; or with magnesium compounds. He recommended fusing a mixture of 4 parts of wolframite with one part of each of calcium carbonate and chloride, and decomposing the product with an acid. If magnesium carbonate be employed, the product contains red crystals of magnesium tungstate which are not decomposed by acids. G. Gin heated a mixture of wolframite and magnesium chloride on the hearth of a reverberatory furnace and found that the manganese and iron are volatilized as chlorides. The aq. extract of the cold mass furnishes a soln. from which, on evaporation, crystals of magnesium tungstate can be obtained. This salt is decomposed by hot, conc. hydrochloric acid leaving insoluble hydrated tungsten trioxide.

When tin is present in appreciable quantities, G. Gin recommended fusing the ore mixed with potassium hydrosulphate in a furnace with the hearth made of silica agglomerated with pitch. The mixture is stirred and run from the furnace. The cold, powdered mass is digested with water—soluble sulphates pass into soln., and an insoluble acid potassium tungstate remains along with silica, stannic oxide, and insoluble sulphates. The dried mass is treated with a warm soln. of ammonium carbonate when the potassium tungstate passes into soln., whilst the stannic oxide, sulphates, and silica remain. The evaporation of the soln. furnishes ammonium tungstate which is converted into tungsten trioxide by ignition. The ammoniacal soln. can be treated with hydrogen sulphide, and ammonium sulphotungstate is deposited in orange-red crystals which, on ignition and roasting, pass into tungsten trisulphide and then to the trioxide. The Elektrochemische Fabrik used sodium hydrosulphate with an excess of sulphuric acid in place of potassium hydrosulphate. The aq. extract contains soluble metal sulphates and sodium tungstate. The metals can be precipitated by electrolysis; and the sodium sulphate crystallized out. Hydrochloric acid then precipitates hydrated tungsten trioxide. H. Brandenburg and A. Weyland, and F. E. Clotten employed a modification of the hydrosulphate fusion process.

The extraction of tungsten trioxide from wolframite by alkali-lye.—Tungsten trioxide can be extracted from wolframite by treatment with conc. soda-lye or potash-lye. The tungsten can be recovered from the liquor by crystallization, by precipitation with acid, or precipitation as calcium tungstate, etc. E. K. Jenckes recommended the process. G. A. Hempel carried out the extraction in an autoclave under press. by mixture of alkali-lye with enough lime to ensure the precipitation of silica and tin, but not enough to precipitate calcium tungstate. The tungsten trioxide is recovered in the usual way. W. B. Gero and C. V. Iredell digested in boiling soda-lye ground wolframite concentrates and added calcium chloride to the resulting soln., whilst the resulting calcium tungstate was digested with boiling hydrochloric acid, and the tungstic acid converted into ammonium paratungstate. The latter was ignited for tungstic oxide. L. Weiss discussed the results obtained by extraction with alkali-lye.

The extraction of tungsten trioxide from wolframite by volatilization as chloride.—The processes based on the volatility of the chloride are not practicable with low-grade ores unless other metals—*e.g.* tin—can be recovered at the same time. In W. H. Dyson and L. Aitchison's process, the wolframite is heated to 600° in a current of equal vols. of chlorine and hydrogen chloride to remove the tin ; and the temp. is then raised to 900° to distil off the iron, manganese, and tungsten chlorides. The distillate is collected in water so as to precipitate the hydrated tungsten trioxide. O. J. Stannard mixed the crushed ore with carbonaceous material, and heated the mixture to redness. The product is then heated at about 300° in a current of chlorine gas, free, or almost free, from air. The volatilized or sublimed mass which results is treated with hot water, with or without the addition of nitric or hydrochloric acid. For the recovery of stannic chloride from wolfram ores the sublimate is heated with hot water and hydrochloric acid, and the resulting soln. of stannic chloride is separated from the precipitated tungstic acid. The process may be made cyclic by heating the mixture of chlorides obtained in a current of dry air and using the chlorine thus recovered for the treatment of further quantities of ore. In a volatilization process devised by P. Jannasch and R. Leiste, the ore is heated in a current of the vapour of carbon tetrachloride, and the tungsten chlorides distilling over are decomposed by mineral acids. F. L. Hahn and W. Franke heated the tungstate with carbon tetrachloride under press. at 250° to 300°, and extracted the mass with acid.

The extraction of tungsten trioxide from wolframite by electrolysis.—R. E. Pearson and co-workers suggested the following process, but it has not been developed industrially. The tungsten ore, or waste-products containing that element are mixed with carbonaceous matter, and ground and mixed to a paste with sulphuric acid, and the mixture is placed on a lead plate which forms the anode of an electrolytic cell containing dil. sulphuric acid. On passing a current through the cell the basic impurities, *e.g.*, iron, manganese, calcium or sodium oxides, in the material on the anode pass into soln., leaving a residue of tungsten or molybdenum oxides. Alternatively the anode may consist of nickel or a nickel alloy, and the electrolyte of caustic soda, whereby soluble sodium tungstate or molybdate is formed and the foreign metals are left as anode slime.

The purification of tungsten trioxide.—The crude tungsten trioxide or sodium tungstate, prepared by these methods, may contain up to 2 per cent. of impurities, the nature of which depends on the ore and the method of extraction. The more common impurities are silica and oxides or salts of iron, manganese, calcium, titanium, tin, and molybdenum. The purity of the metal finally obtained depends largely on the purity of the oxide from which it is reduced. Ductile tungsten, and the tungsten employed for lamp filaments, and thermionic valves must be of a high degree of purity. Tungsten with 0·1 per cent. of iron is almost unworkable for ductile tungsten because of its brittleness. It is comparatively easy to reduce the total impurities to from 0·1 to 0·5 per cent., but elaborate processes are required for a higher degree of purity. When precipitation by an acid is employed as a means of purification, it is advisable to avoid colloidal precipitates because they are very liable to absorb impurities. Colloidal precipitation is favoured by the use of cold, dil. soln. ; conc. soln. are preferable. The subject was studied by L. Moser and J. Ehrlich.[5] The best results are obtained by running the tungstate soln. into the boiling acid ; rapid mixing favours the production of a coarse-grained precipitate. If cold hydrochloric acid of sp. gr. 1·19 is added drop by drop to a cold soln. of the tungstate, the precipitate first formed passes into the colloidal state as more acid is added; and the colloid is coagulated on boiling. If nitric acid be employed, the precipitate does not pass into the colloidal state. The washed precipitate produced by hydrochloric acid is fairly soluble in nitric acid, but the precipitate produced by nitric acid is scarcely soluble in hydrochloric acid. Sulphuric acid stands between nitric and hydrochloric acids in that the precipitate first formed is partly redissolved on adding more acid. If increasing amounts of acetic acid are added to sodium tungstate before adding hydrochloric acid, the initial precipitation does not occur until increasing amounts of hydrochloric acid are added, and the precipitate dissolves more quickly on adding more acid. However, the addition of 5 c.c. of acetic acid to 2 c.c. of a soln. of sodium tungstate gives a precipitate which is not soluble in hydrochloric acid. If tungstic acid be precipitated from sodium tungstate by hydrochloric acid, and allowed to stand, the precipitate is at first white and colloidal, it then becomes yellow and insoluble on the further addition of hydrochloric acid. The precipitated tungsten trioxide always carries down with it some of the salts dissolved in the mother-liquor. Thus, if 0·2 per cent. of iron is present in the soln. of ammonium tungstate run into boiling hydrochloric acid, the precipitate may contain 0·05 per cent. of ferric chloride; and tungstic acid precipitated from sodium tungstate by hydrochloric acid contains from 0·1 to 0·3 per cent. of sodium chloride. These impurities can to some extent be removed by washing with water; but the tungstic acid then becomes colloidal and filtration is impracticable. Washing with water containing 10 per cent. of hydrochloric or nitric acid, prevents the peptization of the tungstic acid; but even then it is not possible to completely remove the soluble impurities—0·09 per cent. of ferric oxide, and 0·06 per cent. of calcium oxide, as well as traces of titanium and molybdenum may be present. The precipitation is carried out in wooden vats or pots of vitreous silica. The sodium tungstate obtained from wolframite is sometimes purified by converting it into calcium tungstate by adding an excess of a soln. of calcium chloride of sp. gr. 1·16, and the washed precipitate is treated with boiling hydrochloric acid of sp. gr. 1·10. The process was described by C. H. Jones, who obtained a sample with 99·53 per cent. WO_3 by this means.

Hydrated tungsten trioxide readily dissolves in aq. ammonia, if it has not been dried at too high a temp., it is markedly less soluble if dried over 170°, and is practically insoluble if heated above 500°. Tungsten trioxide was purified by J. Persoz, F. A. Bernoulli, and A. Riche by dissolving it in aq. ammonia, and again precipitating it with acid. Several repetitions of the process are needed for a product of a high degree of purity. If the ammoniacal soln. of the tungsten trioxide is allowed to stand for some hours and then filtered, the impurity, iron, may pass into soln. The soln. is evaporated in order to obtain white crystals of ammonium paratungstate; these are washed with cold water and dried. One crystallization may not suffice for the removal of iron. The paratungstate, being insoluble in water, is decomposed by boiling with 40 per cent. nitric or hydrochloric acid, and the hydrated tungsten trioxide is dissolved in aq. ammonia and recrystallized as before. The crystallization may be modified by adding sodium or potassium hydroxide to the soln. of ammonium tungstate, when crystals of the complex salt $2R_2O.3(NH_4)_2O.12WO_3.15H_2O$ are obtained. The crystals can be decomposed by dissolving them in soda-lye, the ammonia driven off by heat, and the alkali tungstate soln. run into boiling acid. This modification gives tungsten trioxide free from iron, but it contains 0·1 to 0·3 per cent. of alkali chloride. E. F. Smith and F. F. Exner digested ammonium tungstate with nitric acid (1 : 1) and a little hydrochloric acid; and dissolved the thoroughly washed product in aq. ammonia. The soln. deposited crystals of ammonium paratungstate. After several repetitions of the process, the salt was digested with nitric acid; evaporated to dryness; and ignited. The oxide can also be purified by conversion into the oxychloride, and treatment with acid—O. Ruff, M. E. Pennington and E. F. Smith, and C. Friedheim and R. E. Meyer.

J. Waddell purified tungsten trioxide by fusing the crude oxide with potassium hydrosulphate; and dissolving the cold cake in water to remove the silica. The filtered soln. was fractionally precipitated by adding mercurous nitrate. The first fractions were treated with aqua regia, and the resulting hydrated tungsten trioxide fused with sodium carbonate. The cold mass was dissolved in water, mixed with enough tartaric acid to prevent precipitation when the soln. was acidified with hydrochloric acid. A current of hydrogen sulphide precipitates the molybdenum but not the tungsten. The filtered liquid was then boiled with an excess of conc. hydrochloric acid to precipitate the hydrated tungsten trioxide.

R. E. Pearson and co-workers described an electrolytic process of reducing the oxide—*vide* molybdenum. According to C. H. Fischer, metals which form insoluble sulphates can be removed by dissolving the crude tungsten trioxide in about twice its weight of fused potassium hydroxide mixed with lime; extracting the cold mass with water; and treating the soln. with a large excess of ammonium sulphide to precipitate iron, zinc, etc. The tungsten remains in soln. as polysulphide; it is precipitated as sulphide by adding hydrochloric acid; the precipitate is dried and oxidized by roasting, and the tungsten trioxide, thus formed, is purified by dissolving in potassium hydroxide soln. and reprecipitating with hydrochloric acid. Phosphorus and arsenic can be removed from the soln. of sodium tungstate as ammonium magnesium phosphate and arsenate by oxidizing the soln. with sodium hypochlorite; adding magnesium chloride; boiling the liquid; and adding ammonia and ammonium chloride in excess.

Some work has been done on the separation of molybdenum and tungsten. One series of processes is based on the fact observed by H. Rose.[6] When tartaric acid is added to the sulphuric acid soln. of the alkali salts, and hydrogen sulphide passed into the liquid, the molybdenum is precipitated as sulphide, while the tungsten sulphide is kept in soln. by the tartaric acid (J. Lefort, and J. Waddell). In another series, warm sulphuric acid of sp. gr. 1·378 dissolves the molybdenum from a mixture of the freshly precipitated molybdenum and tungsten trioxides (E. D. Desi, M. J. Ruegenberg and E. F. Smith, and W. Hommel). In a third series, if dry hydrogen chloride be passed over the mixed oxides at 250°–270°, the molybdenum oxychloride, $MoO_3.2HCl$, is alone volatilized (E. Péchard, and H. Debray). In a fourth series, the tungsten is precipitated as pentoxide when a soln. of stannous chloride is added to a boiling soln. of sodium tungstate and molybdate. The molybdenum remains in soln. (B. Mdivani, and E. E. Marbaker). Sodium tungstate free from molybdenum was prepared in the following manner by C. Friedheim and R. Meyer:

> Sodium tungstate, prepared in the usual way, is dissolved in cold water, and to the sat. soln. hydrochloric acid is added until the reaction is only feebly alkaline; the paratungstate thus obtained is crystallized out, and once recrystallized. One half of it is dissolved in boiling water, and hydrochloric and a little nitric acid added; hydrated tungstic acid is precipitated. This is washed thoroughly with hot water and added to a boiling soln. of the other half of the paratungstate, until a portion no longer gives a precipitate with hydrochloric acid. The bulk of the soln. is then filtered, hydrochloric acid is added, and the soln. is boiled and repeatedly sat. with hydrogen sulphide. This precipitates the molybdenum as sulphide, whilst the metatungstate is not attacked. The soln. is filtered, concentrated, oxidized with a few drops of bromine water, and neutralized with soda; pure sodium paratungstate can then be obtained from it by crystallization.

§ 4. The Preparation of Tungsten

For the preparation of the metal of a high degree of purity, the oxide is reduced by heating it in a current of *hydrogen*. This method was used by J. J. Berzelius,[1] F. Wöhler, F. Jean, J. Waddell, W. Majert, C. W. Davis, C. W. Siemens and A. K. Huntington, C. W. Blake, T. Sington, G. Bessa, L. R. Pratt, C. M. Johnson, H. N. Warren, E. R. Schneider, J. B. von Borck, A. Riche, E. Zettnow, R. F. Marchand, Badische Anilin- und Sodafabrik, P. Schwarzkopf, E. Ruhstrat, C. H. Jones, H. E. Roscoe, J. Schilling, E. Thomson, C. W. Davis, J. Philipp, V. I. Spitzin, A. Pacz, etc. G. Chaudron determined the conditions of equilibrium in the system: $WO_3+3H_2 \rightleftharpoons W+3H_2O$, between 600° and 1100°. The trioxide passes through various intermediate stages before it is reduced to metal; there is yellow WO_3; deep blue W_2O_5; and chocolate-brown WO_2. If the reduction is stopped at intervals, these changes in colour succeed one another as the reduction proceeds. Thus, at 400°, the greenish-blue product has the approximate composition $WO_3+W_2O_5$; at 500°, intense blue W_2O_5 is formed; at 550°, dark blue W_2O_5; at 575°, purple-brown $W_2O_5+WO_2$; at 600°, chocolate-brown WO_2; at 650°, brownish-black WO_2+W; at 700°, greyish-black W; at 800°, grey W; at 900°, metallic grey W; and at 1000°, coarse metallic W. The observed values of the constant $K_p=[H_2O]/[H_2]$, corresponded with the reactions: $H_2+2WO_3 \rightleftharpoons W_2O_5+H_2O$, for which J. A. M. van Liempt gave $\log K_1=-2468T^{-1}+3{\cdot}15$; $H_2+W_2O_5 \rightleftharpoons 2WO_2+H_2O$, for which $\log K_2=-817T^{-1}+0{\cdot}88$; and $2H_2+WO_2 \rightleftharpoons W+2H_2O$, for which $\log K_3 =-111T^{-1}+0{\cdot}845$. G. Chaudron's values of log K and T^{-1} are plotted in Fig. 2. The results were confirmed by L. Wöhler and co-workers—*vide infra*. L. Wöhler and R. Günther gave for $WO_3 \rightarrow W_2O_5$, $\log K_1=-1375T^{-1}+2{\cdot}235$; for $W_2O_5 \rightarrow WO_2$, $\log K_2=-1000T^{-1}+1{\cdot}218$; and for $WO_2 \rightarrow W$, $\log K_3=-1904T^{-1}+1{\cdot}554$. W. Reinders and A. W. Vervloet could not obtain satisfactory values for K_1 because

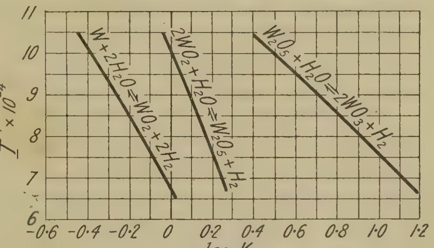

FIG. 2.—Equilibrium between Water, Hydrogen, Tungsten, and its Oxides.

the composition of the blue oxide obtained varied from W : O=1 : 2·20 to 1 : 2·95. H. Alterthum and F. Koref studied this subject—*vide infra*, the individual oxides. G. Chaudron found that if the equilibrium curves are extrapolated, 1 and 2 will intersect at a lower temp., and 2 and 3 at higher temp. Hence, above and below these points there must be equilibria represented by $W_2O_5+5H_2\rightleftharpoons 2W+5H_2O$, and $WO_3+H_2\rightleftharpoons WO_2+H_2O$. At 900°, WO_2 is stable in a mixture of 40 to 55 per cent. of hydrogen, and 60 to 45 per cent. of steam, while W_2O_5 is stable in a mixture of 12 per cent. of hydrogen and 88 per cent. of steam. J. A. M. van Liempt prepared these two oxides by passing hydrogen through water at 85° and 97° respectively, in order to obtain the correct proportion of steam in the gas, and then over a thin layer of tungsten trioxide. If the steam be removed continuously from the sphere of the reaction, the tungsten trioxide is reduced to metal provided the temp. is at least 700°. At lower temp., the time required is too long to be practicable. G. A. Meerson studied this subject and found that the size of the crystals of the trioxide does not influence the size of the crystals of tungsten.

F. Wöhler, and W. Majert reduced red-hot acid potassium tungstate in a current of hydrogen, and washed out the normal tungstate by boiling alkali-lye. E. Defacqz obtained crystals of the metal by heating tungsten disulphide in a current of dry hydrogen; L. von Uslar, by passing a mixture of hydrogen and the vapour of the oxychloride $WOCl_4$ or WO_2Cl_2 through a red-hot tube; H. E. Roscoe, by passing a mixture of hydrogen and the vapour of the chloride WCl_4 or WCl_5 through a tube at about 420°; and F. Wöhler, by passing hydrogen over the amide. Other reducing gases may be used: thus, C. W. Davis found that a 2 hrs.' reduction by *gasoline* vapour at 1080° yielded a product with 98 per cent. tungsten; J. J. Berzelius found that tungsten trioxide, heated with sodium carbonate on charcoal in the inner blowpipe flame, is reduced to metal; and E. D. Clarke reported that he obtained a copper-coloured metal by heating tungsten trioxide before the oxy-hydrogen blowpipe flame.

J. L. Gay Lussac and L. J. Thénard reduced tungsten trioxide to tungsten by heating it with *potassium* or *sodium*. E. Zettnow heated a mixture of tungsten trioxide and sodium under a layer of fused sodium chloride, in an iron crucible, and extracted the cold mass with water, and dil. hydrochloric acid to remove the alkali salts and iron. A. Riche reduced tungsten hexachloride to metal by means of sodium; and J. W. Marden used a modification of the process. A. Burger, A. S. Cachemaille, and H. Kuzel and E. Wedekind reduced tungsten trioxide by heating it in an evacuated tube in the vapour of *calcium*; and washing out the calcium oxide by dil. nitric acid. K. Kuzel and E. Wedekind used this process. L. Weiss and A. Martin found that calcium and L. Weiss and O. Aichel that *mischmetall* are not satisfactory reducing agents. L. Weiss and A. Martin used *magnesium* as a reducing agent; and H. Wright, *tin*. S. M. Delépine reduced tungsten trioxide to metal by means of powdered *zinc* at a red-heat; and washing out the zinc oxide with hydrochloric acid, and the unchanged trioxide by dil. alkali-lye. L. Weiss and A. Martin obtained 99·8 per cent. tungsten by this means. E. Straub obtained alloys by passing the vapour of the required metal over heated tungsten trioxide. H. Goldschmidt found that tungsten trioxide is easily reduced by *aluminium* in the thermite process. An intimate mixture of the trioxide and powdered aluminium, contained in a crucible, can be ignited by a fuse of sodium or barium dioxide mixed with some magnesium powder. As a result, an alloy of aluminium-tungsten is formed and it dissolves in the tungsten. The excess of tungsten trioxide forms an aluminium tungstate, and goes into the slag. O. Voigtländer heated the mixture of tungsten trioxide and aluminium so that after the reduction the temp. is high enough to keep the tungsten in a molten state. The aluminium reduction process was discussed by H. Goldschmidt and C. Vautin, J. W. Marden, G. A. Percival, C. R. Schroeder, H. Lohmann, G. Bessa, W. C. Blake, J. L. F. Vogel, N. Branoic, A. Martin, and F. Kupelwieser. K. Metzger said that the yield is poor. L. Weiss and A. Martin found that the product has 93·36 per cent.

of tungsten, 1·75 per cent. of silicon, 3·68 per cent. of aluminium, and 2·18 per cent. of calcium. A. Stavenhagen used one-third the vol. of liquid air to ignite the mixture of tungsten trioxide and aluminium. W. Prandtl and B. Bleyer recommended a mixture of calcium and aluminium in place of aluminium alone. A. Stavenhagen and E. Schuchard obtained alloys by reducing a mixture of the oxides with aluminium. B. Neumann reduced the oxide with *silicon;* and F. M. Becket found that tungsten trioxide can be reduced by silicon or *boron* when the mixture is heated in an electric furnace.

When tungsten trioxide first attracted attention, it was reduced to a metal by heating it with *carbon* or carbonaceous matter. J. J. and F. de Elhuyar, L. N. Vauquelin and L. Hecht, C. Hatchett, W. Allen and A. Aikin, G. Bessa, D. J. Giles, A. Ruprecht, H. W. Hutchin, and E. Zettnow used this method; while C. F. Bucholz, F. A. Bernoulli, and J. J. Berzelius thus obtained " tungsten " by heating a mixture of carbon and a tungstate. H. Krieg, and E. Defacqz obtained " tungsten " directly by heating a mixture of the tungstate ore and carbon. Slightly less than the theoretical proportion of carbon—coke, anthracite, coal, or charcoal—required for reducing the trioxide to tungsten and carbon monoxide, is intimately mixed with the powdered oxide. The mixture is charged into a crucible, which is then covered, and heated in a furnace. The metal remains as a fine grey powder mixed with coarser crystals, and undecomposed oxide. The coarse crystals are separated by washing out the fine particles which are added to the next charge. F. Filsinger heated a mixture of tungsten trioxide with 10 per cent. of wood-charcoal, and 2 to 3 per cent. of resin. The powdered metal is separated by levigation. It has not a high degree of purity; it contains 80 to 90 per cent. tungsten. At a temp. of 950°, M. R. Andrews and S. Dushman observed that tungsten unites with carbon, forming carbides which are stable up to 2400°; in consequence, tungsten obtained by reduction with carbon always contains some carbide. According to C. W. Davis, in order to obtain a satisfactory reduction of tungsten trioxide to tungsten, the material must be freed from water, which is best effected by a current of air at about 500°. On reducing the dried oxide with carbon, a blue or purple oxide is produced at 650° to 850°, a chocolate-brown mixture of oxides at 900° to 1050°, and metallic tungsten above 1050°. The proportion of carbon required for the reduction ranges from 1 : 10 to 1·6 : 10, according to the temp., time, and other conditions. Excess of carbon can be removed to a considerable extent by washing the product with water. C. J. Butterfield heated a mixture of scheelite and charcoal in a graphite crucible for 4 to 5 hrs. at 1100°–1200°. The reaction with calcium tungstate is symbolized: $CaWO_4+3C=W+CaO+3CO$; and with sodium tungstate: $Na_2WO_4+3C=W+Na_2O+3CO$. The cold mass was powdered, and the metal separated on a shaking table. The product was then washed with dil. hydrochloric acid. C. J. Head mixed finely ground sodium tungstate with ammonium-chloride—or any chloride of the iron or manganese group, and a suitable reducing agent—wood charcoal, anthracite, or preferably sawdust—and heated the mixture in a nichrome crucible at 850° to 950° for 3 to 5 hrs. until all the ammonia was expelled. The reaction is symbolized: $2NH_4Cl+Na_2WO_4+3C=2NH_3+2NaCl+H_2O+3CO+W$. The lower half of the charge is removed and heated to 1000° to 1150°, out of contact with air, whereby the tungsten trioxide is reduced to tungsten powder. The mass is quenched in water, and the insoluble tungsten washed in the usual way. The tungsten can be recovered as calcium tungstate by adding calcium chloride to the washing liquid; the ammonia is also recovered. H. Moissan reduced the oxide by sugar-charcoal in an electric arc furnace. The metal is readily fused in that furnace, but if the heat is not allowed actually to melt the tungsten, and the tungsten trioxide be in excess, the metal can be produced in a form almost free from carbon. The ingot so obtained is fused on the surface but the interior is porous; and the mass touches the carbon crucible only at a few points. Consequently, *le carbone du creuset n'intervient pas*, and the excess of tungsten trioxide is volatilized. G. Gin used a similar process, and added that there is a considerable loss of tungsten trioxide by volatilization. H. Lohmann found that if the metal be heated to near its m.p. in vacuo or in a current of neutral gas, any contained carbon is vaporized without oxidizing or reducing agents being present. E. D. Desi said that at a very high temp. *potassium cyanide* reduces tungsten trioxide to the silver-white metal. H. N. Warren, and R. Saxon reduced the oxide by heating it with *calcium carbide;* the Electric Furnaces and Smelters Ltd. reduced the oxide by a mixture of calcium carbide and silicide, or *ferrosilicon.* L. Kahlenberg and W. J. Trautmann observed that tungsten trioxide is not easily reduced when heated with *silicon;* and the tungstates of barium, lead, and sodium do not yield the free metal or silicide—excepting, perhaps, the case of barium tungstate. F. M. Becket used *silicon carbide* as reducing agent. J. N. Pring and W. Fielding found that tungsten hexachloride is reduced by carbon at 1000° to 1500°. A. E. van Arkel found that the thermal dissociation of a gaseous compound, and the precipitation of the metal on an incandescent filament is a superior method for making tungsten of a high degree of purity. F. Koref recommended heating a filament to 1000° in an atm. of tungsten hexachloride and hydrogen at about 12 mm. press.; and Philips Gloelampenfabriken heated single crystals of tungsten in an atm. of the hexachloride at 1200° to 2400°. In the one case the wire increased in volume. If an iron rod is used, N. Parravano and C. Mazzetti found that an alloy of tungsten and iron is formed. O. L. Mills made alloys of tungsten by fusing in an electric arc, a mixture of the compound of the metal with a mixture of tungsten oxide, tungsten, and tungsten carbide.

L. and H. H. Kahlenberg added zinc to a soln. of a tungstic acid or tungsten trioxide in fused sodium and potassium chlorides, and obtained a black powder of tungsten; the action of aluminium is faster than that of zinc; but iron produces no deposition of tungsten. J. Férée distilled mercury from the amalgam and obtained the finely-divided metal. G. Arrivant prepared 99·35 per cent. tungsten by treating a pulverized tungsten alloy, containing 55 per cent. of manganese, with hydrochloric acid. C. W. von Siemens and J. G. Halske heated an alloy of tungsten with some other metals electrically, in vacuo, and found that the foreign metals distilled off, leaving the tungsten behind.

Early in the nineteenth century, J. G. Children [2] reduced tungsten trioxide by means of an electric current; about the middle of the nineteenth century, M. Junot reduced tungsten electrolytically from a soln. of a tungstate in potassium cyanide and alkali hydroxide; and in 1867, E. Zettnow electrolyzed fused sodium tungstate and obtained a deposit of tungsten on the iron cathode. The metal has not been obtained satisfactorily by the electrolysis of aq. soln. of the tungstates. This fact would not have been anticipated from the ease with which chromium, a member of the same family of elements, can be deposited from aq. soln. E. F. Smith, and W. E. Koerner tried electrolyzing neutral and acidic soln. of sodium tungstate, and found that the liquid turns blue owing to the formation of the blue hemipentoxide which collects as a precipitate at the bottom of the cell; the brown dioxide may also be formed. No metal is deposited. O. Collenberg and K. Nilsson electrolyzed conc. oxalic acid soln. of potassium tungstate at 70° with various metal cathodes. They found that with a tin or lead cathode, the reduction does not go further than the hemipentoxide; while with platinum or mercury cathodes, the reduction does not proceed so far as the hemipentoxide. O. Collenberg and J. Backer failed with hydrochloric acid soln. as electrolytes; L. W. McCay and N. H. Furman failed with hydrochloric acid soln.; and A. Fischer, with an alcoholic soln. of tungsten hexachloride. The Wolframlampen A.G. patented the electrolysis of a soln. of pertungstic acid or its salts in aq. or organic solvents; and the electrolysis of soln. of the salts, say tungsten hexachloride, in suitable organic solvents, say acetone. The subject was discussed by D. B. Keyes and S. Swann. C. A. Mann and H. O. Halvorsen observed that the electrolysis of aq. soln., or of hydrochloric acid soln. with tungsten electrodes, gives a surface film of oxide which makes the tungsten passive and prevents further electrolysis. When a soln. of dry hydrogen chloride in dry alcohol is electrolyzed with a tungsten anode, tungsten chloride goes into soln., but only the brown oxide is deposited on the cathode. A soln. of hydrogen chloride in pyridine does not ionize enough to produce tungsten chloride, and no deposit is obtained on the cathode. A. Rosenheim and R. F. Bernhardi-Grisson found that with a graphite anode and platinum cathode with alcoholic hydrogen chloride soln. of tungsten trioxide, the reduction proceeds only as far as the quinquevalent stage ; and with hydrofluoric acid soln., and a mercury cathode, reduction proceeds as far as the quadrivalent stage. H. Leiser observed that no change occurs in the electrolysis of normal sodium tungstate, but with the metatungstate electrolytic reduction proceeds as far as the blue compound. L. and H. H. Kahlenberg obtained a good deposit by the electrolysis of a mixture of fused sodium and potassium chlorides if less than one part of tungsten trioxide to two parts of fused chlorides is present. R. E. Pearson and E. N. Craig said that tungsten is formed when a direct current is passed through a cell with pasty tungsten trioxide in the cathode chamber, and sulphuric acid as electrolyte. B. Neumann and H. Richter obtained small deposits of tungsten from soln. of the hexachloride in glycerol which forms a compound containing tungsten ions.

Better results have been obtained by the electrolysis of fused tungstates. J. A. M. van Liempt found that the alkali tungstates melt without decomposition between 750° and 950°, while the eutectic mixture of lithium, potassium, and sodium tungstates melts at about 400°. F. M. Jäger and B. Kapma found that the conductivity of the fused salt increases with temp. L. A. Hallopeau found that when molten lithium paratungstate at 1000° is electrolyzed at 3 amp. and 15 volts, the product, after extraction with hot water, conc. hydrochloric acid, and lithium hydroxide soln., consists of crystalline tungsten which is contaminated with more or less platinum derived from the electrodes. The opaque prismatic crystals have the acicular habit, and in some cases contain 99·64 per cent. tungsten. Iron electrodes cannot be used because that metal dissolves in the molten tungsten. J. A. M. van Liempt electrolyzed fused sodium tungstate at 950°, in a vitreous silica crucible, with a current density of 15 amp. per sq. cm. The yield was 80 per cent. of the theoretical. The tungsten is produced by the reduction of the molten tungstate by the nascent sodium liberated at the cathode : $6Na+5Na_2WO_4=W+4Na_4WO_5$. Pure tungsten is obtained so long as the mass remains neutral or weakly alkaline. If it becomes too strongly alkaline the tungsten redissolves. In acid fusions, reduction of W_2O_7 ions by the sodium occurs with the formation of " tungsten bronzes " of the type $M_2(WO_3)_n$. The electrical resistance of these " bronzes " decreases rapidly with rise of temp. owing to the gradual liberation of tungsten. The anode reaction is $WO_4''+Na_2WO_4=Na_2W_2O_7+0{\cdot}5O_2$. When unattackable electrodes are used in a cell without a diaphragm, the products of these electrode reactions react, making the mass alkaline : $4Na_4WO_5+3Na_2W_2O_7=10Na_2WO_4+Na_2O$. The electrolysis may be made continuous under these conditions by gradually adding tungsten trioxide. In the presence of WO_4'', a tungsten anode is oxidized, the oxide dissolving to keep the fused mass neutral. Tungsten may be deposited in an adhesive, polishable layer on copper, nickel, or cobalt by using these metals as cathodes in the electrolysis of fused acid tungstates at 1000°. Lithium acid tungstates give the best results. Repeated layers of tungsten may be thus deposited if the surface layers of " tungsten bronzes " are removed between each electrolysis. The tungsten is formed by the decomposition of " tungsten bronzes " primarily deposited. According to L. Weiss and A. Martin, tungsten trioxide may be readily electrolyzed if it be fused with cryolite, and a current of 250 amp. and 13 to 14 volts be employed. The globules of metal contain 96 per cent. of tungsten. In order to raise the temp. of the bath, alumina may be added, but the aluminium which is then liberated reacts with the tungsten trioxide, forming tungsten in a fine state of subdivision. In the electrolysis of fused barium tungstate with a current of 250 amp. at 20 volts, the resulting metal powder, after washing many times with dil. nitric acid, water, and aq. ammonia, contains 89·58 per cent. of tungsten, and 2·54 per cent. of barium. If barium chloride be also added to the electrolyte, 90·98 per cent. tungsten was obtained and it had 1·99 per cent. of barium. Another process was described by E. W. von Siemens and J. G. Halske. J. A. M. van Liempt coated metals with tungsten by placing a tungsten anode in a porcelain crucible containing lithium tungstate, and the body to be coated as cathode. A current density of 75 milliampères per sq. cm. is used at 0·08 volt. If the coating does not adhere readily to the metal, the metal is first coated with another suitable metal—*e.g.* iron is coated with copper. L. Andrieux obtained the metal by the electrolysis of fused borates.

C. A. Mann and H. O. Halvorsen obtained a deposit on iron when fused lithium chloride is used as an electrolyte, with a tungsten anode and an iron cathode; H. Mennicke also obtained a deposit with fused sodium and tungsten chlorides as electrolyte and a tungsten cathode. L. and H. H. Kahlenberg electrolyzed soln. of tungstic acid or tungsten trioxide in fused alkali chlorides, and in fused sodium tungstate, and obtained smooth deposits of tungsten. They said that the electrolysis of tungstic acid dissolved in a fused mixture of sodium and potassium chlorides yielded good deposits of very pure tungsten when the ratio of tungstic acid to fused chloride was less than 1 : 2; a blue crystalline tungsten bronze, $Na_2O.W_4O_{14}$, was obtained when the ratio was 1 : 1; a red bronze, $2Na_2O.W_5O_{13}$, when the ratio was 3 : 5; and a violet-bronze, when the ratio was 4 : 5. From soln. of tungstic acid in fused chlorides, zinc and aluminium liberated very finely-divided metallic tungsten, whereas iron had no action; excess of zinc or aluminium yielded alloys of these metals with tungsten. Nickel-tungsten alloys were obtained by electrolysis of mixtures of nickel chloride, alkali chloride, and tungstic acid. L. Andrieux obtained the metal by the electrolysis of a soln. of the trioxide in fused borate and fluoride. L. St. C. Broughall electrolyzed a soln. of a tungsten salt in liquid ammonia at a low temp. or high press. J. Férée obtained tungsten by the electrolysis of a hydrofluoric acid soln. of the trioxide, using a mercury cathode; and K. S. Jackson and co-workers found that best conditions are to use a $4·6N$-acid at 95°, and a current density of 0·65 to 1·0 amp. per sq. cm. Hydrochloric and sulphuric acids should not be present in the electrolyte.

According to J. J. Runner and M. L. Hartmann,[3] 90 per cent. of the tungsten extracted from ores is employed in the preparation of *ferrotungsten* containing 50 to 85 per cent. tungsten. R. M. Keeney described the preparation of the alloy by the reduction of tungsten ores by carbon in crucibles—*vide supra*—prior to the introduction of the electric furnace about 1900. The reduction of the ores by the aluminium thermite process—*vide supra*—has also been employed. A. J. Rossi reduced ferberite with aluminium in an electric furnace obtaining an alloy with 75·9 per cent. W; 21·4, Fe; 1·6, Si; 0·08, S; and 0·9, C. G. Gin produced ferrotungsten by reducing scheelite or artificial calcium tungstate by 20 per cent. ferrosilicon in an electric furnace having two contiguous hearths in series, with ferrosilicon electrodes, and an intermediate electrode of fused ferrosilicon. The scheelite is placed on the melted bath of ferrosilicon, and the silicon oxidizes at the expense of the tungsten trioxide, and forms a slag; the iron forms ferrotungsten. A common method of producing ferrotungsten is to reduce the ore wolframite, ferberite, and hubnerite in an electric furnace with carbon. The manganese either volatilizes or passes into the slag. The product usually contains more carbon than is desired in ferrotungsten for steel making, and it is therefore decarburized.

The decarburization process described by D. A. Lyon and co-workers, and R. M. Keeney involves heating the metal in the electric furnace in the presence of tungsten trioxide, hammer scale, or iron oxide. In this way, the carbon can be reduced to 0·15 per cent. The oxidation of carbon by iron oxide entails losses as iron tungstate, but this loss can be reduced by adding silica, which results in the formation of ferrous silicate. G. Gin recommended casting the carburized tungsten in the form of electrodes, which are used with a soft steel intermediate electrode. The bath above the metal is of tungsten oxide and magnesium aluminate. The electrodes melt, and their carbon is burnt out by the tungsten oxide. A. Lederer reduced the carbon content of tungsten from 2·5 to 0·04 per cent. by heating the metal in dry hydrogen to 1200° to 1300°; the Vereinigte Gluhlampen A.G. recommended using a mixture of hydrogen sulphide and hydrogen; the Zirkon Glühlampenwerke A.G. employed phospham; and E. W. von Siemens and J. G. Halske heated the metal electrically in acetic acid vapour. F. M. Becket dephosphorized the metal by feeding the solid metal in a finely-divided state on to the surface of a molten basic oxidizing bath—say scheelite and lime—at a temp. equal to or above the m.p. of the ferrotungsten. E. W. von Siemens and J. G. Halske discussed the removal of oxides from the metal.

Ductile tungsten.—In connection with the manufacture of incandescent filament lamps,[4] the good results with tantalum filaments stimulated the examination of the scarcer metals, and tungsten, in its turn, was tried. The tungsten produced at that time was so hard and brittle that, unlike tantalum, it could not be drawn into filaments. The filaments were therefore prepared by a process of squirting similar to that employed in preparing carbon filaments. The powdered metal mixed with some binding agent—gum, gelatine, a soln. of nitrocellulose in amyl acetate, pinene hydrochloride, etc.—was squirted through a die, dried, and heated. The tungsten powder was also mixed with cadmium amalgam, and after squirting through a die, the cadmium and mercury were removed by volatilization. The colloidal metal was also tried as a source of tungsten for manufacturing filaments. Here no binding agent is required. Filaments have also been made by the Wolframlampen A.G., and A. Just and F. Hanaman by introducing a glowing metal or carbon filament in an atm. of tungsten oxychloride, WO_2Cl_2 or $WOCl_4$, and an excess of hydrogen. Tungsten is thus deposited on the filaments—*e.g.* according to the conditions, the carbon may be wholly or partially replaced, $WO_2Cl_2+2C+H_2=2HCl+2CO+W$; or $WO_2Cl_2+3H_2=2HCl+2H_2O+W$—and the filament thus consists of a core of metal or carbon enclosed in a tube of tungsten.

The tungsten filaments prepared by these processes were strong and elastic, but were incapable of taking the slightest permanent set when cold, although they were ductile at a very high temp. The ductility of tungsten was shown by W. D. Coolidge[5] to be conditioned by the purity of the metal. According to O. Ruff, the metal must be entirely free from oxide; iron and nickel and non-metallic impurities like sulphur, and phosphorus must be entirely absent; and it should not contain more than about 0·1 per cent. of carbon. Before working, the metal should be sintered almost to the m.p. in order to obtain it in as dense a condition as possible. The British Thomson-Houston Co. obtained ductile tungsten by working a heated body of coherent tungsten so as to transform the metal by repeated rolling, hammering, swaging, or drawing into a form which shows a conchoidal fracture and ultimately becomes very fibrous. C. J. Smithells, and others have described the essential details of the process. The powder is first pressed into briquettes; this is then heated in hydrogen at 900° to 1050° to sinter the powder; then formed by heating it in hydrogen to nearly its m.p.; it is then worked into a rod by mechanical hammering called "swaging"; and after that it is drawn successively through smaller and smaller dies, at 400° to 650°, until the wire has the required diameter. The draw-plate is lubricated with a mixture of deflocculated graphite and water. The wires appear blue-black owing to the surface coating of oxide and graphite; and they are cleaned by being electrically heated to dull redness in an atm. of hydrogen; or by treating the wire with a hot soln. of soda-lye, sodium dioxide, hydrogen dioxide and ammonia.

P. Schwarzkopf and S. Burgstaller obtained ductile tungsten by the method indicated in connection with ductile molybdenum. The addition of less than one per cent. of thoria to the tungsten trioxide before the reduction was shown by Westinghouse Metallfaden-Glühlampenfabrik to make the product more ductile—possibly, according to Z. Jeffries, and F. A. Fahrenwald, by preventing recrystallization. The filaments in use are liable to recrystallize and revert to their original hard, brittle condition. This shows itself by irregular thickenings. A. Lederer said that the thickenings are longitudinal when a direct current is used, and with an alternating current there is a kind of sliding motion between adjacent parts of the filament which results in fracture. These defects are alleviated by using an alloy of tungsten with one of the rare metals instead of tungsten alone. The thorium oxide-tungsten filaments were studied by W. Geiss and J. A. M. van Liempt.

J. Férée [6] prepared pyrophoric tungsten by the distillation of mercury from tungsten amalgam. H. Kuzel obtained **colloidal tungsten** by treating it alternately with dil. soln. of acid and neutral reagents. 10 kgrms. of the metal were heated for 24 to 48 hrs. with 75 kgrms. of 15 per cent. hydrochloric acid, well agitated, decanted, and washed with distilled water, until some colloidal metal began to pass into the filtrate. The metal was then treated for 24 hrs. with 75 kgrms. of a one per cent. soln. of potassium cyanide, washed with distilled water, and heated with 75 kgrms. of a one per cent. soln. of ferrous sulphate. After washing to remove the iron salts, the residue is treated with a 2 per cent. alcoholic soln. of monomethylamine, or a 0·5 per cent. soln. of sodium hydroxide. When the process is repeated several times, the metal is almost completely peptized in distilled water. H. Schulze employed an analogous method of dispersion in 1885. The process was discussed by E. D. Desi, J. Pintsch, A. Pacz, F. J. Planchon, A. Lottermoser and W. Riedel, and E. W. von Siemens and J. G. Halske. A. Lottermoser discussed the colloidal content of tungsten powder. J. Billitzer obtained the colloidal metal by making an electric arc between tungsten electrodes under water. T. Svedberg prepared the **isobutylalcosol** by the electric dispersion method—**3**. 23, 10—and C. H. von Hoessle prepared hydrosols by electric dispersion. L. Hamburger studied the properties of thin films.

The term *single crystal*, or *unicrystal*, is applied to a wire or rod the whole of which is composed of one crystal. The term is not usually applied to the isolated crystals, say, when tungsten is deposited from its vapour. One-crystal wires were studied by G. Tammann,[7] J. Czochralsky, B. Duschnitz, I. Tarjan and P. Tary, Z. Jeffries, J. Pintsch, and H. C. H. Carpenter and C. F. Elam. Single crystals of tungsten wire were prepared in 1914 by J. Pintsch by drawing the ordinary squirted tungsten filament, containing a little thoria, through a zone raised to 2000° to 2200° in an atm. of hydrogen, and at a rate of about 3 metres per hour. The process was modified by F. S. Goucher, and R. Jacoby. The diameter of the single crystals of tungsten was increased by F. Koref, by glowing the wire in the vapour of tungsten hexachloride in the presence of hydrogen: $WCl_6=W+3Cl_2$, and $WCl_6+3H_2=W+6HCl$. The tungsten forms an adherent deposit on the wire, and as growth proceeds, the wire assumes a crystalline contour—four-, six-, or eight-sided—depending on the orientation of the crystal with respect to the axis of the wire. When the diameter of the wire has been increased 3 or 4 times, any further deposition results in the formation of new crystals with a different orientation. The microscope and the X-radiograms show that the structure of the deposit is identical with that of the original crystal. The subject was investigated by H. Fischvoigt and F. Koref, and by A. E. van Arkel. J. A. M. van Liempt also developed a method of increasing the diameter of single crystals by electro-deposition from acid lithium tungstate.

§ 5. The Physical Properties of Tungsten

The **colour** of the metal prepared by J. J. and F. de Elhuyar,[1] by the carbon reduction process, is steel-grey, with a strong metallic lustre. If slowly reduced at a high temp. the powder is coarse-grained, and grey, but if reduced slowly at a low temp., it is fine-grained and black (F. Wöhler, J. J. Berzelius, H. E. Roscoe, and M. E. Pennington and E. F. Smith). C. W. Siemens and A. K. Huntington said that the metal which has been fused is white and brittle, with a very close grain. The metal as prepared by F. Wöhler, by hydrogen reduction, is a silver-grey or tin-white powder. H. von Wartenberg said that the purified metal has the colour of highly polished platinum; and L. Weiss added that it has a colour resembling that of mercury. C. J. Smithells and H. P. Rooksby observed that the microstructure of a sample of tungsten showed small grains with sub-boundaries having a nearly uniform orientation in each crystal; these sub-boundaries are formed under the influence of stresses formed during the rapid cooling of the metal. E. Zettnow said that the powder consists of tabular **crystals** which are probably tetragonal prisms, but, as was shown by P. Debye, the crystals are cubic. This is proved by the interference figures and the **X-radiograms.** The space-lattice is a body centred cube, Fig. 3; the length of the edge of the cube is

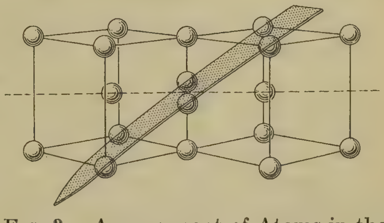

Fig. 3.—Arrangement of Atoms in the Tungsten Crystal, and the (112)-plane.

$a=3{\cdot}18\times10^{-8}$ cm.; A. W. Hull gave 3·272 A.; and W. P. Davey gave $a=3{\cdot}155$ A. The distance of closest approach of the atoms is $2{\cdot}732\times10^{-8}$ cm.; and if the at. wt. is 184, the calculated density is 19·32, which approaches the highest observed values. A. E. van Arkel, F. Skaupy, K. Becker, E. Schmid, T. Fujiwara, H. C. Burger, W. Herme-Rothery, J. Leonhardt, W. Rosenhain, J. Hengstenberg, and R. Gross and N. Blassmann studied this subject. F. S. Goucher found that between ordinary temp, and the m.p., no change occurs in the space-lattice except that due to thermal expansion; so that there is no evidence of an allotropic form of tungsten. The powder, spluttered films, and worked tungsten have all the same lattice structure —*vide infra*, tensile strength. A. E. van Arkel, F. S. Goucher, J. Hengstenberg and H. Mark, W. G. Burgers, H. C. Burger, and E. Schiebold discussed the deformation of the lattice by mechanical action—*vide infra*—and W. Braunbek, by raising the temp. J. A. M. van Liempt, and F. Koref and H. Wolff observed no measurable difference respectively in the heats of combustion, and from the heats of dissolution of worked and unworked tungsten. W. Geis and J. A. M. van Liempt calculated an increased energy content of 775 cals. per gram-atom of tungsten by cold working of the metal. They observed no evidence of a compression of the space-lattice by compression or rolling, and concluded that the phenomenon is physical and has to do with electrons; it is not a question of structure or of crystallography. G. Tammann and M. Straumanis, T. Fujiwara, and M. Ettisch and co-workers discussed the structure of hard-drawn tungsten wires. The **cleavage** is about the (100)-plane, but the slip planes on deformation are the (112)-planes—Fig. 3. E. Sutter obtained over-growths with iron. A polished section of wire or rod does not show the crystalline structure, but inclusions like thoria are visible. J. Leonhardt studied the crystal's structure. The metal is most rapidly attacked by etching reagents on the (112)-plane, and the **corrosion figures,** as shown by B. Schmidt, R. Gross and N. Blassmann, and C. J. Smithells, differ from those obtained with metals like iron, which, although having the same lattice structure, etch most readily on the (100)-planes, and show cubic etch-pits. The grain structure readily appears when the polished surface is etched for $\frac{1}{2}$ to 10 minutes with boiling 3 per cent. hydrogen dioxide; with a cold soln. of equal vols. of 10 per cent. sodium hydroxide and 30 per cent. potassium ferrocyanide; or with a hot soln. of hydrofluoric and nitric acids and water (3 : 1 : 4). Electrolysis etching is more difficult to control. R. Gross and co-workers found that when a hollow tungsten cylinder, in which the direction of the crystallographic axis was constant throughout, was etched with an alkaline soln. of potassium ferrocyanide, six equal faces were developed on the interior, and six on the exterior of the cylinder. The interior faces were set at 30° to the adjacent exterior faces. This relative position is in accordance with the rule that the exterior faces developed on an etched cylinder are the planes of maximum soln. velocity, those on the interior the planes of minimum velocity.

When the temp. of a pressed ingot of tungsten is raised by the passage of an electric current, no change in **grain-size** occurs below 1000°–1050°; above that temp., the average grain-size increases, and the sp. gr. of the ingot increases, until, for a given temp., equilibrium is attained, and no appreciable change in structure takes place. The equilibrium grain-size is larger the higher the temp., and equilibrium is apparently reached in about 15 minutes. According to H. Alterthum, true equilibrium should not be attained until the ingot consists of one crystal; and if the period of heating be sufficiently prolonged at temp. a little below the m.p., this state is nearly attained. The time required to form the nuclei of crystals decreases rapidly as the temp. is raised. Thus, at 3000°, the time required for the formation of nuclei is 180 min.; at 3100°, 110 min.; and at 3200°, 45 min. S. Ohashi found the relation between the temp., $\theta°$, of crystallization and the time, t, of heating for the recrystallization of single crystal wires of tungsten is $\theta=1250-250\log t$. Z. Jeffries and R. S. Archer gave 1200° for the lowest temp. of recrystallization. According to G. A. Meierson, the growth of crystals of tungsten does not commence below 1200° if the powdered metal be heated in a stream of dry hydrogen. Should the latter contain moisture, growth commences at 1050°, and is accompanied by loss in weight of the sample. These effects are due to the formation of tungsten dioxide, which is volatile at 1050°. This, on being reduced, deposits tungsten on the crystals. Similarly, the formation of large crystals of tungsten in the reduction of tungstic anhydride is due to the volatility of the oxides WO_3 and W_2O_5, which assumes measurable proportions at 850° and 900°, respectively. Where tungsten is prepared by the reduction of the trioxide the magnitude of the crystals of the latter has no influence on that of the product. Similarly, it is possible to prepare large crystals of dioxide by slow reduction of trioxide at an appropriate temp.

The ingot is not uniformly heated by the electric current. Z. Jeffries, and C. J. Smithells have shown that there may be a difference of 150° between the centre and the surface, and between the middle portion and the ends fitted with water-cooled contacts. The largest crystals are produced at the lowest temp. capable of producing exaggerated growth; the average grain-size of the metal decreases as the temp. rises. Hence, also, since the rate of growth increases rapidly with temp., larger grains are formed in the centre of the ingot than in the outer layers; and the large grains absorb their smaller neighbours. Exaggerated growth occurs from about 2500° to 2800°; below this range of temp., the ingot remains fine-grained—Fig. 4; and above, grain growth occurs throughout the metal without any marked contrast developing. Z. Jeffries found that this effect is exaggerated when there is any obstruction to the growth of the grains. For example, the presence of, say, 0·75 per cent. of thoria, increases the differences in the grain-size by restraining the growth of the small grains, while the large grains grow around and include the obstruction. F. Sauerwald observed that the growth of the grains of loose tungsten powder under its own weight occurs at about 2500°, the exact temp. depends upon the size of the grains, and on the magnitude of the press. Thus, grain-growth can be detected at 950° with powder of 0·6μ average diameter, and with 3μ diameter grain-growth occurs 70° higher. With a 0·6μ powder, grain-growth occurs at 1200° with a press. of 10 tons per sq. in.; at 1050°, with a press. 2½ times as great; and at 900°, with a press. 4 times as great. The cause of the growth of the grains is attributed to a reduction in the surface energy when the grain-size increases; the finer the particles, the more readily do the grains grow, and this is favoured by the greater the number of contacts with fine grains than with coarse ones. Z. Jeffries and R. S. Archer gave 1200° for the recrystallizing temp. of tungsten. The subject was studied by J. A. M. van Liempt. M. Ettisch and co-workers found that the crystallites in soft wires are irregularly arranged, and in hard wires regularly. The subject was discussed by C. J. Smithells and co-workers, F. Sauerwald, W. G. Burgers, and H. P. and W. P. Davey. T. Fujiwara found that when the crystals of tungsten are deposited by the action of steam on polycrystalline and unicrystalline tungsten rods heated in moist hydrogen, the crystals formed on polycrystalline rods were rhombic dodecahedra with the (110)-faces sometimes appearing as hexagonal prisms, and some of the crystals were laminated. In the case of unicrystalline rods, the crystals on the etched surface had the same orientation as the parent crystal to which they were united by a (110)-plane.

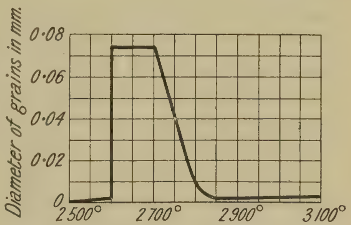

Fig. 4.—The Effect of Temperature on the Grain-size of Tungsten.

The early determinations of the **specific gravity** of tungsten were too low, no doubt owing to the impurity of the metal. For instance, J. J. and F. de Elhuyar[2] gave 17·6; C. F. Bucholz, 17·4; W. Allen and A. Aiken, 17·22; F. A. Bernoulli, 17·1 to 18·2; E. Zettnow, 17·20 to 18·4 at 17·5°; L. von Uslar, 16·54 to 18·26 at 21°; A. Riche, 17·2; and H. E. Roscoe, 19·129 at 17°/4°. Among the more recent determinations, G. Arrivant gave 15·8; J. Waddell, 18·5; L. A. Hallopeau, 18·68 at 0°; H. Moissan, 18·7; M. E. Pennington and E. F. Smith, 18·64 at 0°; E. F. Smith and F. F. Exner, 19·0; A. Stavenhagen, 16·6; S. M. Delepine, 18·61 to 18·67; L. Weiss, 18·72 at 20°; H. von Wartenberg gave 17·6 to 18·3 for massive tungsten, and 19·0 to 19·2 for the powder. F. Koref found the sp. gr. of unannealed tungsten to be 19·19; and after heating to 1050°, 19·23; 1225°, 19·23; 1525°, 19·26; 1900°, 19·26; 2200°, 19·26; and 2500°, 19·26. C. G. Fink found the value 18·81 before drawing into wire, and 19·30, 19·58, and 19·86 when drawn into wire respectively 150, 10, and 1·5 mils in diameter. W. Geiss and J. A. M. van Liempt observed that the cold working of tungsten leads to 19·35 for the density. This is in agreement with the value computed from the X-radiogram. This means that there is no evidence of a compression of the space-lattice by hammering or rolling. P. Hidnert and W. T. Sweeney gave 19·211 for 99·98 per cent. tungsten. From the X-radiograms, H. C. Burger obtained 19·37 when that of sodium chloride is 2·164. According to J. W. Avery and C. J. Smithells, there are changes in the sp. gr. of wires produced by the effects of the lubricant on the surface during the drawing of the wire; by the oxidation of fine wires; and by surface tension effects when small masses are weighed in liquids. The surface impurities must be removed before the sp. gr. of the metal is determined; and the extent of the attack on the underlying metal affects the sp. gr. Thus, a wire of 0·05 mm. diameter and sp. gr. 18·50, had a sp. gr. of 18·51 after it had lost 0·1 per cent. by etching with a soln. of sodium dioxide; 18·92 after a loss of 3·87 per cent.; and 18·91 after a loss of 14·50 per cent. With coarser wires, the change in the sp. gr. is smaller. This means that the wires have an outer layer of smaller sp. gr. than the mass of the wire, and representing a larger proportion of the whole wire, the more its diameter is reduced. The sp. gr. of a tungsten ingot increases rapidly as its diameter is reduced by rolling, etc., so that after a 75 per cent. reduction in sectional area, the sp. gr. is 19·23—the value deduced from the X-ray spectral data is 19·32. This initial increase is due to the closing of the pores in the metal; a subsequent decrease in the sp. gr. is connected with the break up of the crystal grains. The results with 99·998 per cent. tungsten, *A*, and tungsten with 0·75 per cent. thoria, *B*, with wires of diameter *d* mm., are as follows:

d	56	5·0	3·0	1·0	0·3	0·05	0·03
A	17·0	18·45	19·20	19·23	19·22	19·20	18·95
B	17·25	18·70	19·09	19·10	19·00	18·97	18·82

M. L. Huggins estimated the **atomic radius** of tungsten to be 1·58 A.; L. Vegard gave 1·04 A. Observations were made by V. M. Goldschmidt, L. Pauling, and E. T. Wherry from which it follows that the value for sexivalent tungsten is 0·88 A., for quadrivalent tungsten 0·66 to 0·68 A.; and for typical tungsten atoms, 1·37 A. H. G. Grimm, J. C. Slater, and A. M. Berkenheim studied the at. radius; and P. Vinassa, the mol. number. H. Schröder, and E. Donath and J. Mayrhofer discussed the atomic volume; and I. Traube, the at. soln. vol. L. von Uslar said that the **hardness** of tungsten is greater than that of agate; and H. Moissan added that when free from carbon it does not mark glass; and it may be filed with ease. C. G. Fink gave 4·5 to 8·0 for the hardness on Moh's scale; J. R. Rydberg, 9·0; and L. Wiss, 6·5 to 7·5. A. G. Worthing and W. E. Forsythe gave for the hardness respectively on Rockwell's and the sclerescopic scales: One-inch ingot, 20, and 45; the same ingot when swaged to 0·75 in. gave for the surface: 39, and 55·5, and for the centre: 23, and 35; and swaged tungsten gave 45, and 83—for compression, the values for tool-steel are respectively 61 and 95, showing that tungsten is only slightly less hard than tool-steel. E. W. Engel gave 290 for Brinell's hardness; and said that the metal can be filed and ground, but not easily machined. According to F. Koref, fine tungsten wires consisting of a single crystal may be softened by tempering for a short time above 2100° without recrystallization taking place, provided that the amount of deformation which the metal has undergone does not exceed a certain critical limit depending on the nature of the drawing and the thickness of the wire. Thick wires readily recrystallize after only slight reduction in area, whereas thin wires may be reduced 80 per cent. before recrystallization sets in on tempering. All metallic single crystals appear to be strained internally during growth, and unless this strain is removed by suitable tempering the metal works badly and readily recrystallizes on subsequent annealing. The density of the wires increases during tempering and the electrical resistance also changes. E. Ruhstrat found that if tungsten be heated in the electric arc, and abruptly quenched, it becomes so brittle that it can be ground to a fine powder.

H. Moissan observed that tungsten can be welded like iron by hammering at a temp. below its m.p.—*vide supra*, ductile tungsten. Z. Jeffries found a progressive increase in the **tensile strength** of an ingot of tungsten as it is swaged and drawn into wire. Taking the diameter in mils (a mil is 0·001 inch) and the tensile strength in lbs. per sq. in., he found for an ingot 200 mils × 250 mils, 18,000; for swaged rod, 216 mils diam., 50,600; 125 mils, 107,000; 80 mils, 176,600; and 26 mils, 215,000; and for drawn wire, 18 mils, 264,000; 7·23 mils, 340,000; 578 mils, 366,000; 5·50 mils, 378,000; 3·96 mils, 483,000; and 1·4 mils, 590,000. The tensile strength of the drawn wire between 3 and 20 mils is an exponential function of the diameter, and increases more slowly with the finer sizes. F. S. Goucher found also that with a single crystal loaded in tension, the time required for fracture to take place is an exponential function of the load and temp. C. J. Smithells added that the hardness can be reduced by annealing, but it cannot be removed without exceeding the temp. of recrystallization. Coupled with great strength, drawn tungsten wire is markedly ductile at ordinary temp. C. G. Fink gave for the tensile strength of tungsten wires 5·0, 2·8, 1·5 and 1·2 mils in diam., the respective values 460,000, 480,000, 550,000, and 580,000 lbs. per sq. in. J. Königsberger gave 270 to 285 kgrms. per sq. mm. for the tensile strength of tungsten wires; and 100 to 120 kgrms. per sq. mm. for single crystal wires. R. Tajime found the tensile strength of tungsten wire containing one per cent. of thorium, and having a diameter of 0·076 mm., is, in vacuo:

	27°	523°	1323°	1723°	2123°	2523°	2883°
Tensity .	310	200	70	20	9	4·5	1·5 kgrms. per sq. cm.

F. von Göler and G. Sachs gave the results in Fig. 5 for the tensile strength in kgrms. per sq. mm. of 0·1 mm. wires which have been heated to different temp.

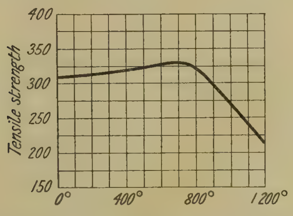

Fig. 5.—The Tensile Strength of Tungsten Wires heated to different temperatures.

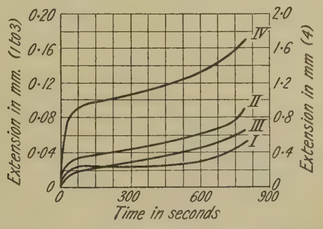

Fig. 6.—The Elongation of Single Crystals of Tungsten under Constant Load.

S. J. Wright gave $3{\cdot}886 \times 10^{12}$ dynes per sq. cm. for Young's modulus. C. H. Jones gave values for wires ranging up to 427 kgrms. per sq. mm.

F. S. Goucher showed that with single crystal wires extended under a constant load, there is first a rapid extension which hardens the metal, and thereafter, the extension continues at a uniform rate until the wire breaks. There is no change in the orientation of the crystal when it is in the most favourable position for slip and the sectional area is decreasing, hence it follows that the resistance to slip is proportional to the applied stress—Curves I to III, Fig. 6. With a multicrystal wire, the observed effect is the joint effect of all the crystals in which slip occurs, so that the extension—time curve has the same form—Curve IV, Fig. 6. With an aggregate of fine crystals the same relation may not be true because the rate of hardening may be modified by the crystal boundaries. When the diameter of single crystal wires is reduced by drawing through dies, they rapidly lose their characteristic ductility, becoming hard and eventually brittle; at the same time there is an increase in the tensile strength which is at first rapid. Thus, F. Koref found for the one-crystal wire prepared by J. Pintsch's process:

Diameter .	0·160	0·149	0·142	0·125	0·070 mm.
Tensity .	105·5	135	137	149	178 kgrms. per sq. mm.

The hardness may be removed by heating the wire to a high enough temp., so that the one per cent. elongation of the hardened wire increases 8 per cent. on annealing. Thus, for a single crystal wire 0·07 mm. diam., the tensile strength was 119 kgrms. per sq. mm.; when drawn to 0·052 mm., 133; when annealed 10 min. at 1500°, 130; 10 min. at 1800°, 130; 0·5 min. at 2100°, 130; and 10 min. at 2100°, 119. According to F. Koref, recrystallization occurs on heating if the reduction in area exceeds 60 to 80 per cent.; the temp. at which this occurs is lower the greater the amount of deformation, and it may occur at a temp. below that required for the removal of the hardness. Single crystal wires can therefore be reduced in area by alternately drawing and annealing to remove hardness provided the reduction in area at each stage does not exceed a critical value. F. Koref discussed the effect of crystal structure on the mechanical properties of tungsten; E. C. Bain and Z. Jeffries, the effect of mechanical work on the crystalline structure; and H. B. de Vore and W. P. Davey, the preferred orientation caused by mechanical work. F. S. Goucher measured the rate of flow of tungsten single crystals under constant load at 1000° K. and 2000° K. The results show an internal hardening which increases rapidly in the early stages of deformation and which tends to become proportional to the increase of stress in the later stages; this stage occupies the major portion of the time required for the fracture of such crystals. The hardening is greater at the lower temperature, and there is evidence that the rate of deformation is an important factor in the hardening process. This hardening may be removed by annealing at 2500° K. for 2 min. An X-ray study of these crystals at all stages of their deformation reveals distortions—crystallographic in nature—which increase progressively with the degree of deformation. Annealing these crystals produces no apparent alteration of this distortion.

Z. Jeffries and R. S. Archer found the effect of temp. on the tensile strength of two kinds of tungsten wire (No. 1—cold drawn; No. 2—annealed—Fig. 7), and observed that the tensile strength increases on a falling temp. but is lower at —185° than at room temp. This effect has been observed only with tungsten. The effect of temp. on the reduction in area, Fig. 8, increases with rising temp. The reduction in area is greater with the cold drawn than with the annealed wire. The effect of temp. on the elongation increases on a falling temp., Fig. 9, until

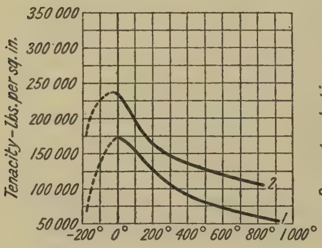

FIG. 7.—The Effect of Temperature on the Tensile Strength.

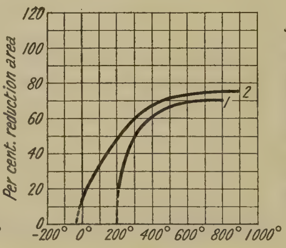

FIG. 8.—The Effect of Temperature on the Reduction in Area.

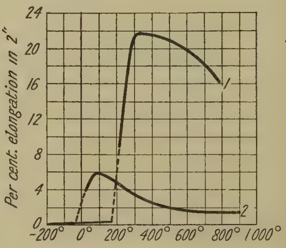

FIG. 9.—The Effect of Temperature on the Elongation.

the region of low temp. brittleness is attained. The maximum elongation occurs at lower temp. the greater the amount of cold working, but the actual elongation at this maximum decreases as the amount of working increases. Comparing the elongation and tensile strength curves, it follows that the development of brittleness is accompanied by a sharp rise in the tensile strength. F. S. Goucher also found that the tensile strength of drawn wire is greatest at about 0° but falls off rapidly at about 727°, probably owing to recrystallization. Long crystals produced by annealing at about 2727° have a lower tensile strength at 0°; and a single crystal wire, containing 2 per cent. of thoria, has a tensile strength about 3 times that of tungsten alone. The load in kgrms. per sq. mm. required to fracture a single crystal wire in one minute at different temp. is illustrated by Fig. 10. Most of the fractures below 527° are intercrystalline, showing that the crystal is stronger than the crystal boundaries. There are sharp changes in the curves near 577°, 1327°, and 2377°; these are said to be consistent with the electrical resistance curve of I. Langmuir; and with the thermal expansion curve of A. G. Worthing. The meaning of the discontinuities is unknown. W. E. W. Millington and F. C. Thompson also studied the plastic deformation of wires of single crystals of tungsten. P. Hidnert and W. T. Sweeney added that the "transformation points appear to be erroneous, and inconsistent with the work of other investigators."

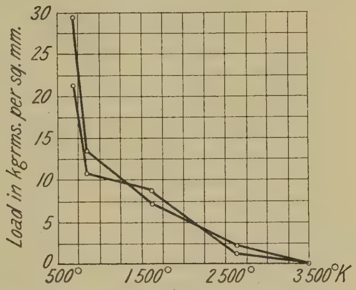

Fig. 10.—The Tensile Strength and Temperature Curve of Single Crystal Wires.

E. Grüneisen said that tungsten has the highest known **elastic limit** with the possible exception of iridium. S. J. Wright gave for Young's modulus $E = 3{\cdot}886 \times 10^{12}$ dynes per sq. cm., taken longitudinally. W. Geiss found the modulus of elasticity E can be represented as a function of the temp., T° K. for single crystal wires by $E=E_0\{(T_m-T)T_m^{-1}\}^{0\cdot263}$, where T_m denotes the m.p. on the absolute scale, and E_0 the modulus at 27°, or 40,000 kgrms. per sq. mm. H. Schönborn found the elasticity of drawn wire is in accord with Hooke's law, and varies from 34,800 to 37,300 kgrms. per sq. mm. at room temp., and falls to 3200 kgrms. per sq. mm. at 1027°. H. L. Dodge studied the effect of temp. on the elasticity of tungsten. He gave $35{\cdot}5+10^{11}$ dynes per sq. cm. at 20°, a value rather lower than C. G. Fink's $41{\cdot}4 \times 10^{11}$ dynes per sq. cm. The modulus was found to decrease uniformly with a rise of temp. up to 1000°, at which temp. it is $32{\cdot}3 \times 10^{11}$ dynes per sq. cm. A. L. Kimball and D. E. Lovell gave $38{\cdot}7 \times 10^{11}$ dynes per sq. cm. for the elastic modulus of swaged tungsten; and W. Widder, $E=E_{20}\{1 \times 0{\cdot}0003472(\theta-20)\}$. The **torsion modulus** of tungsten was found by W. Schriever to be greater than that of any other known material, the value at 2527° being equal to that for steel at room temp. W. Geiss gave for the torsion modulus G, as a function of the temp., T° K., $G=G_0\{(T_m-T)T_m^{-1}\}^{0\cdot263}$, where T_m denotes the m.p. on the absolute scale, and G_0, the modulus at 0°, or 17,100 kgrms. per sq. mm. at 27°. L. P. Sieg found large variations with different samples of tungsten. According to W. Schriever, the torsion varies from 9000 to 22,000 kgrms. per sq. mm. at room temp. and decrease slightly with temp. up to 727°; between 727° and 1727° the modulus falls more rapidly, being 3060 kgrms. per sq. mm. at 1727°. The value for equiaxial tungsten is greater than for drawn wire, and increases with grain-size. Both the torsion modulus and the tensile strength increase as the diameter of the wire decreases. J. Konigsberger gave $8{\cdot}1 \times 10^{11}$ to $9{\cdot}1 \times 10^{11}$ C.G.S. units for the torsion modulus of tungsten wires, and $15{\cdot}5 \times 10^{11}$ to 18×10^{11} C.G.S. units for single crystal wires. E. Edwards and co-workers examined the increase in the torsional stiffness produced by increasing the tension of tungsten wires. S. J. Wright gave $1{\cdot}514 \times 10^{12}$ dynes per sq. cm. for the **modulus of rigidity** of tungsten.

T. W. Richards and E. P. Bartlett found the **compressibility** of tungsten to be $2\cdot85\times10^{-7}$ at 20°, and it appears to be smaller than that of any known metal. P. W. Bridgman found the vol. compressibility of single crystal wires to be: $-\delta v/v=2\cdot18\times10^{-7}p-1\cdot4\times10^{-12}p^2$ at 30°; and $-\delta v/v=3\cdot18\times10^{-7}p-1\cdot5\times10^{-12}p^2$ at 75°; for swaged rod, $-\delta v/v=2\cdot93\times10^{-7}p-1\cdot5\times10^{-12}p^2$ at 30°; and $-\delta v/v=2\cdot95\times10^{-7}p-1\cdot5\times10^{-12}p^2$ at 75°; and for drawn wire, $-\delta v/v=3\cdot15\times10^{-7}p-1\cdot6\times10^{-12}p^2$ at 30°; and $-\delta v/v=3\cdot16\times10^{-7}p-1\cdot5\times10^{-12}p^2$ at 75°. The compressibility β, at 30° for drawn wire and swaged rod are, respectively, $\beta=0\cdot0_6315$ and $0\cdot0_6293$; $\delta\beta/\beta\delta p=0\cdot0_4102$ and $0\cdot0_4102$; $-\delta\alpha/\alpha\delta p=0\cdot0_52$ and $0\cdot0_54$; and $-\beta^{-1}(\delta\alpha/\alpha\delta p)=1\cdot24$ and $13\cdot7$, where α denotes the coeff. of thermal expansion. L. H. Adams gave $\delta\beta=-0\cdot03$. T. W. Richards gave for the **internal pressure,** 13,400 megabar at 20°; R. F. Mehl gave 1020 kilomegabars, and for the maximum disruptive press., 3570 kgrms. per sq. mm. K. Iokibe and S. Sakai gave for the **viscosity** of tungsten, at 16°, $\eta=9\cdot37\times10^8$; and G. Subrahmaniam, $8\cdot638\times10^8$. A. L. Kimball and D. E. Lovell also made observations on the internal friction of tungsten. P. W. Bridgman studied the effect of pressure on the rigidity. For the **diffusion** of carbon, and of thorium in tungsten, *vide infra;* G. Grube and K. Schneider, and J. Laissus studied the diffusion of tungsten into iron; and J. M. Eglin, of barium into tungsten.

C. G. Fink[3] found the coeff. of **thermal expansion** of a tungsten wire, 0·005 in. diam., to be $\alpha=0\cdot0_5336$ between 20° and 100°; and he gave $\alpha=0\cdot0_543$ for tungsten. I. Langmuir gave $0\cdot0_538$ between 1000° and 1500°; $0\cdot0_544$ between 1500° and 2000°; and $0\cdot0_541$ between 1000° and 2000°. H. L. Dodge obtained $0\cdot0_5456$ over the range 20° to 675°. If l be the length of the filament at 300° K., then, for a temp., T° K., between 1200° K. and 2500° K., $\delta l/l=0\cdot00245(T-300)\times10^{-3}+0\cdot000567(T-300)^2\times10^{-6}$. A. G. Worthing obtained $0\cdot0_5444$ at 27°; $0\cdot0_556$ between 1000° and 1500°; $0\cdot0_566$ between 1500° and 2000°; $0\cdot0_561$ between 1000° and 2000°; or $0\cdot0_5519$ at 1027°; and $0\cdot0_5726$ at 2027°. If l_0 is the length at 300° K., and l the length at a temp. T° K. between 1200° K. and 2700° K., $\delta l/l_0=0\cdot0_5449(T-300)+0\cdot0_{12}24(T-300)^3$; and for temp. T° K. between 300° K. and 2700° K., $\delta l/l_0=0\cdot0_5444(T-300)+0\cdot0_{10}45(T-300)^2+0\cdot0_{12}22(T-300)^3$; or

T° K. . .	330°	1200°	1500°	1800°	2100°	2400°
α . . .	$0\cdot0_5444$	$0\cdot0_5506$	$0\cdot0_5550$	$0\cdot0_5606$	$0\cdot0_5674$	$0\cdot0_5754$

The results of A. G. Worthing can be represented by $l=l_{27}(1+0\cdot0_5444\theta+0\cdot0_{10}45\theta^2+0\cdot0_{12}220\theta^3)$, and D. W. Berlin's results were in agreement with this. W. Widder gave 0·00000456 at 20°, and 0·0000038 at −190°. K. Becker gave $0\cdot0_575$ between 18° and 2200°; $0\cdot0_566$ between 18° and 1750°; and $0\cdot0_558$ between 18° and 1380°. J. Disch gave:

	−190° to 0°	−100° to 0°	0° to 100°	0° to 200°	0° to 300°	0° to 400°
α . . .	$0\cdot0_538$	$0\cdot0_541$	$0\cdot0_545$	$0\cdot0_546$	$0\cdot0_547$	$0\cdot0_548$

or, if l_0 refers to the length at 0° and l the length at θ°, $l=l_0(1+0\cdot0_5446\theta+0\cdot0_973\theta^2)$ between 0° and 400°; and $l=l_0(1+0\cdot0_5445\theta+0\cdot0_8328\theta^2)$ between −190° and 200°. F. S. Goucher said that there is evidence of discontinuities in the thermal expansion at about 850° K., 1600° K., and 2650° K., but P. Hidnert and W. T. Sweeney and others have not been able to confirm this statement. P. Hidnert and W. T. Sweeney represented their results between −105° and 502° by $l=l_0(0\cdot0_5428\theta+0\cdot0_958\theta^2)$; and they found the average values to increase regularly with temp.:

	−100° to −50°	−50° to 0°	0° to 50°	50° to 100°	100° to 200°	200° to 300°	300° to 400°
α . . .	$0\cdot0_542$	$0\cdot0_543$	$0\cdot0_543$	$0\cdot0_544$	$0\cdot0_545$	$0\cdot0_546$	$0\cdot0_547$

	400° to 500°	−100° to 0°	0° to 100°	0° to 200°	0° to 300°	0° to 400°	0° to 500°
α . . .	$0\cdot0_548$	$0\cdot0_542$	$0\cdot0_543$	$0\cdot0_544$	$0\cdot0_545$	$0\cdot0_545$	$0\cdot0_546$

and for the range −100° to 500°, $\alpha=0\cdot0_545$. W. D. Coolidge gave 0·35 cal. per cm. per degree for the **thermal conductivity** of tungsten; S. Weber, 0·383 cal.

per cm. per degree or 1·605 watts per cm. per degree at 0°, and T. Barratt and R. M. Winter, 0·476 cal. per cm. per degree at 17°, and 0·472 cal. at 100°. The relation of the thermal and electrical conductivities was studied by E. Grüneisen and E. Goens. A. G. Worthing found that the thermal conductivity in watts per cm. per degree increases linearly from 1000° K. to about 2500° K.:

T° K. . .	1000°	1300°	1600°	1900°	2200°	2500°	2800°
Conductivity	0·84	0·93	1·02	1·09	1·15	1·21	1·27

C. Zwikker gave for the thermal conductivity, k watts per cm. per degree:

T° K. . .	1800°	2000°	2200°	2400°	2600°	2800°
k . . .	1·22	1·29	1·33	1·37	1·405	1·43

H. V. Regnault[4] found the **specific heat** of tungsten to be 0·03342; and L. Weiss, 0·0358. J. Dewar gave 0·0095 between —253° and —196°; P. Nordmeyer and A. L. Bernoulli, 0·0357 between —185° and 20°; A. W. Grodspeed and E. F. Smith, 0·0338 between 20° and 100°; H. Mache, 0·0336 between 0° and 100°; E. Defacqz and M. Guichard, 0·0340 between 15° and 93°; and 0·0375 between 15° and 423°; M. von Pirani, 0·033 at 340°; 0·036 at 1000°; and 0·041 at 1350°; W. Geiss and J. A. M. van Liempt gave 0·0323; O. M. Corbino, 0·0334; whilst K. K. Smith and L. I. Bockstahler gave 0·045 between 2375° K. and 2475° K.—this is eq. to an at. ht. of 8·3. K. K. Smith and P. W. Bigler found 0·0479 for the sp. ht. at 2095° to 2212°. The last-named results were discussed by P. F. Gaehr. H. A. Jones and co-workers gave $C_p=4\cdot70+0\cdot0015T$. W. Geiss and J. A. M van Liempt observed no perceptible difference in the sp. ht. of cold-drawn and of crystallized metal. The corresponding **atomic heat** varies from 1·75 between —253° to —196° to 8·75 between 2095° and 2212°. F. Wüst and co-workers gave $C_p=6\cdot17$ at 100°, and 6·72 at 1500°. F. Lange found for the sp. ht. 0·47 at —240°; 1·00 at —230°; 1·65 at —220°; 2·26 at —210°; 2·78 at —200°; 3·25 at —190°; and 3·69 at —180°; and W. M. Latimer obtained 6·0 for the at. ht., C_p, between 250° and 900°. F. M. Jäger and E. Rosenbohm gave for temp. up to 1300°, and for tungsten free from oxide, $c_p=0\cdot02744+0\cdot132672\times10^{-4}\theta-0\cdot091488\times10^{-8}\theta^2+0\cdot067812\times10^{-11}\theta^3$, or abbreviated, $c_p=0\cdot0274412+0\cdot0000132\theta$. H. Danz gave:

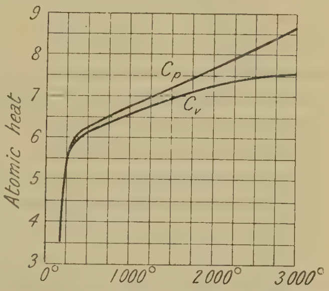

Fig. 11.—The Effect of Temperature on the Atomic Heats of Tungsten.

	400°	500°	600°	700°	800°	900°
C_p . . .	7·199	7·304	7·409	7·515	7·620	7·724
C_v . . .	7·092	7·180	7·264	7·347	7·429	7·506

C. Zwikker gave the following results, Fig. 11, for the at. ht. of tungsten at different temp. on the absolute scale:

°K. . .	100°	200°	300°	600°	900°	1200°
C_p . . .	3·77	5·32	5·90	6·23	6·57	6·90
C_v . . .	3·77	5·30	5·87	6·15	6·44	6·71
°K. . .	1500°	1800°	2100°	2400°	2700°	3000°
C_p . . .	7·23	7·56	7·89	8·22	8·56	8·89
C_v . . .	6·96	7·18	7·36	7·50	7·62	7·70

F. M. Jäger and E. Rosenbohm made analogous observations. A. Magnus and H. Danz gave for the at. ht. of 99 per cent. tungsten over the range 400° to 900°, $C_p=6\cdot7807+0\cdot0010475\theta$; and A. Magnus and H. Holzmann, $C_p=5\cdot8947+0\cdot0_383338\theta$ between 100° and 900°; and H. A. Jones and I. Langmuir gave $C_p=4\cdot7+0\cdot0015T$ for the at. ht. between 900° and the m.p.; C_p is here expressed in cals. per gram-atom per degree. Since the vol. of a wire 1 cm. long and 1 cm. diamter is $\frac{1}{4}\pi$ c.c., the conversion factor from cals. per gram-atom to watt seconds per degree is $\pi \times 19{\cdot}35 \times 4{\cdot}185/4 \times 184 = 0{\cdot}3456$. He discussed the application of P. Debye's formula. A. G. Worthing obtained for the at. ht., 6·20 at 330° K.; 6·50 at 1200° K.; 6·95 at 1500° K.; 7·40 at 1800° K.; 7·85 at 2100° K.; and 8·30 at 2400° K.; and for the at. ht. at constant vol. he gave 5·95 at ordinary temp., 6·25 at 1200° K., and 7·35 at 2400° K. A. G. Worthing also found that E. Grüneisen's relation a/C_p rises from $7{\cdot}16 \times 10^{-7}$ at 330° K. to $9{\cdot}08 \times 10^{-7}$ at 2400° K. E. D. Eastman and co-workers computed $C_p - C_v = 0{\cdot}050$ Cal. per degree per mol. A. Magnus and H. Holzmann, O. M. Corbino, L. I. Bockstahler, and H. Hunkel also obtained values in close agreement with those of A. G. Worthing. J. Maydel discussed some relations of the sp. ht.; and W. M. Latimer, the thermal energy of the electrons in tungsten.

According to C. W. Siemens and A. K. Huntington,[5] tungsten can be fused in the electric arc furnace; H. Moissan also fused the metal in the arc furnace, and noted that it is less fusible than chromium and molybdenum. L. Weiss fused the metal by heating it in the electric arc, between graphite electrodes; and the Allgemeine Electrizitäts Gesellschaft obtained fused tungsten from rods made of the compressed powder as anodes for the electric arc. There are difficulties in determining the m.p. of the highly purified metal with a disappearing filament pyrometer: (i) The fixing of the thermometer scale; and (ii) when the pyrometer is focussed on the surface of the molten metal the observed "brightness" temp. has to be corrected for the spectral emmissivity. If a block of fused tungsten be under black body conditions, *i.e.* contained in an enclosed vessel whose walls are uniformly heated to a temp. T, its temp. will be T; if the block of tungsten could be removed without altering its temp., and its brightness matched with the disappearing filament pyrometer, its temp. would appear to be at some lower temp. say, T_b, called the *brightness temperature.* If instead of matching the brightness of the tungsten, its colour be matched against that of the black body, it will appear to have another temp., say, T_c, called the *colour temperature* with tungsten, the colour temp. is always higher than the true temp. by about 0·6 per cent. at 1000° K., and 2·3 per cent. at 3500° K. The brightness temp. is related to the true temp. by the equation $T^{-1} - T_b^{-1} = C_2^{-1}\lambda 2{\cdot}303 \log_e e\lambda$, where $e\lambda$ is the spectral emissivity for a wave-length λ, and C_2 is a constant. If the temp. of the block of tungsten be measured by comparing the rate of radiation of energy with that of the black body, its temp., say T_r, is called the *radiation temperature,* will be lower than the true temp. This subject was discussed by C. Zwikker, R. Davis and K. S. Gibson, E. Lax and M. Pirani, F. Wolfers, H. A. Jones, F. Henning and W. Heuse, M. L. Phillips, H. Hunkel, and H. C. von Alphen. C. Zwikker gave $T^{-1} - T^{b-1} = \lambda C_2^{-1} 2{\cdot}303 \log_e e\lambda$, where $C_2 = 14{,}330\mu$ degree. A. G. Worthing and W. E. Forsythe found for the corresponding temp., up to the m.p. (3655° K.):

True temp., T .	1000°	1500°	2000°	2500°	3000°	3500°	3655° K.
Colour temp., T_c .	1006°	1517°	2033°	2557°	3094°	3646°	3817° K.
Brightness temp., T_b	966°	1420°	1857°	2274°	2673°	3053°	3165° K.
Radiation temp., T_r	581°	991°	1428°	1859°	2286°	2704°	— °K.

H. von Wartenberg gave 2800° to 2850° for the **melting point** of tungsten; M. von Pirani, 3100°, and 3250°; O. Ruff and O. Goecke, 2575° for 99·2 per cent. tungsten, and O. Ruff gave 2650° for the pure metal. C. W. Waidner and G. K. Burgess said that the m.p. is 3080°; W. E. Forsythe, 3027°; W. R. Mott, 3402°; M. von Pirani and A. R. Meyer gave 3100°; I. Langmuir, 3267°; and G. P. Luckey, and A. G. Worthing, 3357°—and 3372° to 3392°—M. von Pirani and H. Alterthum obtained 3387° for the m.p. of tungsten melting under black body conditions; and F. Henning and W. Heuse similarly obtained 3370°. G. P. Luckey found that the effect of the pressure of the atmosphere of nitrogen on the m.p. is represented by 3350° at 1 atm. press.; 3321° at 8 atm.; 3309° at 14 atm.; 3289° at 21 atm.; and 3291° at 28 atm. P. Woog discussed the hollow-ing out of tungsten bars by central fusion by the passage of a heavy electric current; and L. P. Sieg, the relation between the m.p. and the coeff. of elasticity.

C. W. Siemens and A. K. Huntington, and H. Moissan noted the volatilization of tungsten when it is melted in the electric arc furnace. E. Tiede and E. Birnbräuer found that in a vacuum furnace tungsten at 2450° yields a sublimate of rhombic or rhombohedral crystals—as indicated above, the crystals are cubic. When the sublimate condenses in a crystalline form on hot surfaces, a mirror is formed on a cold surface. M. Arndt observed that when an electric arc with a tungsten anode is heated in vacuo, the vaporized metal condenses in films. M. R. Mott gave 6300° for the **boiling point**; I. Langmuir calculated 4727°; and C. G. Fink, 3700°. According to I. Langmuir, the **rate of evaporation** of tungsten in vacuo, m grms. per sq. cm. per second, at T° K., is $\log m=15\cdot402-47444T^{-1}-1\cdot4\log T$:

T° K.	1600°	2000°	2400°	2800°	3200°	3655°
m .	$3\cdot7\times10^{-20}$	$2\cdot32\times10^{-14}$	$1\cdot58\times10^{-10}$	$8\cdot28\times10^{-8}$	$8\cdot79\times10^{-6}$	$4\cdot70\times10^{-4}$

The subject was discussed by H. A. Jones and co-workers, and M. R. Andrews. C. Zwikker gave $\log M=11\cdot92-4\cdot84\times10^4T^{-1}-0\cdot368\log T-0\cdot00016T$, where M denotes the number of grams evaporated per sq. cm. per second, and

T° K. .	1500°	2000°	2500°	3000°	3400°
M .	$0\cdot0_{21}178$	$0\cdot0_{13}155$	$0\cdot0_{9}833$	$0\cdot0_{5}105$	$0\cdot0_{4}708$

G. R. Fonda found that the rate of evaporation is independent of the diameter of the wire between 0·051 and 0·254 mm.; but it is affected by the grain-size. Thus, for a fine-grained wire at 2900° K., M has a mean value of 4×10^{-7}, but with a coarse-grained wire, $M=2\cdot6\times10^{-7}$. The rate of evaporation determines the limit of temp. at which the filament lamp can be operated. I. Langmuir showed that the rate of evaporation is reduced if the filament is surrounded by an atmosphere of a neutral gas. G. R. Fonda found that with a wire 0·051 mm. in diameter, the rates of evaporation in vacuo and in nitrogen were respectively $M=420$ and 21; and with a 0·69 mm. wire in nitrogen and in argon $M=13$, and 9 respectively. W. H. Rodebush observed the value of A in the equation for the number of electrons, n, evaporating from a metal filament per sq. cm. per sec., $n=AT^{-\frac{1}{2}}e^{-b/T}$, to be $1\cdot48\times10^{26}$ when the calculated result at 2000° K. is $6\cdot00\times10^{26}$. The subject was studied by S. Weber, F. J. Wilkins, E. Oosterhuis, and G. R. Fonda. The last-named observed that the rate of evaporation of tungsten filaments at 2870° K. in a mixture of argon with 14 per cent. nitrogen varies from 2×10^{-9} to 230×10^{-9} grm. per sq. cm. per sec. as the pressure is reduced from 1650 to 0 mm. A. G. Worthing and W. C. Baker observed that the rate of evaporation of tungsten is positively affected by strong electrostatic fields, the effect disappears if the field strength is less than a million volts per cm. H. Alterthum studied the effect of salt vapours on the evaporation of tungsten. The volatility of tungsten is increased in a vacuum lamp if the metal has been sprayed with various salts—particularly the halogen salts. Reaction occurs between the filament and the wall as well as on the filament and at the wall. I. Langmuir found that the **vapour pressure** of tungsten, p mm., can be represented by $\log p=15\cdot502-47444T^{-1}-0\cdot9\log T$, for

T° K.	2000°	2400°	3200°	3400°	3540°	5100°
p .	$6\cdot5\times10^{-12}$	$4\cdot92\times10^{-8}$	$4\cdot67\times10^{-5}$	$3\cdot20\times10^{-4}$	0·08	760

The values at the m.p., 3540° K., and the b.p., 5110° K., have been obtained by extrapolation. P. Winternitz also calculated values for the vap. press. of tungsten: $\log p=-48982\cdot72T^{-1}+1\cdot78\log T+3$, so that $p=1$ at 5100°; and J. A. M. van Liempt gave $\log p=-46440T^{-1}+9\cdot15$. W. Herz said that the **heat of fusion** has a value between 1000 and 5000 cals.; and I. Langmuir, that the latent **heat of vaporization** at a temp. T° K. is $\lambda=218,000-1\cdot8T$ cals. per gram-atom. This is greater than the heat developed by any known chemical reaction. P. Winternitz gave 223,900 cals. per gram-atom at room temp.; M. R. Andrews, 177,000 cals.;

and F. S. Mortimer, 201,200 cals. L. Hamburger and co-workers discussed the trouble attending the use of tungsten filaments by the sublimation of the metal on to the walls of the glass bulbs. J. A. M. van Liempt gave 40·49 to 41·62 for **Trouton's constant**; and I. Langmuir, 3·5 for the **chemical constant**—F. Simom gave 0·012. M. Delépine and L. A. Hallopeau gave for the **heat of oxidation,** (W,3O)=195·41 Cals. at constant vol., and 196·3 Cals. at constant press.; and (W,2O)=131·4 at constant press. L. Weiss gave 321·08 Cals. per eq. for the heat of combustion. J. E. Moose and S. W. Parr gave 1059 cals. per gram, or 194·9 Cals. per mol.; W. G. Mixter, 196·3 Cals. per mol. J. A. M. van Liempt observed that the difference between the heats of oxidation per gram atom of worked and unworked tungsten, *viz.* 193·5 and 195·0 Cals. is within the limits of experimental error; and F. Koref and H. Wolff found the heats of dissolution of cold-drawn, and recrystallized tungsten show no measurable difference. G. N. Lewis and co-workers, and E. D. Eastman gave 8·4 for the at. **entropy** of tungsten at 25°; R. C. Tolman, 53·7 at 25°; B. Bruzs gave 8·4 at 25°, and 27·4 at the m.p.; and W. Herz, 14·60. The subject was discussed by W. M. Latimer, W. Herz, and by E. D. Eastman and co-workers. R. D. Kleeman discussed the internal and free energy of tungsten.

H. von Wartenberg[6] found the **index of refraction** of tungsten to be $\mu=2{\cdot}76$; the **absorption coefficient,** $k=2{\cdot}71$; and the **reflecting power,** $R=48{\cdot}6$ per cent., for $\lambda=0{\cdot}579\mu$. A. G. Worthing found μ and k for tungsten at 27° to be respectively 3·86 and 0·81, and at 1627°, respectively 3·85 and 0·89. W. W. Coblentz found for the percentage reflecting power, R, of tungsten for light of wave-length λ:

λ	0·4	0·5	1·0	2·0	4·0	6·0	8·0	10·0	12·0
R	47·0	49·3	62·3	84·6	92·8	94·6	95·6	95·5	96·3 per cent.

J. T. Littleton found at room-temp., $R=54{\cdot}5$ per cent. when $\lambda=0{\cdot}589\mu$. The subject was discussed by G. Jaffé. F. E. Dix and L. H. Rowse gave for the indices of refraction, μ, extinction coeff., μk, and percentage reflecting power, R:

λ	670	630	570	490	450	370	350
μ	1·52	1·42	1·28	1·11	1·08	0·87	0·82
μk	3·65	3·60	3·27	2·94	3·38	2·78	2·57
R	70·9	70·2	67·8	66·0	69·1	69·0	67·1

W. Weniger and A. H. Pfund studied the reflecting power of tungsten; and R. Hamer examined the effect in the ultra-violet. A. Grau studied the luminosity curves of tungsten. A. G. Worthing measured the **spectral emissivity,** e, by heating tungsten tubes drilled with small holes, and measuring the ratio of the brightness of holes (under black body conditions) to the brightness of the outer tungsten surface. He found for temp. up to the m.p. 3655° K.:

	T° K.	300°	1000°	1500°	2000°	2500°	3000°	3500°	m.p.
e	0·665μ	0·470	0·456	0·445	0·435	0·425	0·415	0·405	0·402
	0·467μ	0·505	0·486	0·476	0·469	0·462	0·455	0·449	0·447
	mean	—	0·464	0·457	0·452	0·446	0·440	0·434	0·433
	colour	—	0·396	0·383	0·370	0·355	0·343	0·329	0·324
	total	0·032	0·114	0·192	0·260	0·303	0·334	0·351	0·304

B. T. Barnes studied the emissivity of carbonized tungsten. E. P. Hyde and co-workers represented the relation between the colour temp., T_c, and the total radiation, $I_r=aT_c^{4\cdot93}$, where a is a constant. C. Zwikker gave for the spectral emissivity, $e\lambda$, for $\lambda=0{\cdot}665\mu$, and the total radiation, I_r, in watts per sq. cm.,

T° K.	1200°	1500°	2000°	2500°	3000°	3400°
$e\lambda$	0·458	0·451	0·440	0·427	0·415	0·407
I_r	1·70	5·52	24·0	69·4	162	291

H. A. Jones gave for the radiation, I_r, from the surface in watts per sq. cm.,

T° K.	273°	300°	500°	1000°	1500°	2000°	2500°	3000°	3655°
I_r	0	0·0416	0·00970	0·602	5·54	23·9	69·2	160·1	399·4

C. Zwikker found that if B is the brightness of a black body at T_c, expressed in international candles per sq. cm., and B_0 the brightness of tungsten at T_b, $B=B_0e^{C_2/2\cdot3303\lambda(T_b^{-1}-T_c^{-1})}$. The subject was discussed by G. Holst and co-workers. The total emissivity, e_T, is given by the relation $I_r=e_T\sigma T^4$, where I_r represents the radiation intensity, *i.e.* the total radiation per unit area, and σ is a constant. The normal brightness, B, at any temp. is the candle power per sq. cm. measured in a direction normal to the surface :

T° K. .	1000°	1500°	2000°	2500°	3000°	3500°	m.p.
B .	0·00012	0·33	20·0	237·5	1257	4220	5740

Tungsten deviates from the cosine law for luminous radiation which requires that an element of the light source shall appear equally bright from any angle Actually, as the angle varies from normal to grazing incidence, the brightness increases and decreases rapidly. The efficiency of the light emissivity of a tungsten filament is measured by the ratio of the input in watts to the light emitted expressed in terms of lumens per watt. Let I_r denote the total radiation intensity in watts per sq. cm. ; and E, the luminous efficiency in lumens per watt :

T° .	300°	1000°	1500°	2000°	2500°	3000°	3500°	3655°
I_r .	0·0015	0·654	5·55	23·72	67·60	153·9	300	360
E .	—	—	0·20	2·78	11·67	27·1	45·9	53·1

E. O. Hulbert measured the variations in the emissivity of tungsten wires for light of wave-length from λ=3200 A. to 5500 A. between 1746° K. and 2785° K., and found :

λ .	3478	3956	4435	4916	5400	5641 A.
E .	0·470	0·484	0·466	0·460	0·447	0·436

Observations were also made by F. Henning, and E. Furthmann. M. Luckiesh and F. K. Moss discussed the luminosity of the tungsten lamp. The eye is not equally sensitive to light of all wave-lengths ; according to B. P. Dudding and C. J. Smithells, there is a maximum in the relative visibility for light of wave-length $0{\cdot}0_455$ cm. The luminous value of the radiation renders it necessary to multiply the energy at each wave-length by the relative visibility. The efficiency, E, increases as the temp. is raised, but at the same time there is a slight decrease owing to the radiation becoming selective, and approaching that of a black body. A. G. Worthing and W. E. Forsythe found for a tungsten wire 1 cm. long and 1 cm. diameter, in vacuo, the following value for the current, C amps., the fall of potential, V volts, the resistance, R ohms, the power, P watts, and the luminous flux, in lumens :

T° K. . .	300°	1000°	1500°	2000°	2500°	3000°	3500°	3655°
R . . .	$0{\cdot}0_5718$	32·73	53·35	75·20	98·40	122·5	147·2	155
V . .	$0{\cdot}0_457$	8·23	30·7	75·5	146·3	247·7	381	428
C . .	$0{\cdot}0_58$	0·251	0·575	1·004	1·487	2·020	2·59	2·76
P . . .	0·00045	2·068	17·62	75·8	217·5	501·0	985	1180
Lumens .	—	0·0012	3·3	208·5	2490	13300	45200	61800

B. E. Shackelford discussed the difference in the brightness of the inner and outer surfaces of a heated tungsten helical filament ; G. Ribaud, the relation between the current and the temp. of tungsten filaments ; and W. Geiss, the relation between the total radiation and the electric resistance. The efficiency of a tungsten filament in vacuo determines its temp., and this enables the temp. scale to be reproduced. R. E. Nyswander measured the selective radiation in the ultra-red and found a maximum for $\lambda=2{\cdot}3\mu$ at 1278° ; for $1{\cdot}9\mu$ at 1547° ; for $1{\cdot}7\mu$ at 1729° ; for $1{\cdot}61\mu$ at 1826° ; for $1{\cdot}52\mu$ at 1934° ; for $1{\cdot}475\mu$ at 1994° ; and for $1{\cdot}425\mu$ at 2063°. The bands of selective emission in the ultra-red observed by R. E. Nyswander were shown by W. W. Coblentz to be atm. absorption bands. The wave-length of the maximum emission of a tungsten filament lamp was $1{\cdot}43\mu$, and with a carbon filament lamp, $1{\cdot}48\mu$. A. H. Taylor discussed the luminous efficiency of tungsten filament lamps ; H. B. Dorgelo, the absorption of light by tungsten ; A. G. Worthing the deviations of the light from the cosine law ; W. E. Forsythe and F. Christison, A. L. Hellgott, and B. T. Barnes, the energy of the radiation ; and H. C. von Alphen, the radiation.

The **emission of electrons** from hot tungsten has been studied by O. W. Richardson,[7] H. Jones and R. Whiddington, N. A. de Bruyne, T. E. Stern and co-workers, H. L. van Velzer and W. R. Ham, E. H. Hall, A. H. Warner, L. P. Smith, W. E. Forsythe and E. M. Watson, R. A. Millikan and C. C. Lauritsen, F. Rother and E. Münder, P. A. Ross, R. J. Piersol, R. S. Bartlett, I. Langmuir, A. C. Davies and R. N. Moss, W. R. Ham and M. W. White, K. K. Smith, H. E. Krefft, W. Hüttemann, L. H. Germer, E. Lorenz, A. T. Waterman, J. M. Eglin, L. A. du Bridge, J. A. Becker and D. W. Mueller, H. Klumb, C. C. Lauritsen and S. S. Mackeown, L. I. Bockstahler, C. del Rosario, S. C. Roy, H. E. Farnsworth, H. E. Ives, H. Hunkel, F. E. Colpitts, H. Nukiyama and H. Horikawa, W. B. Nottingham, C. E. Berger, E. Meyer, E. Spiller, W. H. Brattain, G. P. Thomson, K. Sixtus, H. N. Kozangwsky, C. C. van Voorhis and K. T. Compton, and S. Dushman and co-workers—*vide* tantalum, **9.** 65, 2. According to H. H. Lester, the work, ϕ, done by an electron in escaping from the surface of tungsten is 4·478 eq. volts ; and, according to R. Hamer, the longest wave-length of radiation which can cause photoelectric emission of electrons is 2615 A. S. Dushman and co-workers found for the electronic current, $i=60{\cdot}2T^2e^{-52600/T}$; and the relations between the emission in ampères per sq. cm. and temp. calculated from this equation for well-aged tungsten filaments as well as for thoriated tungsten, are :

$T°$ K.		800°	1500°	2000°	2500°	2800°
Electron emission	tungsten	—	$7{\cdot}58\times10^{-8}$	$8{\cdot}92\times10^{-4}$	0·267	3·12
	Th-tungsten	$1{\cdot}20\times10^{-11}$	$1{\cdot}82\times10^{-2}$	9·55	117·5(2300°)	—

C. Zwikker made observations on this subject ; he found for the thermionic emission, $i=60{\cdot}2T^2e^{-52230/T}$ amp. per sq. cm., or

$T°$ K.	1500°	2000°	2500°	3000°	3400°
i	$0{\cdot}0_6102$	0·00112	0·302	14·9	149

I. Langmuir found that higher values for electron emission are obtained from filaments containing 1 to 2 per cent. thoria. With an ordinary thoriated filament, the thorium is present as the dioxide, and the electronic emission is the same as for tungsten alone ; but if the temp. is raised above 2600° K., the thoria reacts with the tungsten to form thorium. This reaction was studied by C. J. Smithells. I. Langmuir found that the thoriated filament heated to 2600° K. gives the normal value for tungsten at 1500° K. since the thorium metal will have evaporated from the surface. It is therefore necessary after flashing the thoriated filament at 2800° K. for, say, 3 min. to lower the temp. to about 2000° K. to allow the thorium to diffuse to the surface from the interior. The emission at 1500° K. is then 100,000 times the value for tungsten alone—*vide supra.* If the temp. is kept below 1900° K., this high value is retained indefinitely, but it is destroyed above 2200° K. owing to the volatilization of the thorium. According to A. S. Cachemaille, and the British Thomson-Houston Co., the presence of reducing agents like carbon, or boron, or tungsten carbide favours the reduction of the thoria to thorium. W. G. Burgers, and J. A. M. van Liempt discussed this subject. I. Langmuir and K. H. Kingdon found that the thorium surface is destroyed by bombardment with positive ions. The lowest voltage, V, at which spluttering occurs in different gases ; and the ratio, n, of the thorium atoms removed to the number of impacting ions at 150 volts, are :

	H	Ne	Ar	Cs	Hg	He
V	600	45	47	52	55	(35)
n	0	0·023	0·080	0·084	0·044	0·00015

I. Langmuir and co-workers, and J. A. Becker also found that if the tungsten filament be heated to 1200° in the sat. vapour of cæsium, the cæsium is attracted by the tungsten surface, and provided the temp. is below 1200° K., the metals evaporate so slowly that the surface becomes covered with a layer of cæsium ions, and the electron emission is greatly augmented. If the filament has a layer of adsorbed ions, the cæsium ions are retained more firmly. According to S. Kalandyk, iodine decreases the positive emission of a new tungsten filament, but does not affect one previously heated. It also increases the negative emission from tungsten. W. H. Crew found that light augments the emission of electrons from hot filaments. R. H. Fowler discussed the electron theory of thermionic emission; C. C. van Voorhis and K. T. Compton, the work of condensation of the electrons; and M. Pirani and H. Schönborn, electronic collision. J. A. M. van Liempt tried with good results the association of 0·1 to 3 per cent. of hafnia in place of thoria in tungsten lamp filaments.

W. A. Jenkins [8] found that slow-moving positive ions are emitted by tungsten when its temp. exceeds 2500°. R. L. Kenworthy, L. P. Smith, E. Meyer, E. T. S. Appleyard, H. B. Wahlin, and P. K. Mitra studied the emission of positive ions from hot tungsten filaments; and S. Kalandyk, from filaments in iodine vapour. C. Kenty and L. A. Turner observed that active nitrogen adsorbed by tungsten reduces the thermionic current. O. Stuhlman found that the minimum potential for the emission of secondary electrons is 372 volts, and R. L. Petry observed that secondary electronic emission occurred with the primary potentials, 11·0, 17·1, 25·2, 29·3, 40·5, 46·0, 89·5, and 271·5 volts; S. C. Roy found that the thermionic emission from tungsten between 1900° K. and 2700° K. is due to the photoelectric activity of the radiation from the bodies themselves. R. H. Whiddington discussed the velocity of the electrons liberated from tungsten by X-rays; A. G. Worthing, the pulsating thermionic discharge in evacuated tungsten lamps; H. E. Farnsworth, the electronic bombardment of tungsten surfaces; W. de Groot, the temp. and electronic emission of the tungsten arc; C. Davison and L. H. Germer, A. H. Warner, and T. H. Harrison, the thermionic work function; J. F. Congdon, the kinetic energy of the electrons from a hot tungsten filament; A. C. Davies and R. N. Moss, and N. B. Reynolds, the loss of thermionic activity by thoriated tungsten filaments; and R. Hamer, and H. Klumb, the photoelectric effect.

The visible and ultra-red **spectrum** of an incandescent tungsten wire at 2200° is continuous. The spectrum is plotted in Fig. 12—A. W. Hull.[9] The shaded portion represents the visible part. If the wave-lengths were all reduced ten-thousandfold, the curve would coincide very nearly with the dotted line in Fig. 13. J. N. Lockyer observed the lines 5514·9 and 5492·6 in the oxy-coal gas **flame spectrum.** The **spark spectrum** of tungsten was examined by W. A. Miller, R. Thalén, E. Demarçay, F. Exner and E. Haschek, A. Hagenbach and H. Konen, A. G. G. Leonard, H. W. Vogel, J. H. Pollok, H. B. Lemon, A. G. Worthing and R. Rudy, and J. M. Eder and E. Valenta. The chief lines are 5734 in the yellow; 5514, 5492, 5224, 5071, 5069, 5053, 5015, and 5008 in the green; 4888 and 4843 in the blue; and 4302, 4295, and 4269 in the indigo-blue. E. J. Allin and H. J. C. Ireton, and E. O. Hulbert discussed the spectrum of the spark in water; S. Smith, the spectra of electrically exploding wires; and C. Porlezza and A. Donati, the spectroscopic detection of tungsten. The **arc spectrum** was studied by J. N. Lockyer, M. Belke, W. J. Humphreys, C. C. Kiess and W. F. Meggers, A. Sellerio, F. Exner and E. Haschek, C. B. Hasselberg, O. Hagenbach and H. Konen, W. E. Forsythe and M. A. Easley, and J. M. Eder and E. Valenta; and the **ultra-**

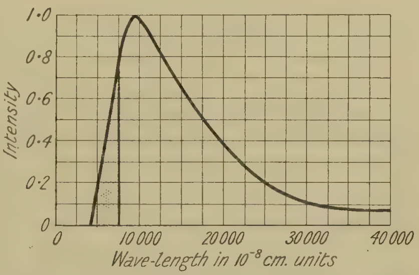

FIG. 12.—The Spectrum of Incandescent Solid Tungsten.

violet spectrum, by W. A. Miller, M. Bayen, O. Lohse, T. Aden, L. and E. Bloch, M. Lulkiesch, V. Schumann, and F. Exner and E. Haschek. According to W. H. Fulweiler and J. Barnes, the light from the tungsten arc under water gives a continuous spectrum in the ultra-violet. The **ultra-red spectrum** is discussed above. M. Luckiesh has shown that the ultra-violet spectrum of tungsten electrodes in quartz bulbs with argon may be considered for some purposes as approximately continuous between $300\mu\mu$ and $400\mu\mu$, although with short exposures the spectrum is fluted. The quartz mercury arc in this region emits many lines, but the spectrum does not approximate continuity. W. E. Forsythe and F. Christison calculated the energy of the ultra-violet spectra.

The influence of *pressure* on the spectrum was examined by W. J. Humphreys; and of a *magnetic field*—the **Zeeman effect**—by P. Zeeman, and R. Jack. H. B. Dorgelo studied the **absorption spectrum** of the vapour. No characteristic absorption spectrum of soln. of the tungsten salts has been observed, and J. Formanek observed no reaction with tincture of alkanna. J. H. Pollok examined the spectra of soln. of tungsten salts; and C. Horner, the spectra of beads of the oxide with boric acid, and phosphoric acid. A. de Gramont said that the lines 2397·110, 3215·578, 3613·793, 4008·769, and 4302·123 are *les raies ultimes*. No **series spectrum** has been observed, but E. Paulson has noted some pairs with constant differences. The subject was studied by P. G. Nutting, H. Beining, O. Laporte, and J. Stock. J. C. McLennan and co-workers discussed the relation between the electronic structure and the spectrum.

The **X-ray spectrum** of tungsten is continuous and it extends over four octaves, from the wave-length $0{\cdot}12 \times 10^{-8}$ cm. to 2×10^{-8} cm. The spectrum illustrated by Fig. 13 was obtained by A. W. Hull[10] with an ionization chamber and an electrometer-current 1·2 milliampères and 100,000 volts. The dotted line was obtained at 70,000 volts, and this was not high enough to excite the K-lines. The diagram represents four lines on the short wave-length end of the spectrum; they form the K-series, and are designated the α' and α doublet, β, and γ. Another group of about 12 lines with wave-lengths nearly ten times those of the K-series form the L-series. The X-ray spectrum was studied by M. de Broglie, P. Günther, J. Herweg, J. Barnes, K. T. Compton and C. H. Thomas, A. H. Compton, A. Smekal, E. Lorenz, A. W. Hull and M. Rice, W. S. Gorton, H. G. J. Moseley, etc. The K-series comprises the lines $\alpha_2\alpha$, 0·21352 A.; $\alpha_1\alpha_1$, 0·20885 A.; α_3, 0·215 A.; $\beta_1\beta$, 0·18436 A.; and $\beta_2\gamma$, 0·17940 A. The limit of the K-absorption is 0·1782 A. The K-series was studied by E. Dershem, W. Duane and co-workers, M. de Broglie, K. C. Mazumder, H. R. Robinson, S. K. Allison and W. Duane, C. B. Crofutt, M. C. Magarian, V. Posejpal, B. Walter, H. Purks, P. A. Ross, A. Bouwers, D. Coster, A. Leide, G. Réchou, C. D. Niven, A. Smekal, P. Auger, C. B. Crofutt, H. G. J. Moseley, J. E. Mack and J. M. Cork, J. M. Cork, B. R. Stephenson and J. M. Cork, F. K. Richtmyer, J. Thibaud and A. Soltan, O. B. Overn, M. Siegbahn, R. Ledoux-Lebard and A. Dauvillier, A. E. van Arkel and W. G. Byrgers, G. Agte and K. Becker, L. Y. Faust, etc. R. Berthold compared the ionizing and photographic effects of the K-series of X-rays. The L-series comprises the lines: $\alpha_2\alpha'$, 1·48452 A.; $\alpha_1\alpha_1$, 1·47348 A.; $\beta_1\beta$, 1·2791 A.; $\beta_2\gamma$, 1·24191 A.; $\gamma_1\delta$, 1·09553 A.; ϵ, 1·67505 A.; η, 1·4177 A.; $\beta_5\zeta$, 1·2118 A.; $\gamma_2\theta$, 1·06584 A.; $\beta_4\nu$, 1·29874 A.; $\beta_3\phi$, 1·26000 A.; $\gamma_3\chi$, 1·05965 A.; and $\gamma_4\psi$, 1·02647 A. The limits of the L-absorption are L_1, 1·2136 A.; L_2, 1·0726 A.; and L_3, 1·024 A. The L-series was studied by G. Wentzel, M. Siegbahn, C. D. Niven, H. Brauns, M. Siegbahn and E. Friman, E. Friman, F. C. Hoyt,

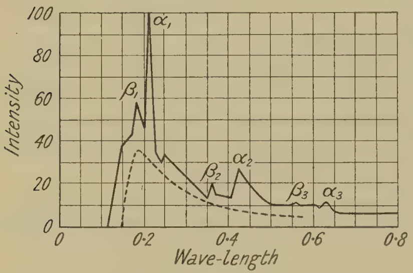

Fig. 13.—X-ray Spectrum of Tungsten (100,000 volts).

O. B. Overn, J. M. Cork, P. Kirkpatrick and I. Mayike, R. Ledoux-Lebard and A. Dauvillier, S. Idei, W. Duane and co-workers, J. S. Rogers, E. Hjalmar, D. Coster, M. de Broglie, E. Dersham, A. Smekal, H. R. Robinson and C. L. Young, E. C. Watson and J. A. van der Akker, Y. Nishina, B. B. Ray, C. B. Crofutt, S. K. Allison and A. H. Armstrong, H. Hirata, J. S. Rogers, U. Yoshida and S. Tanaka, A. Dauvillier, W. H. Love, J. Zahradnicek, A. Sandström, S. Idei, H. J. G. Moseley, etc. The M-series comprises the lines 4·433 A.; 5·167 A.; 5·356 A.; 5·607 A.; γ, 6·083 A.; 6·123 A.; 6·271 A.; β', 6·720 A.; β, 6·733 A., 6·750 A.; η_2, 6·789 A.; η, 6·857 A.; α', 6·948 A.; α, 6·963, 7·349 A., 9·549 A., and 8·948. The limits of the M-absorption are M_1, 6·708 A.; M_2, 6·475 A.; M_3, 5·416 A.; M_3', 5·380 A.; M_4, 4·800 A.; and M_5, 4·365 A. The M-series was studied by M. Thoræus, J. H. van der Tuuk, A. Jönsson, E. Lindberg, E. Lorenz, K. Molin, R. V. Zumstein, G. Wentzel, C. D. Niven, A. Jönsson, E. Hjalmar, M. Siegbahn, D. Coster, and A. Dauvillier; and the N-series and the O-series by C. T. Chu, J. A. Becker, E. Lorenz, C. D. Niven, and O. Stuhlman; and the P-series by C. D. Niven. W. Ehrenberg and co-workers studied the subject. W. Herz gave $5{\cdot}87\times10^6$ for the **vibration frequency.**

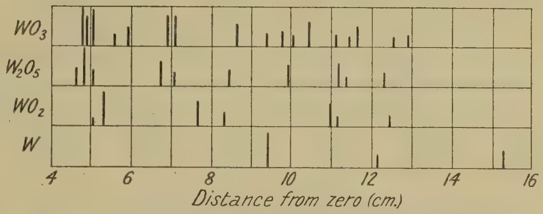

FIG. 14.—X-ray Diffraction Patterns of Tungsten and its Oxides.

C. J. Smithells and H. P. Rooksby's[11] X-ray diffraction patterns of tungsten and its oxides are given in Fig. 14. C. B. Bozzani and C. T. Chu obtained critical values for the X-rays from tungsten at 33·6, 34·6, 39·2, 56·6, and 71 volts. H. R. Robinson studied the secondary corpuscular rays produced by X-rays on tungsten; D. Nasledoff and P. Sharavsky, the intensity of the radiation from X-ray tubes; G. Kirsch and H. Pettersson, the action of α-rays; and G. B. Bandopadhyaya, the photoelectric action of soft X-rays; A. H. Warner, the photoelectric effect. T. E. Aurén found the at. absorption coefficient for X-rays to be 308 when that for lead is 569 and that for water is unity. V. Posejpal, L. M. Alexander, F. W. Warburton and F. K. Richtmyer, and S. J. M. Allen discussed this subject. S. K. Allison and W. Duane, A. H. Compton and A. W. Simon, F. Kirchner, G. Hagen, A. Claasen, and P. A. Ross discussed the scattering of X-rays by molybdenum, and the Compton effect; A. Jönsson, and A. Bouwers, the intensity of the X-rays; G. P. Thompson, the diffraction of cathode rays; G. L. Clark and W. Duane, the secondary and tertiary X-rays from tungsten; K. T. Compton and C. H. Thomas, O. W. Richardson and F. S. Robertson, and J. C. Boyce, the soft X-rays from tungsten; H. R. Robinson and A. M. Cassie, and R. Whiddington, the emission of electrons from tungsten bombarded by X-rays; W. H. Rothery, and R. A. Houstoun, the absorption of X-rays; J. A. Becker, the velocity of electrons exerted by X-rays; O. W. Richardson and co-workers, the excitation voltage of soft X-rays from tungsten; C. C. van Voorhis and K. T. Compton, the heats of condensation of electrons; and U. Nakaya, and L. P. Davis, the effect of oxidation on the emission of soft X-rays. M. de Broglie examined the α-ray spectrum. W. G. Guy observed no evidence of **radioactivity.** G. I. Pokrovsky, however, found evidence of radioactivity when the element is exposed to short-wave radiation—soft X-rays, and γ-rays. N. Koboseff and N. I. Nebressoff observed that free hydrogen atoms are produced by the cathodic polarization of tungsten; and J. K. Roberts discussed the energy between the atoms of helium and tungsten. O. W. Richardson and F. S. Robertson studied the **photoelectric effect;** and A. H. Warner found that the effect with tungsten is limited by a wave-length of 2570 A., and the limit is not affected by temp. up to 1140° K. R. B. Jones gave 2338 A. for the limiting wave-length. T. Pavolini studied the photoelectric effect; E. O. Lawrence and L. B. Linford, the effect with thin films of oxygen, and potassium on tungsten; and R. Suhrmann and F. Breyer, with a film of sodium on tungsten.

J. Lifschitz, and R. T. Dufford investigated the **volta-luminescence** which occurs when an electric current is passed through an electrolyte under certain conditions using tunsten electrodes. P. E. Shaw and C. S. Jex[12] found that when rubbed on glass, tungsten always acquires positive **triboelectricity.** M. Forro and E. Patai found the **contract potential** of sodium against tungsten to be 2·2 volts; I. Langmuir and co-workers measured the contact potentials of tungsten filaments against filaments with adsorbed cæsium; and N. B. Reynolds, the contact potentials of thoriated tungsten filaments.

The **electrical resistance** and the temp. coeff. of the resistance of tungsten wires varies with the different samples. O. Ruff found that rods, a metre long and 2 sq. mm. sectional area, made of the compressed powder and then heated to 2600° to 2650°, had a resistance $R=0{\cdot}5487+0{\cdot}0005144(\theta-1200)+0{\cdot}0_{6}2(\theta-1200)^2$, at a *temperature* between 1200° and 2940°. A. Müller found that a wire a metre long and 1 sq. mm. sectional area, had a resistance of 0·72 ohm. I. Langmuir gave $6{\cdot}37\times10^{-6}$ ohm at 0°, and $90{\cdot}34\times10^{-6}$ ohm at 2027°. For squirted filaments, unused, M. von Pirani gave $R=6\times10^{-6}$ to 12×10^{-6} ohm per cm. cube at 20°; and after being in use for 1000 hrs., $R=5{\cdot}5\times10^{-6}$ to $5{\cdot}7\times10^{-6}$ ohm at 20°. The temp. coeff. between 20° and 100° was 0·415 per cent. per degree. J. H. Dellinger found the sp. resistance of a squirted rod of tungsten, 20 cm. long, and 1·2 mm. diam., to be $0{\cdot}0_{5}63$ to $0{\cdot}0_{5}69$ ohm at 21·8°—this is nearly 4 times the resistance of copper. According to J. W. Avery and C. J. Smithells, the resistance falls rapidly in the early stages of working and reaches a minimum when the density is a maximum; it then increases at a uniform rate which is approximately an exponential function of the diameter.

A. G. Worthing gave for the resistance from 300° to the m.p., 3655°:

$T°$ K. .	300°	500°	1000°	1500°	2000°	2500°	3000°	3500°	3655°
$R\times10^6$	5·64	10·74	25·70	41·85	59·10	77·25	96·2	115·7	121·8

The results can be represented by the relation $R/R_0=(T/T_0)^{1\cdot2}$ between 1000° and 3200°, where R_0 denotes the resistance at 1000°. H. A. Jones gave the results R_1, and C. Zwikker, R_2:

$T°$ K. .	273°	500°	1000°	1500°	2000°	2500°	3000°	3500°	3655°
$R_1\times10^6$	5·00	10·56	24·90	40·35	56·67	73·83	92·00	111·1	117·1
$R_2\times10^6$	—	—	30·9(1200°)	40·2	56·7	74·0	92·3	107·8(3400°)	

H. Pécheux gave $18{\cdot}9\times10^4$ mho for the **electrical conductivity** at 0°; I. Langmuir, $20{\cdot}0\times10^4$ mho at 0°; and M. von Pirani, $17{\cdot}9\times10^4$ mho. For hard-drawn wires, C. G. Fink, and W. D. Coolidge gave for the resistance $R=0{\cdot}0_{5}62$ ohm at 25°, and after annealing, $0{\cdot}0_{5}50$ ohm at 25°—the temp. coeff. of the hard-drawn wire between 0° and 70° was 0·51 per cent. per degree; S. Weber gave $0{\cdot}0_{5}49$ at 0°, with a temp. coeff. of 0·46 per cent. between 0° and 23°. M. von Pirani observed no marked difference in the temp. coeff. of drawn and squirted wires at high temp. He found:

	−180°	0°	20°	100°	200°	500°	1000°	1500°	2000°
R .	$0{\cdot}0_{6}98$	$0{\cdot}0_{5}512$	$0{\cdot}0_{5}56$	$0{\cdot}0_{5}745$	$0{\cdot}0_{5}990$	$0{\cdot}0_{4}179$	$0{\cdot}0_{4}336$	$0{\cdot}0_{4}514$	$0{\cdot}0_{4}711$

From these measurements, O. M. Corbino calculated the temp. coeff. of the resistance R at $\theta°$ to be $\alpha=(dR/d\theta)/R$, or $\alpha=0{\cdot}00124$ at 800°; 0·00094 at 1050°; 0·00081 at 1250°; 0·00067 at 1450°; 0·00075 at 1800°; and 0·00076 at 1850°. A. Schulze gave $\alpha=0{\cdot}00413$ from 20° to 100°; 0·0050 from 400° to 800°; 0·0058 from 1000° to 1200°; and 0·009 up to 2000°. A. A. Somerville found at 25°, 100°, 500°, and 1000°, $\alpha=(dR/d\theta)/R_0$, the respective values 0·0046, 0·0050, 0·0057, and 0·0089, and his results for the resistance, and the temp. coeff. of the resistance are plotted in Fig. 15. P. W. Bridgman gave for the temp. coeff. 0·00322 between 0° and 100°; and L. Holborn gave for a wire 0·1 mm. in diameter which had been heated for a long time in vacuo, α=0·00435, 0·00465, and 0·00547, respectively at —135°, 50°, and 350°, and for the ratio of the resistance R at θ°, and R_0 at 0° :

	−78·3°	−80°	−100°	−120°	-140^0	−160°	−180°	−192·8°
R/R_0 . .	0·6509	0·644	0·557	0·469	0·382	0·295	0·208	0·1529

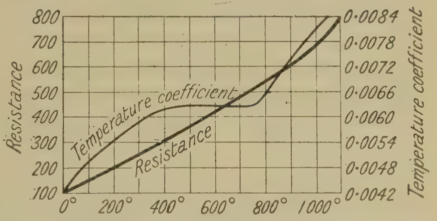

FIG. 15.—The Effect of Temperature on the Resistance of Tungsten.

W. Geiss and J. A. M. van Liempt gave for the sp. resistance of purified single crystals of tungsten, R=$0{\cdot}0_5491$ ohm., and the temp. coeff. 0·00481. The electrical conductivity is not affected by the orientation of the crystal, and the same values were obtained when the single crystals were converted by drawing and annealing into fine-grained metal. They found that the sp. resistance is increased 160 per cent. by the cold working of the metal, and the temp. coeff. of the resistance is reduced 60 per cent. The mixture law, that for solid soln., the product of the sp. resistance and the temp. coeff. remains constant, applies to a pure metal after working in the cold. The change in conductivity is not due to lattice modification, nor to change in orientation of atomic axes ; it is connected, as is also the change in mechanical properties, with the intercrystalline relations. By cold working, as also by taking up a solid soln. component, the energy content of a metal is increased : calculation from the electrical measurements indicates an increase of 775 cals. per gram atom of tungsten after cold working. F. Koref noted a change in the electrical resistance of single crystal wires by tempering. According to J. Tsukamoto, the sp. electrical resistance of drawn tungsten wire containing one per cent. of thorium, is dependent upon the fineness of the tungsten powder from which the wire was made, on the time of sintering, and on the temp. of drawing. At 20°, the sp. resistance of a rod, 0·47 cm. sq., is 6·1 microhms, which falls to a minimum of 5·7 microhms on drawing down to a diameter of 4·5 mm. Further drawing increases the resistance to 6·0 microhms at 0·35 mm. diameter, and to 7·1 microhms at 0·015 mm. diameter. J. C. McLennan and co-workers studied the conductivity at low temp., 2·2° K., and found the temperature-resistance curve to be normal. E. Grüneisen and E. Goens studied the relation between the electrical and thermal conductivities ; W. Geiss and J. A. M. van Liempt found that tungsten conforms with Matthiessen's rule as to the constancy of the product of the sp. resistance and the temp. coeff. of the resistance and for the ratio of the resistance R at θ°, and R_0 at 0°. B. Beckman measured the influence of *pressure ;* and P. W. Bridgman found for press., p, up to 12,000 kgrms. per sq. cm., and for temp. 0° to 100°, the press. coeff. of the resistance :

		0°	25°	50°	75°	1000°
	R . .	1·000	1·0743	1·1486	1·2229	1·2973
Press. Coeff.	0 kgrm. .	$-0{\cdot}0_51487$	$-0{\cdot}0_51497$	$-0{\cdot}0_51507$	$-0{\cdot}0_51518$	$-0{\cdot}0_51530$
	12,000 kgrms.	$-0{\cdot}0_51373$	$-0{\cdot}0_51399$	$-0{\cdot}0_51409$	$-0{\cdot}0_51426$	$-0{\cdot}0_51442$
	average .	$-0{\cdot}0_51430$	$-0{\cdot}0_51444$	$-0{\cdot}0_51458$	$-0{\cdot}0_51472$	$-0{\cdot}0_51486$

E. D. Williamson gave 0·9838 for the ratio of the resistance at pressures of 12,000 kgrms. and 1 kgrm. per sq. cm. U. Fischer found for the effect of pressure on the resistance $-(1/R)(dR/dp)$, at 15°, 0·1°, —185°, and —252·7°, the respective values $0{\cdot}0_5159$, $0{\cdot}0_5155$, $0{\cdot}0_528$, and $0{\cdot}0_5495$. H. Rolnick found that under a *tensile stress* the fractional change of resistance is $\delta R/R$=0·000194. R. Becker and F. Born found a difference of less than 5 per cent. in the conductivity parallel and perpendicular to the direction of rolling. G. Tammann and M. Staumanis discussed the effect of cold work on the electric resistance ; A. Denissov, the effect of the electric current on the temp. of a thin wire ; the effect of the press. of hydrogen on the electrical resistance of a filament; and P. Kapitza, the effect of a magnetic field on the electrical conductivity. K. Höjendahl, A. T. Waterman, and O. Feussner discussed the electronic theory of conductivity. S. Smith measured the conductivity of the vapour of tungsten. I. Langmuir and co-workers calculated the losses at the leads of tungsten filament lamps.

A. G. Worthing, in his study of the effect of the direction of the heating current on the temp. variation near a leading in wire of a tungsten filament lamp, measured the thermoelectric force—the **Thomson effect**—and found for the Thomson effect at 1800°, 2000°, and 2200° in microvolts per degree, respectively, −18, −22, −26, and −30. Tungsten appears to be the only known metal with a positive temp. coeff. for the Thomson effect, σ. C. Zwikker gave for the Thomson effect in millivolts per degree:

T° K.	1800°	1900°	2000°	2100°	2200°	2300°	2400°
σ .	−18	−20	−22	−24	−26	−28	−30

P. W. Bridgman found the Thomson effect with a couple composed of one branch of uncompressed metal, and the other compressed at p kgrms. per sq. cm., to be, in joules per coulomb × 10 per degree of temp.:

	p	0°	40°	80°	100°
σ	2,000 .	2·0	2·3	2·6	2·8
	6,000 .	8·5	7·8	6·5	5·6
	10,000 .	3·5	10·2	18·7	23·5
	12,000 .	9·3	13·1	17·3	19·8

The positive effect at the two extremes of press. rises with temp. at a constant press., but at intermediate press. it rises and falls with a rise of temp. H. E. Smith measured the effect of tension on the Thomson effect in a tungsten wire, and he found that the coeff. increases with tension, but when the stress is relieved, the original value is not restored even though the stress is below the elastic limit; the coeff. undergoes a regular cycle of changes with a repeated application and removal of the stress, Fig. 16. With tungsten of 99·95 per cent. purity, and a tension expressed in dynes per sq. cm., the Thomson effect, σ, expressed in cals. per coulomb per degree, is:

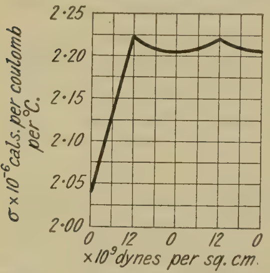

FIG. 16.—The Effect of Tension on the Thomson Effect.

Tension × 10^9	0	2·95	5·90	8·85	11·80 dynes
$\sigma \times 10^6$.	2·038	2·079	2·106	2·163	2·222 cals.

P. W. Bridgman found the Thomson effect against lead, at atm. press., to be represented by $\sigma=0·0341(\theta+273)10^{-6}$ volts per degree. The **Peltier effect,** P, joules per coulomb × 10^6, between compressed and uncompressed tungsten, rises with temp. and press.:

	p	0°	40°	80°	100°
P	2,000 . .	5·9	7·7	9·5	10·4
	6,000 . .	17·2	23·1	29·0	32·0
	10,000 . .	30·4	37·5	48·3	55·4
	12,000 . .	35·7	45·9	58·0	64·8

The value with the tungsten-lead couple is $p=(1·594+0·0341\theta)/(\theta+273)\times10^{-6}$ volt. P. W. Bridgman found the **thermoelectric force** of a couple, E, composed of compressed and uncompressed tungsten, for values of the press. up to 12,000 kgrms. per sq. cm., to be positive; and is about 20 times as great as the value for molybdenum; the thermoelectric force also increases regularly with press. and temp. Expressing the thermoelectric force E in volts × 10^{-6}:

	p	0°	40°	80°	100°
E	2,000 . .	0·22	0·94	1·98	2·53
	6,000 . .	0·65	2·76	5·92	7·60
	10,000 . .	1·12	4·61	9·75	12·61
	12,000 . .	1·33	5·56	11·76	15·41

The thermoelectric force of the *tungsten-lead* couple is $E=(1\cdot594\theta+0\cdot01705\theta^{2})10^{-6}$ volt. W. W. Coblentz obtained for the thermoelectric force, E microvolts, for the *tungsten-copper* couple, a maximum value for E in the curve at 40° :

	−200°	−100°	0°	20°	40°	100°	150°	200°	250°
E .	−600	−240	0	20	22	−38	−160	−340	−590

W. M. Latimer found the thermoelectric force of the *tungsten-silver* couple to be —2·5 microvolts at 100° ; —6·0 at 200° ; —9·2 at 400° ; and —9·8 at 700°. E. Blumenthal found the Peltier effect for tungsten against molybdenum to be $4\cdot69\times10^{-3}$ gram cal. at ordinary temp., and $29\cdot3\times10^{-3}$ gram cal. at 1017°. W. Rohn studied the thermoelectric force of tungsten against nickel. S. Morugina gave for the thermoelectric force of the *tungsten-tantalum* couple 10·3 millivolts at 1060° ; 16·0, at 1520° ; the *tungsten-molybdenum* couple, S. Morugina gave —3 millivolts at 1000° and at 1500° ; and 1·5 millivolts at 2000°. A. G. Worthing also studied the tungsten-tantalum couple—*vide* tantalum. E. F. Northrup found the thermoelectric force of the *tungsten-molybdenum* couple, E microvolts, between 0° and 1000° to be represented by $E=4\cdot61\theta-0\cdot00436\theta^{2}$, with, at most, a 4 per cent. error. The value of E decreases up to 530°, and then rises, being about the same as at 0° near 1150°, so that at this temp. the direction of the current is the opposite to what it is at 0°—*vide* Fig. 17. Below that temp., at the hot junction, the current flows from the tungsten to the molybdenum. The high m.p. of tungsten makes it valuable in the construction of thermocouples for high temp., but they can be employed only in the presence of a reducing atmosphere—say hydrogen, or a mixture of hydrogen and nitrogen. M. von Pirani and G. von Wangenheim used a couple of tungsten against an alloy of molybdenum with 75 per cent. of tungsten to measure the m.p. of molybdenum. It could be used up to 3000° ; below 1600°, the current at the hot junction flows from the tungsten to the alloy, and reaches a maximum of about one millivolt at about 600° ; at 1200°, the current reverses and reaches 6 millivolts at 3000°. G. Borelius found that the thermoelectric force of the iron-tungsten couple at ordinary temp., with tungsten which had been successively heated at different temp., and each time rapidly cooled, shows periodic changes when the e.m.f. is taken as a function of the heating temp. R. Saxon found that when a piece of tungsten is placed between, but not touching, two electrodes immersed in water and a current is passed between the electrodes, the surface of the intermediate metal remains bright on the side nearest the cathode, but becomes oxidized on the side nearest the anode, whilst, in some cases, a mixture of oxygen and hydrogen in the ratio of <1 : 2 is evolved.

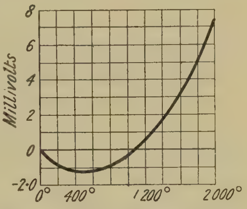

Fig. 17.—The Thermoelectric Force of a W–Mo Couple.

R. D. Kleeman and W. Frederickson [13] found that in distilled water, tungsten assumes a negative charge when an electric current is sent through the liquid. A. S. Russell and S. W. Rowell said that the position of tungsten in the electrochemical series is approximately the same as that of molybdenum (*q.v.*). H. H. Willard and F. Fenwick examined tungsten as an electrode material. According to W. Muthmann and F. Fraunberger, active tungsten, like iron and chromium, can assume a **passive state,** although in some respects the behaviour of tungsten is different from that of chromium. Its electrode potential is not a constant, but is dependent on the treatment the metal has previously received. Tungsten is made passive by treatment with the oxidizing agents, chromic acid, nitric acid, and ferric chloride, as well as by hydrochloric and sulphuric acids. The highest **electrode potential** which passive tungsten can receive by treatment with chromic acid, is 0·88 volt in a N-soln. of potassium chloride ; in air, the potential ranges from 0·35 volt to —0·03 volt. The metal is activated by polishing, and its potential is then —0·58 volt ; and this can be raised to —0·70 volt by cathodic polarization in water. Cathodic polarization in acids or in alkali-lye also activates the passive metal. With a tungsten anode and platinum cathode, M. le Blanc and H. G. Byers found that when sulphuric, hydrochloric, and nitric acids in normal soln. are used as electrolytes, tungsten is practically unattacked. In soln. of phosphoric acid and of sodium hydrophosphate at high temp., it dissolves in the sexivalent form; at low temp., however, the current efficiency is smaller. In oxalic acid with small currents and at high temp., the current efficiency reaches the theoretical value, but is much less with relatively large currents at room temp. The current efficiency also approximates to the theoretical value in normal soln. of potassium hydroxide and of ammonium sulphide. The change from the active to the passive (relatively insoluble) form of the metal is favoured by increasing the current density and by lowering the temp. They say it is improbable that the passivity is conditioned by the formation of a layer on the surface of the metal; it is more likely to be connected with a change in the reaction velocity. L. B. Flexner and E. S. G. Barron measured the potential of the tungsten electrode in various oxidation-reduction systems. M. Katalinic observed a faint luminescence about a tungsten anode in conc. sulphuric acid at voltages exceeding 60. A. Thiel and W. Hammerschmidt found the **over-voltage** with tungsten and $2N$-H_2SO_4 to be 0·157 volt at 25°. S. J. French and L. Kahlenberg studied the gas-metal electrode with tungsten and oxygen, hydrogen, or nitrogen.

According to E. Newbery, tungsten under anodic treatment in dil. sulphuric acid, dissolves readily and shows no signs of passivity. The surface acquires a very brilliant, polished appearance. In alkali-lye, it behaves in the same way as bismuth. O. Sackur discussed the passivity of tungsten. W. E. Koerner found that tungsten dissolves anodically in aq. soln. of ammonium hydroxide, or hydroxylamine; in methyl-, ethyl-, and propyl-ammonium hydroxides to form the respective paratungstates; and at high current densities the tungsten becomes passive. Tungsten also dissolves anodically in aq. soln. of potassium and sodium hydroxides to form orthotungstates; and it becomes passive with high current densities. Tungsten dissolves in non-aqueous soln. of hydrochloric acid, potassium chloride or fluoride, sodium chloride, etc., forming the respective halogen salts without becoming passive; and it dissolves to a slight extent in aq. soln. of hydrochloric, sulphuric or nitric acid, and potassium fluoride, chloride, bromide or iodide with the formation of tungsten hexahydroxide, but the metal becomes passive. The metal remains active only at very low current densities.

The passivity of tungsten is due to oxide films, ranging in colour from brown, blue and green to yellow. The colours are pronounced and can be followed as the electrolysis proceeds. The films are independent of the dissolved cation or anion. They are due to the OH-ions reacting with the tungsten. The passivity is a function of the colour of the film, the colour varying with the amount of oxygen present. The passivity varies directly with the current, time and temp., and inversely with the solubility of the film, the vol. of electrolyte and the diffusion velocity. If the film dissolves as rapidly or more rapidly than it is formed, the tungsten will remain active. The films can be dissolved and the passivity destroyed. Soln. of potassium hydroxide and ammonia render passive tungsten active. Soln. of acids and salts make passive tungsten active if allowed to react for some time on it. Passive tungsten has been made active overnight in distilled water. I. Langmuir and K. H. Kingdon studied the contact potential differences between a clean, unheated tungsten filament, and the same filament coated with a film of thorium, cæsium, or oxygen.

In conjunction with the anodic soln. of tungsten, the electrochemical eq. was determined. Tungsten dissolves sexivalently in a soln. of ammonia with 100 per cent. efficiency. From the loss in weight of a tungsten anode in ammonia and the coulombs of current, the **electrochemical equivalent** was found to be 0·3173 mgrm. per coulomb—the theoretical value is 0·3175 mgrm. per coulomb.

W. E. Koerner found the single electrode potential of tungsten in normal soln., referred to the standard hydrogen electrode, to be —0·656 volt for KCy; —0·315 volt for KOH; —0·238 volt for NH_4OH; 0·193 volt for H_2SO_4; 0·256 volt for HCl; 0·311 volt for HNO_3; 0·522 volt for KF; 0·053 volt for KCl; 0·589 volt for KBr; and 0·733 volt for KI. The electrode potential varies with the nature of the electrolyte. The metal is negative to the electrolyte with soln. of the bases; and positive with acid and salt soln. The soln. tension or solubility of a metal in an electrolyte is a function of the electrode potential; and the solubility therefore is greatest in soln. of the bases, and least in soln. of salts. Tungsten is more soluble in soln. of potassium cyanide than of the hydroxide; and more soluble in potassium hydroxide than in aq. ammonia; it is more soluble in sulphuric acid than in hydrochloric acid, and more soluble in hydrochloric acid than in nitric acid. The order of solubility in soln. of the salts—KF, KCl, KBr, and KI—is in order named. O. Bauer gave for the potential of tungsten against a one per cent. soln. of sodium chloride and a normal calomel electrode, —0·260 volt at the start falling to —0·235 volt in 1 hr., and —0·240 volt in 120 hrs. A. Fischer and co-workers measured the electromotive force of the cell with tungsten in an alcoholic soln. of tungsten hexachloride, against a calomel electrode in contact with an alcoholic soln. of lithium chloride, and found for soln. with one-sixth mol of the hexachloride in v litres:

v .	1·30	2·82	5·82	9·84	123	417	925
E.m.f.	0·504	0·492	0·474	0·465	0·399	0·362	0·349 volt.

They calculated the normal potential of tungsten in an alcoholic soln. of sexivalent tungsten to be 0·68 volt; and in aq. soln., 0·61 volt. These values are based on questionable assumptions. They infer that tungsten is nearly as noble a metal as silver; and in the electrochemical series, tungsten occupies a place between antimony and mercury. Passivity was not observed. W. E. Koerner obtained normal soln. of tungsten hexahydroxide in sulphuric, hydrochloric and nitric acids by electrolyzing the acids at low current densities between tungsten electrodes. Measurements of the e.m.f. of cells were made with tungsten in a N-soln. of the acid, and with tungsten in a sat. soln. of tungsten hexahydroxide. These combinations were concentration cells with the conc. of the hexahydroxide zero. With $W^+ \mid H_2SO_4$; $W(OH)_6 \mid H_2SO_4 \mid W^-$, the e.m.f. was 0·117 volt.; with HCl in place of H_2SO_4, 0·057 volt; and with HNO_3 in place of H_2SO_4, 0·009 volt. Hence, tungsten hexahydroxide is most soluble in sulphuric acid, and least soluble in nitric acid. True soln., not colloidal soln., are formed; and tungsten occurs in the cation.

O. W. Richardson and F. S. Robertson found that the voltage-current curve between a hot tungsten filament and mercury vapour is shifted to the negative along the voltage-axis by increasing the press. of hydrogen. This change is taken to represent the contact difference of potential as influenced by the gas press. W. E. Koerner showed that tungsten is negative to soln. of the bases so that voltaic cells are formed if it be combined with a metal—*e.g.* mercury or silver—positive to these soln., with N-NaOH sat. with mercuric oxide, the potential of mercury is 0·168 volt (hydrogen zero); and with the N-NaOH sat. with silver oxide, the potential of silver is 0·378 volt (hydrogen zero); and with the tungsten employed in the experiments, the electrode potential in N-NaOH is —0·704 volt (hydrogen zero). A cell with tungsten and mercury in N-NaOH sat. with mercuric oxide has an e.m.f. of 0·872 volt—the mercury being positive; similarly with tungsten and silver in N-NaOH sat. with silver oxide, the e.m.f. is 1·082 volt, the silver being positive. If $10N$-NaOH be used with the mercury-tungsten combination, the e.m.f. is 1·050 volt. The e.m.f. with the cell $Hg^+ \mid Hg_6W_7O_{24} \mid Na_6W_7O_{24} \mid W^-$ is 0·552 volt; with $Cu^+ \mid Cu_3W_7O_{24} \mid Na_6W_7O_{24} \mid W^-$, 0·395 volt; and with $Cd^- \mid Cd_3W_4O_{24}Na_6W_7O_{24} \mid W^-$, 0·434 volt. Experiments were made with storage cells having tungsten and tungstic acid for the positive electrode and tungsten for the negative electrode, and sulphuric acid as electrolyte. The e.m.f. before charging was 0·08 volt, and after charging 3·00 volts; 24 hrs. after charging the e.m.f. had dropped to 0·2 volt. No change of colour was observed. The best combination tried had, before charging, tungsten as positive electrode and tungsten and tungstic acid as negative electrode. During charging the yellow tungsten acid was reduced through a series of coloured oxides to a blue-black compound, probably W_2O_5. The tungsten of the positive electrode became covered with a brown film, presumably WO_2. Before charging, the e.m.f. 0·08 volt was observed; and immediately after charging the e.m.f. was as high as 6·20 volts. This value did not remain constant because, 24 hours after charging, 0·75 volt was obtained. This value remained constant for two weeks. A. L. Clark studied the polarization capacity of tungsten. L. W. Walter, and A. Günther-Schulze observed that with many electrolytes, tungsten shows the **electrolytic valve action**; the critical voltage with strong acids is, as a rule, higher than with aluminium, and not so high as with tantalum. This rectification of alternating currents by tungsten was discussed by S. Dushman, R. E. Russell, and G. S. Meikle; the cathodic disintegration, by E. Blechschmidt; the surface pitting of tungsten filaments, by E. S. Davenport; contact potential with adsorbed films, by I. Langmuir and K. H. Kingdon; the tungsten arc, by W. B. Nottingham, S. H. Anderson and G. G. Kretchmar, W. B. Nottingham, W. de Groot, and W. Wehrli; electrokinetic potential, by A. Coehn and O. Schafmeister; C. del Rosario, and J. Taylor, the sparking potentials of discharge tubes with tungsten electrodes; P. Bächtiger, the tungsten arc; and H. Nagaoka and T. Futagami, the spluttering of tungsten by the disruptive discharge in a magnetic field. E. K. G. Stückelberg said that the temp. of the tungsten cathode in an electric arc is 2600° to 3300° K. J. S. Forrest discussed the glow discharge on the active electrode of a rectifying cell.

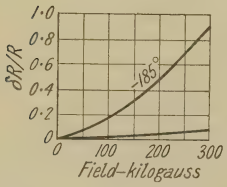

Fig. 18.—The Effect of Magnetic Fields on the Electrical Conductivity.

According to H. Moissan,[14] tungsten is not ferromagnetic; but is paramagnetic. L. Weiss also said that the metal is non-magnetic. K. Honda gave $0·33\times10^{-6}$ for the **magnetic susceptibility** between 18° and 1100°; while M. Owen obtained for the metal, free from iron, $0·252\times10^{-6}$ in a magnetic field of 26 kilograms; and $0·222\times10^{-6}$ for an infinitely strong magnetic field. The result is independent of the temp. Some observations on this subject were made by S. Meyer; and by D. M. Bose and H. G. Bher. P. Kapitza's observations on the effect of magnetic fields on the electrical conductivity are summarized in Fig. 18.

§ 6. The Chemical Properties of Tungsten

Owing to the effects of passivity, and the effects of ignored impurities, descriptions of the chemical behaviour of tungsten are not always consistent. F. Fisher and F. Schrötter[1] observed that no combination occurs when tungsten is disintegrated electrically beneath liquid **argon.** According to A. Sieverts and E. Bergner, **hydrogen** is very little absorbed by tungsten below 1200°. E. Martin studied the occlusion of hydrogen by the metal. I. Langmuir showed that if a tungsten wire is heated at 1300° K. to 1500° K. in hydrogen under a press. of 0·001–0·020 mm., the hydrogen slowly disappears. There is a distinct fatigue effect, but the substitution of a new section of wire does not restore the action. The hydrogen is not absorbed by the wire, but is deposited on the glass, especially if the latter is cooled by liquid air. On allowing the wire to cool and then removing the liquid air, hydrogen is liberated, and does not re-condense if the liquid air is replaced. If the hydrogen is now pumped out and oxygen admitted, the oxygen will disappear and be replaced by a small quantity of hydrogen. It is suggested that the hydrogen dissolves in the wire in the atomic condition, and that some of the atoms, leaving the wire, diffuse into the tube cooled by liquid air, or become adsorbed by the glass, and remain in the atomic conditions, thus retaining their chemical activity. M. A. Schirmann utilized the property of tungsten for absorbing the last traces of gas in order to convert a high vacuum into an extreme vacuum. T. Weichselfelder and B. Thiede obtained a **tungsten hydride,** presumably WH_3, analogous with CrH_3, by shaking dry hydrogen with an ethereal soln. of phenyl magnesium bromide in which the dry chloride of the metal is suspended. G. Hägg studied the mol. vol.

The finely-divided metal was found by J. Férée to be pyrophoric in **air**; and E. Zettnow, and L. von Uslar found that when the finely-divided metal is heated, it becomes dark blue, and then suddenly glows to form tungsten trioxide. A. Burger found the metal produced by the calcium reduction oxidizes in air when heated to 300° or 400°. A. Riche found that the crystalline powder is not changed by a month's exposure to dry or moist **oxygen** at ordinary temp., but at a red-heat, it burns to the trioxide; a similar result is obtained at a rather higher temp. in air. E. R. Schneider added that the volume is at the same time markedly increased. A. Stavenhagen, L. Weiss, and H. Moissan observed that the metal prepared in the electric arc-furnace is stable in air after it has acquired a blue oxide film. N. B. Pilling and R. E. Bedworth discussed the rate of oxidation; and L. O. Bannister, the coloured oxide films. N. B. Pilling and R. E. Bedworth found that the weight w of oxygen taken up by a metal in the time t is in accord with the parabolic oxidation law $w^2=kt$, where k is a constant. They gave 3·30 for the critical density ratio—*vide* iron. With most metals, J. S. Dunn found that k

increases regularly with temp. in accord with $k=ae^{b/RT}$, where a and b are constants, and e, R, and T have their usual meaning. J. S. Dunn found an irregularity in the curve showing the values of log k at different temp., as indicated in Fig. 19. This is explained by the assumption that tungstic oxide is not a chemical individual, but consists of a mixture of α-WO_3 and β-WO_3, and the equilibrium between the two is shifted with rise of temp. The β-form, produced in excess at the higher temp., is less permeable to oxygen than is the α-form, and a kink occurs in the curve in the range of temp. on which the change from an excess of the β-form to an excess of the α-form occurs. E. Zettnow observed that the metal prepared at a white-heat oxidizes at a red-heat only with difficulty, while that prepared at a red-heat, readily oxidizes under these conditions, and the finely-divided metal obtained by reducing the oxide with sodium is partially oxidized during the washing and drying. M. A. Schirmann studied the production of vacua by absorbing oxygen on the surface of a tungsten filament heated in oxygen at a low press. C. G. Fink found that drawn wires of ductile tungsten retain their lustre indefinitely long in air; and L. Weiss added that compact tungsten is very little affected by air. When heated, a superficial film of oxide is formed which is not much affected by one or two hours' heating to redness.

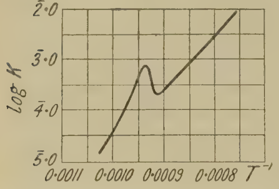

FIG. 19.—The Rate of Oxidation of Tungsten at different Temperatures.

The metal with a conchoidal fracture is more resistant towards chemical agents—particularly oxidation—than is that with a granular fracture. According to I. Langmuir, when a tungsten wire is heated in oxygen at a low press. it oxidizes to WO_3 at about 800° K., but on raising the temp. to 1200° K. the oxide volatilizes, and leaves the metal clean and bright. At temp. above 1200° K. oxygen at press. below 0·02 mm. acts on a tungsten wire at a rate which is proportional to the press. of the oxygen and the surface of metal exposed, and increases rapidly with the temp. No fatigue effect can be observed. The velocity is not affected by varying the temp. of the bulb.

L. von Uslar said that the metal obtained by the thermal decomposition of tungsten oxychlorides by hydrogen is not affected by many weeks contact, with cold or hot **water.** J. J. and F. de Elhuyar, and A. Riche also observed that water has no action on tungsten; but at a red-heat, water vapour oxidizes tungsten forming a mixture of the trioxide and the blue oxide. C. J. Smithells and co-workers found that with an incandescent tungsten filament in water vapour, the metal is oxidized at the hotter parts of the filament, and the oxide is reduced to metal in the cooler parts: $W+2H_2O \rightleftharpoons WO_2+2H_2$. The atomic hydrogen also formed, as shown by I. Langmuir, can reduce tungstic oxide at ordinary temp. L. Wöhler and W. Prager studied the influence of steam on tungsten; the reaction $W+2H_2O \rightleftharpoons WO_2+2H_2$ is a balanced one, in which the equilibrium constant $K=p_{H_2O}/p_{H_2}$ is 0·65 at 828°; 0·82 at 868°; 0·99 at 941°; and 1·29 at 1036°. The reaction was studied by W. Reinders and A. W. Vervloet, etc.—*vide supra*, the reduction of tungsten trioxide to metal. H. Alterthum and R. Becker studied the formation of fogs—aerosols of tungsten oxides, formed in tungsten filament lamps by the action of oxygen or water-vapour. W. Guertler and T. Liepus observed no action by sea-water, sea-water and air, or rain-water and air in 8 days; nor any reaction by a soln. of **hydrogen dioxide** in soda-lye in 48 hrs. L. J. Thénard said that the reaction is at first feeble, but later is more vigorous, part of the oxygen escapes free and part oxidizes the metal. A. Lottermoser studied the catalytic decomposition of hydrogen dioxide by tungsten. C. G. Fink observed that tungsten is rapidly attacked when heated with **sodium dioxide**; and H. Moissan, that it is also attacked by **lead dioxide.**

According to H. Moissan, **fluorine** attacks tungsten, at ordinary temp., with incandescence forming a volatile fluoride. A. Riche, H. Davy, and L. Weiss observed that, at 250°–300°, dry **chlorine,** free from air, forms the hexachloride, but if air or moisture be present, two oxychlorides are formed. I. Langmuir found that when chlorine, under a low press., is contained in a bulb with a heated tungsten filament, the metal is attacked with the formation of the hexachloride. The velocity of the reaction reaches a maximum at about 1500° K., and becomes very small at higher temp. W. Guertler and T. Liepus, and L. von Uslar found that tungsten is not attacked by chlorine-water in 8 hrs. A. Riche, and H. E. Roscoe observed that tungsten at a bright red-heat is attacked by **bromine** forming, according to J. B. von Borck, the pentabromide; if air moisture be present, A. Riche observed that an oxybromide is formed; and tungsten at a red-heat unites with **iodine,** forming, according to A. E. Roscoe, the diiodide. L. Weiss observed that bromine and iodine superficially attack the metal at a red-heat. V. I. Spitzin and L. Kaschtanoff said that tungsten at 500° to 600° is not attacked by **hydrogen chloride.** According to W. E. Ruder, neither hot nor cold **hydrofluoric acid** attacks tungsten; nor is the surface of the polished metal dulled when evaporated with the acid. H. Moissan also observed that hydrofluoric acid has but a slight action on tungsten; and similarly also with hydrochloric acid. J. J. and F. de Elhuyar said that this acid has no action; and A. Riche, that there is a slow action and the liquid becomes blue. C. G. Fink added that ductile tungsten is but slowly attacked; and L. Weiss that the compact metal is not attacked by the dil. or conc. acid. W. Guertler and T. Liepus observed no action by 10 or 50 per cent. hydrochloric acid in 8 hrs. W. Rohn said that while 10 per cent. acid had no action in 24 hrs., the hot acid dissolved 0·01 per cent. in an hour. According to W. E. Ruder, wrought tungsten is insoluble in hydrochloric acid of any conc. at room temp. and only very slightly so at 110°. After 45 hrs., hot conc. acid of sp. gr. 1·15 showed no effect upon the tungsten. After 175 hrs., however, a black coating of oxide formed and the metal lost 0·5 per cent. in weight. In dil. acid, at 110°, it lost 0·05 per cent. after 22 hrs., but showed no further loss after 50 hrs. After 175 hrs. the metal was coated with tungstic oxide and there was a gain in weight of 1 per cent. due to oxidation. This oxide formed an adherent coat and protected the metal against further loss.

A. Riche, and J. B. von Borck found that molten or boiling **sulphur** acts slowly on the metal. According to E. F. Smith and H. Fleck, tungsten is not acted on by **sulphur monochloride,** but if chlorine be present, tungsten hexachloride is formed. N. Domanicky classed tungsten with the metals either not acted on by sulphur monochloride, or else acted on with extreme slowness. E. F. Smith and V. Oberholtzer found that the vapour of sulphur monochloride forms a sulphochloride. A. Rich observed that the vapour of **carbon disulphide** transforms heated tungsten into the disulphide; L. Weiss, that **hydrogen sulphide** darkens the surface of tungsten at a red-heat, but it produces no marked change. J. Férée found that the pyrophoric metal becomes red-hot forming the sulphide when it is exposed to a current of hydrogen sulphide. W. Guertler and T. Liepus observed no reaction by a 10 or 50 per cent. soln. of **sodium sulphide** in 48 hrs., or by a 4 per cent. soln. of sodium sulphide containing 8 per cent. alkali in 8 hrs. C. H. Ehrenfeld observed that **sulphur dioxide** forms a little blue, green, or brown oxide; and J. Férée, that pyrophoric tungsten becomes red-hot in hydrogen sulphide or in sulphur dioxide, forming tungsten sulphide. E. D. Desi said that **sulphurous acid** acts on tungsten to form the 5 : 14-oxide (*q.v.*). J. J. and F. de Elhuyar said that **sulphuric acid** has no action on tungsten; H. Moissan, that there is a slight action forming, according to A. Riche, a blue liquid; C. G. Fink, that the action of sulphuric acid on the ductile metal is very slow; L. Weiss, that while dil. sulphuric acid is without action, the conc. acid forms a blue liquid; and E. D. Desi, that the conc. acid at a high temp. forms sulphur dioxide and some intermediate tungsten oxides (*q.v.*). R. H. Adie said that sulphur dioxide appears at 175°, but no hydrogen sulphide. W. E. Ruder observed that sulphuric acid, at room temp., has no effect upon wrought tungsten nor has the dil. acid at 110°. Conc. acid attacks it very slowly at 110°, the loss in weight being 0·1 per cent. after 18 hrs., 0·16 per cent. after

40 hrs., and 0·63 per cent. after 175 hrs. At a higher temp. the action is hastened, for at 200°, 0·62 per cent. was lost in 4 hrs. In another experiment 1·18 per cent. dissolved in 8 hrs. W. Guertler and T. Liepus observed no reaction in 8 hrs. with a 10 per cent. sulphuric acid, or 20 per cent. sulphuric acid sat. with sodium sulphate. W. Rohn found that 10 per cent. sulphuric acid had no action in 24 hrs. in the cold; 0·01 per cent. dissolved in the hot acid in an hour. C. G. Fink observed that fused **potassium hydrosulphate** readily attacks the metal.

H. Moissan found that **nitrogen** at a red-heat does not attack tungsten; and A. Sieverts and E. Bergner, that there is no reaction at 1500°. E. Martin studied the absorption of nitrogen by the metal. C. J. Smithells and H. P. Rooksby found that the dinitride is formed by an incandescent tungsten filament in nitrogen. I. Langmuir showed that when a tungsten lamp containing nitrogen at low press. is run for some time, the nitrogen gradually disappears—*vide* tungsten nitride, **8**. 49, 12. N. R. Campbell made some observations on this subject; and M. A. Schirmann discussed the production of vacua by this means. C. Kenty and L. A. Turner studied the effect of surface layers of active nitrogen on tungsten filaments; and observed that a clean tungsten surface, at a dull red-heat, in an atm. of activated nitrogen, becomes covered with a layer of nitrogen one-atom deep. I. Zschukoff observed no reaction with tungsten and nitrogen below 1250°. E. J. B. Willey measured the rate of decay of active nitrogen in the presence of a tungsten filament. C. Matignon and E. Desplantes observed that when the finely-divided metal is shaken up in a flask with 10 c.c. of aq. **ammonia** at ordinary temp., the metal is oxidized. W. Guertler and T. Liepus observed no action with 10, 50, or 70 per cent. soln. of ammonia in 48 hrs.; but S. L. Malowan found that the metal is attacked. C. H. Kunsman and co-workers, and F. Hahn used tungsten as a catalyst in the synthesis of ammonia (*q.v.*); C. H. Kunsman, and R. E. Burk studied the action of tungsten on ammonia. F. W. Bergstrom observed little if any reaction with **potassamide.** C. H. Ehrenfeld found that when heated with **nitrous oxide,** tungsten trioxide is formed. Similarly with **nitric oxide,** and, added F. Emich, the action of nitric oxide is very similar to that of oxygen provided the temp. of the former gas is kept below red-heat, the temp. of decomposition. C. H. Ehrenfeld found that **nitrogen peroxide** when heated with tungsten oxidizes it to tungsten trioxide. J. J. and F. de Elhuyar, L. von Uslar, E. Zettnow, A. Riche, and H. Moissan observed that tungsten is easily oxidized by warm **nitric acid** to yellow tungsten trioxide. C. G. Fink observed that the ductile metal is but slowly attacked; and L. Weiss, that the compact metal is superficially oxidized by hot nitric acid, or aqua regia. A. Stavenhagen, and L. von Uslar said that the metal is not attacked if heated many days with fuming nitric acid, or with aqua regia. According to W. E. Ruder, conc. nitric acid at 110° shows no action after 48 hrs. other than a slight dulling of the bright, metallic surface. The dil. acid, however, produces the yellow oxide on the surface. There is a slight gain in weight after 15 hrs. and then no further change even after 175 hrs.' immersion. J. J. and F. de Elhuyar, A. Riche, and H. Moissan found that it is readily oxidized to tungsten trioxide by aqua regia. W. E. Ruder found that aqua regia at room temp. oxidizes the surface of tungsten to the trioxide. After 215 hrs. the loss in weight was 0·31 per cent. At 110°, the chlorine was all driven off in about 4 hrs. and the tungsten disc had lost 0·1 per cent. and it was covered by a tough, greenish-yellow deposit. If this coating of oxide was allowed to remain, continued boiling in fresh aqua regia had no further effect upon the metal. W. Guertler and T. Liepus observed no action in 24 hrs. with 50 per cent. nitric acid, or with hot or cold, 10 per cent. acid; nor did aqua regia have any action. W. Rohn added that 10 per cent. nitric acid had no perceptible action in 8 hrs. in the cold, the hot acid dissolved 0·06 per cent. in one hour. W. E. Ruder, and H. Moissan found that a mixture of nitric and hydrofluoric acids rapidly dissolves tungsten with the evolution of nitric oxide, and the production of tungsten trioxide. L. Weiss added that the tungsten dissolves as hexafluoride or oxytetrafluoride. H. Moissan, and C. G. Fink observed that fused **sodium nitrate** readily attacks the metal. H. Moissan found that **phosphorus** does not combine with tungsten at a red-heat, but they react at a high temp. W. Rohn found that a 10 per cent. soln. of **phosphoric acid** dissolves 0·03 per cent. of tungsten in the cold in 24 hrs., and if hot, 0·001 per cent. in one hour. M. Wunder and B. Janneret also noted the dissolution of tungsten by phosphoric acid of sp. gr. 1·75, at 230°.

H. Moissan observed that when tungsten is heated with **boron** in the electric furnace, a boride is formed which rarely scratches the ruby; and similarly with **silicon.** When the metal is heated with **carbon,** it readily undergoes cementation. A. Riche, and C. W. Siemens and A. K. Huntington noted that the metal dissolves carbon; and H. Moissan, that 18·8 per cent. of carbon can be dissolved by tungsten. G. Tammann and K. Schönert, C. Zwikker, and M. R. Andrews and S. Dushman studied the diffusion of carbon in tungsten; and W. Geiss and J. A. M. van Liempt found that carbon diffused into a pressed bar at 1500°; but not into a single crystal at 1900°. M. R. Andrews, O. Ruff, G. Agte and H. Alterthum, and A. Westgren and G. Phragmen studied the action of carbon on tungsten. M. A. Schirmann studied the production of vacua by absorption of carbon monoxide at a low press. in bulbs containing a heated tungsten filament. S. Hilpert and M. Ornstein found that when the finely-divided metal is heated in **methane**—mixed with hydrogen to suppress the dissociation: $CH_4 \rightleftharpoons C+2H_2$—the carbide WC is formed at 800°; and when heated in **carbon monoxide** at 1000°, the carbide W_3C_4 is formed. According to I. Langmuir, if a tungsten filament is heated at 2200° K. in carbon monoxide under a press. of 0·001–0·020 mm., the gas slowly disappears. The behaviour of the gas resembles that of nitrogen; each atom of tungsten combines with one mol. of carbon monoxide, probably with formation of a compound, WCO. The rate of attack is independent of the press., probably owing to the velocity of the reaction being so great that the rate of evaporation of the compound formed determines the rate of reaction. The temp. coeff. of the reaction velocity is strongly negative. The interaction of carbon dioxide and hydrogen on the surface of tungsten was studied by C. N. Hinshelwood and C. R. Prichard, and B. S. Srikantan. J. Férée observed that tungsten when pyrophoric becomes red-hot in carbon monoxide. W. Guertler and T. Liepus observed no action by **carbon dioxide** and air after an exposure of less than 8 hrs. At 1200°, tungsten forms a blue oxide when heated with carbon dioxide; and water saturated with carbon dioxide slowly attacks the metal. Molten sodium carbonate dissolves tungsten slowly, but a fused mixture of sodium carbonate and nitrate dissolves it rapidly. According to W. E. Ruder, tungsten is slowly dissolved by fused sodium or potassium carbonate, or by mixtures of the two. A loss of about 2·5 per cent. was noticed in 4 hrs.; and when potassium nitrate was present, the loss was 32 per cent. in 6 hrs. C. Beindl used tungsten as a catalyst in the synthesis of hydrocyanic acid from nitrogen, hydrogen, and carbon monoxide. M. R. Andrews and S. Dushman found that **naphthalene** is decomposed by incandescent tungsten above 1500°. W. Rohn observed that 10 per cent. **acetic acid** has no action on tungsten; and W. Guertler and T. Liepus observed no action by acetic acid in 48 hrs., or by **citric acid,** or **tartaric acid** in 24 hrs. The Regina Bogenlampenfabrik found that finely-divided tungsten rapidly absorbs 6 to 10 per cent. of **pyridine** or **quinoline.** The products were used in the preparing lamp filaments. P. C. Allen and C. N. Hinshelwood, and A. Korcynsky studied tungsten as a catalyst in reactions with organic compounds; and O. Schmidt, as a hydrogenation catalyst.

The compounds of tungsten with the **metals** are discussed below. According to A. Riche, S. L. Malowan, and S. M. Delepine and L. A. Hallopeau, water made feebly alkaline with potassium hydroxide dissolves a little tungsten, forming the alkali tungstate; a conc. soln. of **potassium hydroxide** rapidly dissolves tungsten without giving off any hydrogen. L. von Uslar said that the boiling lye does not attack the metal, and W. E. Ruder observed that a soln. of potassium hydroxide of any conc. does not attack wrought tungsten, but the fused alkali attacks the metal slowly. In this case there was 31 per cent. loss in weight after 15 hrs., and in about 40 hrs. the disc had all dissolved. A. Stavenhagen also observed that the metal is slowly dissolved by the fused alkali, forming, according to S. Hilpert and M. Ornstein, traces of potassium and hydrogen, $W+6KOH \rightarrow W(OH)_6+6K$; $W(OH)_6+2KOH \rightarrow K_2WO_4+4H_2O$; and $4K+4H_2O \rightarrow 4KOH+2H_2$. W. Guertler and T. Liepus observed no action by a 10 or 50 per cent. soln. of **sodium hydroxide** in 48 hrs. W. E. Ruder said that a soln. of **chromium trioxide** in sulphuric acid does not attack tungsten. For the action of **alkali carbonate,** *vide supra.* A. von Wartenberg and H. Möhl found that tungsten reduces **alumina** at 2000° in an atm. of nitrogen, forming tungsten dioxide : $4Al_{gas}+3WO_{2gas}=3W+2Al_2O_3+700$ cals., or, if the alumina is vaporized, $4Al_{gas}+3WO_{2gas}=3W+2Al_2O_{3gas}+570$ cals., because the heat of vaporization of alumina is —130 Cals. Hence, in the former case, if $K=[Al]^4[WO_2]^3$, then $\log K=-153000T^{-1}+12{\cdot}3 \log T+21$; and, in the latter case, if $K'=[Al]^4[WO_2]^3/[Al_2O_3]^2$, $\log K'=-12450T^{-1}+8{\cdot}75 \log T+15$. In the former case, at 2500° and 3000°, log K is respectively 3 and 13, and in the latter case, log K' is respectively 0 and 3·5 at these temp. In the case of **zirconia,** $Zr_{gas}+WO_{2gas}=W+ZrO_2+150$ cals., and if $K=[Zr][WO_2]$, then $\log K=-3300T^{-1}+3{\cdot}5 \log T+6$, and at 2500° and 3000°, log K is respectively 5 and 7. Similarly with **thoria** which is also reduced by tungsten. According to C. J. Smithells, at 2580° K., no reaction was perceptible between tungsten and thoria in 24 hrs. ; at 2600° K., some reaction occurred ; and at 2750° K., the thoria was completely reduced by the tungsten. Z. Jeffries and P. Tarsov found that a little thorium is produced by dissociation when a thoriated tungsten filament is heated to a high temp. Thoria is slightly soluble in tungsten at high temp. The behaviour of thoria on heated tungsten filaments was discussed by W. G. Burgers and J. A. M. van Liempt. W. Samter and K. Schröter found that tungsten is dissolved by a bath of fused **sodium nitrite and nitrate.** W. Guertler and T. Liepus observed no reaction by a soln. of **magnesium chloride** in 8 hrs. E. F. Smith found that tungsten precipitates copper incompletely from a soln. of a **copper salt ;** and it behaves like molybdenum towards soln. of **silver salts,** precipitating silver, but the action of tungsten on soln. of **gold salts** is somewhat slower than that of molybdenum. Tungsten slowly reduces a soln. of **mercuric chloride** to mercurous chloride ; W. Guertler and T. Liepus observed that a soln. of mercuric chloride (1 : 500) is decomposed by tungsten at 90°. The subject was also studied by J. S. de Benneville. E. F. Smith found that soln. of **cadmium salts** and of **bismuth salts** are not affected by tungsten ; and the metal has no action on neutral, alkaline, or acidic soln. of lead salts.

C. G. Gmelin [2] made some observations on the physiological action of tungsten salts.

Some reactions of analytical interest.—The reactions of tungsten were discussed by A. A. Noyes and W. C. Bray,[3] and F. L. Hess. The **mineral acids**—hydrochloric, sulphuric, and nitric acids—with a soln. of sodium tungstate produce in the cold a white, amorphous precipitate of hydrated tungsten trioxide ; and when the soln. is boiled, the precipitate becomes yellow owing to the formation of yellow tungstic acid, which is insoluble in dil. acids, but appreciably soluble in conc. acids. Free tungstic acid slowly dissolves in a boiling soln. of an alkali tungstate forming a metatungstate which does not give a precipitate with mineral acids. If the soln. of a metatungstate is boiled with an excess of acid, insoluble tungstic acid is slowly precipitated. With **phosphoric acid,** soln. of the alkali tungstates give a precipitate of a complex alkali phosphatotungstate which is soluble in an excess of phosphoric acid. The presence of phosphoric acid hinders the precipitation of tungstic acid by the mineral acids. Many **organic acids**—*e.g.* citric and tartaric acids—give no precipitate with alkali tungstates owing to the formation of stable, soluble complex salts, and they hinder the precipitation of tungstic acid by mineral acids, they also interfere with the action of several other reagents—*e.g.* reducing agents. No precipitate is formed when acidified soln. are treated with **hydrogen sulphide ;** and **ammonium sulphide** gives no precipitate, but, according to W. T. Taggart and E. F. Smith, if a salt—*e.g.* manganese salt—is present which gives a precipitate with ammonium sulphide, tungsten sulphide may be precipitated. If the soln. containing an excess of ammonium sulphide be treated with an acid, light brown tungsten trisulphide is precipitated; it is soluble in a soln. of ammonium sulphide. Soln. of the tungstates give white precipitates with soln. of **barium or calcium chloride, lead acetate,** and **silver or mercurous nitrate.** E. Zettnow added that one part of tungstic acid in 20,000 parts of water gives a white coloration with lead acetate; and with 1 in 40,000, an opalescence. A brown precipitate is produced by tincture of galls, or **tannin** when the soln. is acidified (M. Barber). The effect of **reducing agents** is to form a blue coloration—*e.g.* if a soln. of an alkali tungstate is treated with zinc and hydrochloric acid, the tungstic acid first precipitated forms blue tungsten hemipentoxide; stannous chloride first produces a yellow coloration, but when hydrochloric acid is added and the soln. warmed, a blue precipitate is formed. E. Zettnow added that one part of tungstic acid in 1000 parts of water treated with sulphuric acid and stannous chloride gives a brownish-yellow colour; with 1 in 10,000, the colour is white; and with 1 in 20,000 a pale opalescence is produced. Sodium hypophosphite, and sulphurous acid in a warm acidified soln. produce a blue coloration; **dihydroxymaleic acid** forms a brown colour which immediately turns blue (H. J. H. Fenton); mercurous nitrate and potassium iodide give a blue coloration (E. Kafka, and E. Pozzi-Escot); but with ferrous sulphate, the ochre-yellow precipitate is not coloured blue by acids. The reduction test was discussed by G. Torossian, and M. L. Hartmann. J. H. Muller observed that salicylic acid gives a yellow coloration with alkali tungstates and molybdates but no precipitate; and J. H. de Boer, that **alizarin sulphonic acid** gives a violet coloration. According to E. F. Smith, quinine sulphate, and chloride, and cinchonidine, and benzidine hydrochloride, acetate, and chloride precipitate tungstic acid quantitatively from soln. of its salt. Aniline hydrochloride does not give a precipitate with sodium and ammonium tungstates, and metatungstates, but does so with the paratungstates but not after boiling. The three sodium and ammonium tungstates are incompletely precipitated by *o*-toluidine and pyridine hydrochlorides. A little tungstic acid gives a deep reddish-brown coloration with **potassium ferrocyanide,** and after some time a reddish-brown jelly. E. Zettnow said that one part of tungsten trioxide in 1000 parts of water acidified with a little sulphuric acid gives a dark orange-yellow colour; with 1 in 10,000, a greenish-yellow colour; and with 1 in 20,000, a pale yellow colour.

Some uses of tungsten.—Some unique properties of tungsten have important industrial applications.[4] It has a high density exceeding that of lead. Its m.p. is higher than that of any known metal; its tensile strength exceeds that of iron and nickel; it is paramagnetic and elastic so that it has been tried in electrical meters, and non-magnetizable watch-springs. It can be drawn into thinner wires than any other metal, and this fact, coupled with its chemical stability, offers possibilities in making suspensions for galvanometer needles,[5] and cross-hairs for telescopes; and for thin wires in surgical operations in place of gold or silver wires. The greatest use of tungsten is in the preparation of iron or steel alloys, *e.g.* in the preparation of high-speed tool steels (*q.v.*). Tungsten forms alloys with many of the metals, and some of them have valuable properties although in many cases the cost of the alloy is out of proportion with its usefulness. The *stellite* alloy described by E. Haynes[6] is an alloy of cobalt, chromium, and tungsten (75 : 20 : 5) with or without additions of other metals. It is a competitor for some high-speed cutting steels. J. T. Bottomley proposed an alloy called *platinoid,* composed of nickel, zinc, copper, and tungsten for conductivity wires. E. Weintraub patented an alloy with 40 to 80 per cent. of platinum for use in electrical contacts, jewellery, etc. *Partinium* is an alloy of aluminium and tungsten employed in automobile construction; *sideraphite,* an alloy of iron with nickel, copper, aluminium and tungsten; *minargent,* an alloy of copper, nickel, and tungsten; and *backford,* an alloy of copper, tin and tungsten. F. A. Fahrenwald discussed the use of alloys of tungsten and molybdenum as substitutes for platinum for contact points in sparking coils, voltage regulators, and other electrical instruments. Gold-coated tungsten dental pins are also used in place of platinum. E. Groschuff and F. Mylius found that malleable tungsten under the trade-name *iridam*, proposed as a substitute for platinum, is too brittle for thin-walled crucibles, and it is attacked by hydrochloric acid. According to E. Haynes, an alloy of tungsten, chromium, and cobalt (20 : 15 : 65) is hard, and can be used for cutting tools and surgical instruments, being unaffected by organic acids and ordinary antiseptics. A similar alloy with nickel is called *amaloy*. P. Monnartz discussed the use of tungsten in raising the acid resisting properties of iron-chromium alloys. The alloys of tungsten were discussed by H. Mennicke, H. Leiser, A. Hoenig, J. W. Richards, J. S. de Benneville, J. J. Runner and M. L. Hartmann, etc.—*vide infra*. The use of tungsten as a filament in incandescent lamps has been previously discussed. J. Trowbridge and S. Sheldon [7] recommended tungsten as an alloy metal for mirrors in physical apparatus. The use of tungsten as a valve electrode and as a rectifier has been previously indicated. W. Fehse [8] recommended it for resistance wires for the Tungsten arc-lamp as a source of ultra-violet light; [9] and tungsten anode in the mercury lamp [10] have been tried. Tungsten wire has also been used as a resistor in wire-wound electrical furnaces—*e.g.* by F. Fischer and E. Tiede,[11] A. H. Compton, and F. A. Fahrenwald. The " metal," widia, is obtained by pressing and sintering tungsten carbide alloyed with cobalt.[12] R. Eisenmann [13] used tungstic acid as a substitute for chromic acid in the chromic acid cell; J. Harden,[14] and J. H. Robertson and D. Jankower used tungsten for making crucibles. Wrought tungsten targets for X-ray tubes are in general use. The high sp. gr. of the metal is here an advantage.[15] The targets are sometimes made with a surface of tungsten on a backing of some other metal, as silver or copper which conducts away the heat more rapidly. Colloidal tungsten was recommended by R. Kruger [16] as a substitute for bismuth in X-ray photographs of the gastro-intestinal canal. Calcium or cadmium tungstate [17] is used with the addition of, say, sodium vanadate to prevent the glare on fluorescent screens on X-ray work.

Tungsten has been tried by F. Haber,[18] as a catalyst in the manufacture of hydrogen cyanide ; and C. Beindl used it with good results as a catalytic agent in the synthesis of ammonia ; in the interaction of hydrogen and carbon dioxide ; [19] in the splitting of alcohol into ethylene and water ; [20] and in organic combustion analyses.[21] There are some miscellaneous applications of tungsten compounds in the chemical laboratory [22]—*e.g.* silicotungstic, and phosphatotungstic acid, etc. M. Luckiesh [23] studied the tungsten filament lamp in therapeutics. Tungsten oxide, and tungstates have been used in dyeing ; [24] as a mordant [25] for rendering textile fabrics non-inflammable ; as a pigment [26]—*e.g.* the blue oxide forms the so-called *mineral blue* or *blue carmine ;* the trioxide, *mineral yellow ;* copper and chromium tungstates ; and the group of complex tungstates of the alkalies and alkaline earths known as *tungsten bronzes ;* and for pottery and glass colours.[27]

§ 7. The Atomic Weight and Valency of Tungsten

There is a close relationship between the valencies of chromium, molybdenum, and tungsten. Tungsten appears to be *bivalent* in the halides WCl_2, WBr_2, and WI_2, but the mol. wt. of these salts has not been determined. The observations of R. F. Bernhardi-Grisson [1] on the electrolytic reduction of tungstic acid, and of O. Olsson, and others on the complex chlorides, show that compounds with *tervalent* tungsten have probably been formed. The existence of the tetrahalides—WCl_4 and WI_4—as well as of the disulphide shows that *quadrivalent* tungsten can exist, although not established by mol. wt. determinations. A number of well characterized compounds of *quinquevalent* tungsten has been prepared, and the results have been confirmed by vapour density determinations by H. E. Roscoe, and H. Debray. O. Ruff and F. Eisner's hexafluoride shows that tungsten can also behave as a *sexivalent* element. This is confirmed by the existence of the hexachloride, oxyhalides, and the trioxide. N. V. Sidgwick discussed the co-valency of tungsten. The salts of pertungstic acid, HWO_4, or $HO.WO_3$, prepared by E. Péchard show that septivalent tungsten may exist.

Tungsten compounds were analyzed by M. H. Klaproth,[2] C. F. Bucholz, and J. J. and F. de Elhuyar, and the results led J. J. Berzelius to infer that the sulphide has the mol. ratio $W : S = 1 : 2$, and tungstic anhydride, $W : O = 1 : 3$. He added: "Tungsten and molybdenum form a similar series of oxides, and in its normal salts the acid anhydride contains three atoms of oxygen to one atom of oxygen in the base. The tungstates are also isomorphous with the molybdates indicating that the internal constitution is the same." This hypothesis makes the at. wt. of tungsten approximate 184. This is in agreement (i) with the vap. density determination of H. Debray, and O. Ruff and F. Eisner, and not in agreement with J. Persoz's assumption that the tungsten is quinquevalent in tungstic acid. (ii) It agrees with the at. ht. determinations of P. Nordmeyer and A. L. Bernoulli, of A. W. Grodspeed and E. F. Smith, and of E. Defacqz and M. Guichard. (iii) It is in accord with the isomorphism between the tungstates and molybdates observed J. J. Berzelius, and R. Funk. (iv) It is in harmony with the electrochemical eq. observed by M. Leblanc and H. G. Byers, E. F. Smith, A. Rosenheim and E. Dehn, and W. E. Koerner. (v) It is also in accord with the at. number, and the high frequency spectrum of H. G. J. Moseley. (vi) It agrees with the position of tungsten in the periodic table as a number of the chromium family. J. N. Frers discussed the place of tungsten in the periodic table.

The observations of F. J. Malaguti, F. Wöhler, A. Riche, H. V. Regnault, and J. C. G. de Marignac are not suited for fixing a value for the at. wt. of tungsten. General reviews of the at. wt. of tungsten were made by L. Meyer and K. Seubert, W. Ostwald, F. W. Clarke, and J. Meyer. The determinations include: (i) A series, based on the ratio $WO_3 : W$ obtained by reducing the trioxide to the metal, includes that of J. J. Berzelius, 188; E. R. Schneider, 184·2, and later, 184·0; R. F. Marchand, 183·9; J. B. von Borck, 183·7; J. B. A. Dumas, 184·0; F. A. Bernoulli, 184; J. Persoz, 184; H. E. Roscoe, 183·5; and J. Waddell, 184·3. (2) Another series, based on the ratio $W : WO_3$ obtained by oxidizing the metal to the trioxide, includes that of E. R. Schneider, 183·9; R. F. Marchand, 184·3; J. B. von Borck, 184·4; F. A. Bernoulli, 187; H. E. Roscoe, 183·5; M. E. Pennington and E. F. Smith, 184·9; O. L. Shinn, 184·0; E. F. Smith and W. L. Hardin, 184·1 to 184·8; and E. F. Smith and F. F. Exner, 184·07. (3) A series, based on the loss of water by tungstic acid involving the ratio $WO_3 : 3H_2O$, gave F. A. Bernoulli 186·62; and E. F. Smith and E. D. Desi, 184·7. (4) A series, based on the dehydration of barium metatungstate involving the ratio $BaW_4O_{13}.9H_2O : 9H_2O$, gave C. Scheibler 184·0. E. F. Smith and W. L. Hardin discussed these results. (5) H. E. Roscoe obtained 184·1 from the ratio $WCl_6 : 6AgCl$, and 183·9 from the ratio $WCl_6 : W$. (6) E. F. Smith and F. F. Exner obtained 184·10 from the ratio $WCl_6 : WO_3$. (7) E. Zettnow analyzed ferrous tungstate and obtained 183·6 from the ratio $FeWO_4 : FeO$. (8) The analyses of silver tungstate furnished E. Zettnow with the value 183·6 from the ratio $Ag_2WO_4 : Ag_2O$, and also from the ratio $Ag_2WO_4 : 2AgCl$. (9) T. M. Taylor measured the carbon dioxide displaced by tungstic acid from carbonates and obtained 183·5 from the ratio $WO_3 : CO_2$, and likewise E. F. Smith and F. F. Exner obtained 183·6. (10) G. E. Thomas obtained 184·7 by measuring the water of crystallization in sodium tungstate. F. W. Clarke's general review gave 184·575 for the best representative value; and J. Meyer's, 184·1. The International Table for 1929 gave 184.

The **atomic number** of tungsten is 74. F. W. Aston[3] found that tungsten has four **isotopes** with the respective mass numbers 182, 183, 184, and 186; and the respective percentage abundances 22·6, 17·2, 30·1, and 30·0 per cent. The corresponding at. wt. is 183·96 in agreement with the representative value 184 now employed. The isotopic form reported by M. Gerber, was rendered improbable by the negative results of P. Barbe. N. Bohr's view of the **electronic structure** is symbolized: (2) for the K-shell; (4,4) for the L-shell; (6,6,6) for the M-shell; (8,8,8,8) for the N-shell; (4,4,4) for the O-shell; and (2) for the P-shell. The subject was discussed by E. C. Stoner, A. Dauvillier, O. Feussner, H. G. Grimm, J. D. M. Smith, and C. D. Niven. Neither E. Rutherford and J. Chadwick, nor H. Pettersson and G. Kirsch, reported any observations on the **atomic disruption** of tungsten when bombarded by α-rays. The subject was discussed by G. I. Podrowsky.

G. L. Wendt and C. E. Irion attempted to decompose tungsten by rapidly discharging a condenser holding 30,000 to 45,000 volts through a tungsten wire 4 cm. long and 0·035 mm. diam., either in vacuo or in carbon dioxide at 1 atm. press. In this way, a momentary temp. above 20,000° was produced in the wires, which were entirely dissipated, no smoke, dust or solid residue being found after the explosion. Abundant quantities of gas were present after the explosions in vacuo, and a spectroscopic examination of this showed the strong yellow helium line, and two red, one bright blue, and one pale violet line was also observed but have not been identified. About the same weight (mean 0·173 mg.) of tungsten furnished from 3·62 to 0·30 c.c. of gas unabsorbable by potassium hydroxide. If the whole of the tungsten had been decomposed into helium the volume of gas would have been 4·0 c.c. The results were questioned by D. M. Goetschius, and attempts to verify the observations by H. V. A. Briscoe and co-workers, S. Smith, and W. D. Harkins and S. K. Allison showed that G. L. Wendt and C. E. Irion's statements are based on erroneous observations. L. Thomassen observed no sign of change in an X-ray tube after the tungsten had been bombarded 90 hrs.

§ 8. Alloys and Intermetallic Compounds of Tungsten

Alloys of **copper** and tungsten were prepared by J. J. and F. de Elhuyar,[1] and F. A. Bernoulli obtained them by the simultaneous reduction of both metals. The alloys were said to be difficult to melt. J. Percy hoped that alloys with tungsten might be hard, and resist oxidation, but on trial, the results were unsatisfactory. C. L. Sargent obtained the alloy by reducing the mixed oxides with sugar charcoal in the electric arc furnace; and E. W. von Siemens and J. G. Halske reduced copper tungstate by hydrogen. C. Liebenoff obtained the alloys by dipping a lead plate in a soln. of copper and tungsten in dil. sulphuric acid. The brownish-red metals are ductile. When heated electrically in vacuo, the copper distils off. T. Kniesche, and E. W. L. Biermann, and P. Berthier reported alloys with 10 per cent. tungsten. D. Kremer, and H. List added that copper does not form homogeneous alloys with tungsten. O. Rumschöttel tried to make alloys by the simultaneous reduction of copper and tungsten oxides by the aluminothermite process; but found that as the molten alloy cools, the tungsten separates out. He also found that the tungsten separates from ternary alloys of tungsten, copper, and aluminium, nickel, or cobalt; similar results were obtained with quaternary alloys of tungsten, copper, and zinc with iron, cobalt, or nickel. J. G. Escard studied the tungsten-copper alloys. H. List said that a satisfactory regulus can be obtained only in the presence of a third element, say, silicon; the resulting ternary alloy is golden-yellow, and tough.

J. J. and F. de Elhuyar prepared alloys of **silver** and tungsten, which they said were pale brown, spongy, and malleable. F. A. Bernoulli was not able to alloy these metals. E. F. Smith said that when tungsten is placed in an ammoniacal soln. of silver nitrate, the silver is quantitatively precipitated. J. J. and F. de Elhuyar also obtained an alloy with **gold** which they described as being yellow and difficult to melt. G. Fuchs said that before alloying silver or gold with tungsten one of the metals is first alloyed with nickel, iron, or aluminium. A gold alloy containing 75 parts of gold to 10 to 15 of tungsten and 10 to 15 parts of nickel, may be used in jewellery as a substitute for platinum. It can be cast, hammered, and rolled and takes a much finer polish than does platinum. An alloy of 80 parts of fine silver, 10 to 15 of nickel, is said to have a greater strength than the gold alloy. It is much less affected by atmospheric oxidation than silver and takes a better polish. These alloys may also find technical application on account of their resistance to acid attack.

F. Wirth mentioned the use of an alloy with **beryllium** as a hardening agent for the filaments of incandescent lamps. H. List was not able to obtain alloys either with **calcium** and tungsten or with **magnesium** and tungsten. J. J. and F. de Elhuyar, and F. A. Bernoulli obtained an alloy of **zinc** and tungsten by the simultaneous reduction of the mixed oxides. The alloy loses zinc when heated. H. List added that zinc does not alloy with tungsten. J. G. Escard studied the alloys of tungsten, copper and zinc. H. von Miller, and F. Jones discussed the action of tungsten on brass.

A. S. Russell and co-workers found that the solubility of tungsten in **mercury** is very small, being of the order of 10^{-5} grm. per gram of mercury. R. F. Bernhardi-Grisson, and G. Tammann and J. Hinnüber obtained **tungsten amalgam** by the electrolysis of a soln. of tungsten trioxide in alcoholic hydrochloric acid and a mercury cathode. The solubility of tungsten in mercury is less than that of molybdenum. J. Férée obtained the amalgam by the electrolysis of a soln. of tungstic acid in hydrochloric acid using a mercury cathode. A. S. Russell found that metals are removed from their amalgams by oxidizing agents in the order Zn, Mn, Cu, Cr, Fe, Mo, Co, Hg, Ni, W.

F. Wöhler and F. R. Michel melted a mixture of tungsten trioxide, cryolite, potassium sodium chloride, and **aluminium** (1 : 2 : 2 : 1), and removed the excess of aluminium from the cold regulus by hydrochloric acid. There remained rhombic, prismatic crystals of sp. gr. 5·58, which were hard, and brittle. Cold, conc. acids had no action on the alloy, but hot nitric acid forms tungsten trioxide; hot hydrochloric acid dissolves the alloy forming a deep brown soln. of a lower chloride. Hot soda-lye removes all the aluminium leaving tungsten behind. H. Moissan, H. Schirmeister, J. W. Richards, and A. Stavenhagen prepared alloys of the metal; H. List said that the mixed metals do not form a homogeneous alloy, but in the presence of a third metal—cobalt, nickel, iron, or silicon—homogeneous alloys may be formed. Some tungsten separates from the ternary alloys of tungsten and aluminium with cobalt, iron, or silicon. L. Guillet studied the alloys in some detail, but without reference to the equilibrium diagram. He obtained them by igniting mixtures of aluminium and tungsten trioxide by a mixture of aluminium and 80 per cent. of barium dioxide. The alloys have a crystal structure. They are not attacked by oxygen at ordinary temp. or below a red-heat, but at a red-heat, tungsten trioxide, the blue oxide, and alumina are formed. Boiling water acts slowly, and the metal acquires a protective film of oxide. Chlorine has no action at ordinary temp., but at about 300°, volatile aluminium trichloride and tungsten hexachloride are formed. Hydrochloric acid acts slowly, but the Al_4W alloy is vigorously attacked by the boiling acid. Sulphuric acid acts slowly; and conc. boiling nitric acid slowly forms tungsten trioxide which is reduced to the blue oxide by the aluminium, and then oxidized to the trioxide once more. Potash-lye does not decompose the cold alloy, but when hot, there is a rapid attack which is more vigorous, the greater the proportion of contained aluminium. L. Guillet obtained what he regarded as **aluminium ditungstide,** AlW_2, from a mixture of tungsten trioxide and aluminium in the mol. proportions $Al : W_5$. The sp. gr. of the black, crystalline powder is 12·75 at 20°—the mixture rule gives a sp. gr. of 13·06. It is not attacked by aqua regia. A mixture of tungsten trioxide and aluminium in the mol. proportions $Al : W_4$ furnished **aluminium tritatungstide,** Al_3W, in quadratic prisms of sp. gr. 6·31 at 20°—theoretical value, 6·38. It is slowly decomposed by aqua regia. Similarly, tungsten trioxide and aluminium in the mol proportions $Al_4 : W$, gave lamellar crystals of **aluminium tetritatungstide,** Al_4W, of sp. gr. 5·56 at 20°—theoretical 5·62. The alloy is quickly decomposed by aqua regia. W. Campbell and J. A. Mathews obtained an alloy corresponding with Al_8W in thin monoclinic crystals readily attacked by aqua regia; and one with hexagonal crystals of Al_7W, which is not affected by aqua regia, and is slowly attacked by a fused mixture of alkali carbonate and nitrate. A. von Zeerleder studied the resistance of the Al–W alloys to acids. D. A. Roche prepared W–Al–Sb alloys; M. R. Whitmore and F. T. Sisco, R. L. Roman, C. Berg, G. Roman, and R. Wallace, W–Al–Cu alloys. The term *wolframinum* is a trade-name for one of the ternary alloys; and *partinium*, for an alloy of aluminium, copper, tin, antimony, and tungsten.

H. List said that tungsten does not alloy with **tin,** but J. J. and F. de Elhuyar described the alloy, and R. L. Roman, R. B. Wheatley, and the Hannoversch Industriegesellschaft prepared alloys of tin and tungsten with other metals. J. G. Escard studied the W–Sn–Cu alloys. H. von Miller, R. B. Wheatley, and J. Webster discussed the effect of tungsten on the copper-tin bronzes. H. List, and F. A. Bernoulli could not prepare alloys with **lead** by the direct union of the metals. J. J. and F. de Elhuyar reduced a mixture of tungsten trioxide with lead in a carbon crucible; F. A. Bernoulli used a mixture of lead oxide and tungsten trioxide; and A. Stavenhagen and E. Schuchard, a mixture of tungsten trioxide, lead oxide, and aluminium powder. The alloys were also prepared by H. Falkenberg, H. Kuzel, and H. Lieber. S. Inouye prepared alloys with up to 30 per cent. of tungsten. The thermal diagram is shown in Fig. 20. At 1300°, lead dissolves a maximum of 30 per cent. of tungsten. The temp. of primary crystallization could not be detected with less than 5 per cent. of tungsten. Tungsten crystallizes first, and the eutectic appears to be almost pure lead. No evidence of the formation of a compound on the lead side could be found, and it is improbable that there could be one on the tungsten side, on account of the low b.p. of lead. H. Falkenberg, and L. F. von Grotthuss-Call alloyed tungsten with lead and antimony for use as a bearing metal. L. Freiherr prepared ductile alloys of **thorium** and tungsten by reducing a mixture of thoria and tungsten trioxide—*vide supra*, ductile tungsten. S. Dushman and I. Langmuir, and P. Clausing discussed the diffusion of thorium in tungsten; A. St. John observed no evidence of an alloy of tungsten and thorium in thoriated tungsten filaments.

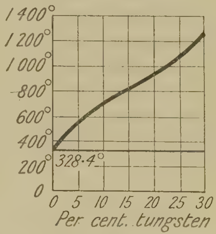

Fig. 20.—Freezing-point Curve of the Lead–Tungsten System.

F. A. Bernoulli, and C. L. Sargent obtained alloys with **antimony,** but not with **bismuth.** C. L. Sargent prepared alloys of tungsten and **chromium** by melting a mixture of the oxides and carbon in an electric furnace; and T. Goldschmidt obtained them by the aluminothermite process. E. Haynes also found that tungsten alloys with chromium and cobalt in all proportions. F. A. Fahrenwald, E. C. Bain, and Z. Jeffries prepared alloys of **molybdenum** and tungsten by compressing the reduced powders into briquettes, and heating them with an electric current in an atm. of hydrogen; and A. Stavenhagen and E. Schuchard, by the thermite process. W. Geiss and J. A. M. van Liempt observed no diffusion between the two metals in hydrogen at 2400° during 2 hrs., but with a pressed bar, diffusion occurs in 15 min. at this temp. H. Mennicke said that the compound *tungsten hemitrimolybdide*, W_2Mo_3, is formed by reducing molybdenum oxide with tungsten hemitrisilicide in the presence of lime: $W_2Si_3+3MoO_2+3CaO=3CaSiO_3+W_2Mo_3$. The silver-white crystals have a sp. gr. 14·8. A. Stavenhagen and E. Schuchard, and H. Mennicke said that *tungsten molybdide*, WMo, is formed by the aluminothermite process: $WO_3+MoO_3+4Al=2Al_2O_3+WMo$. There is not sufficient evidence to establish either of these products as a chemical individual. The equilibrium diagram, Fig. 21, by F. A. Fahrenwald is approximately a straight line from the f.p. of molybdenum to that of tungsten. W. Geiss and J. A. M. van Liempt, and Z. Jeffries also obtained analogous diagrams. This shows that the metals are completely isomorphous. There is no evidence of chemical combination or of eutectics. The electrical resistance curves, and the curves for the hardness (Fig. 22) of the alloys, are typical of an uninterrupted series of solid soln. Curve *A*, Fig. 22, refers to the metal which has suffered a 60-per cent. reduction, and *B*, the compressed, heat-treated but unforged ingot. Both curves are smoothly convex, and are typical of an uninterrupted series of solid soln. The etching tests agree with the presence of cubic crystals. W. Geiss and

J. A. M. van Liempt studied the electrical resistance and found the results in agreement with the assumption that the alloys form a continuous series of solid soln. According to A. E. van Arkel, the X-radiogram of the 50–50-alloy corresponds with a cube-centred lattice showing that the atoms in the isomorphous crystals are arranged in a space-lattice with definite places for the components. D. Binnie found that the molybdenum-tungsten thermocouple has an e.m.f. of 7 to 8 millivolts per degree at 1500°, and 8 to 9 millivolts at 1600°; and he made high temp. pyrometers with the couples. A. Stavenhagen and E. Schuchard also studied the alloys of tungsten and molybdenum as well as those of W–Mo–Ti, and W–Mo–Cr–Co, and E. W. von Siemens and J. G. Halske, those of chromium and tungsten. According to J. A. M. van Liempt, the corrosion of the alloys by acids, and by water, in some cases, starts rapidly at a particular composition, whilst in others it increases continuously with increase in the percentage of molybdenum. Where a sharp corrosion limit is shown, it is not a constant, but depends on the nature of the reagent, the temperature, and usually also on the time of reaction. The positions of the resistance limits do not agree with G. Tammann's theory. The subject was discussed by G. Tammann. A. Stavenhegen and E. Schuchard obtained his alloys by the thermite process. According to P. Reinglass, tungsten alloys in all proportions with **tantalum**, but with more than 10 per cent. of tantalum, the alloys are hard and brittle; with smaller proportions of tantalum, the alloys may be drawn into wires 0·1 mm. diameter.

§ 9. The Lower and Intermediate Oxides of Tungsten

About half a dozen tungsten oxides have been reported whose individuality is not well-established; and, in addition, there are the more clearly defined hemipentoxide, W_2O_5, the dioxide, WO_2, and the trioxide, WO_3. E. D. Desi [1] obtained a blue product by the action of conc. sulphuric acid on tungsten at 200°; after quickly washing with alcohol and ether, and rapid drying, its composition approximated *tungsten monoxide*, WO, or $W_2O.WO_2$; if boiling conc. sulphuric acid be employed, a mixture of a white and a greenish-blue product is formed—the latter, when separated, washed with alcohol and ether, and rapidly dried, corresponds in composition with *tungsten tetritatrioxide*, W_4O_3. If tungsten be heated with conc. sulphuric acid in a sealed tube at 150°, a blue product with the composition of *tungsten hemitrioxide*, W_2O_3, is formed; and if the temp. in the sealed tube be 180°, the blue product has the composition of *tungsten pentitaenneaoxide*, W_5O_9. When these oxides are treated with ammonia, or alkali-lye, tungsten and the trioxide are formed; and the hemitrioxide precipitates silver in brilliant scales from silver nitrate soln.

Another series of blue-coloured oxides has been reported intermediate between the di- and trioxides. They are formed either by oxidizing the dioxide or by reducing the trioxide. A. Lottermoser suggested that E. D. Desi's oxides, as well as these intermediate oxides, are only mixtures of tungsten and its trioxide. A number of these have been used as blue pigments under the commercial names *wolfram-blue, mineral blue*, and *blue carmine*. E. F. Anthon added that these blues are cheaper than the smalt blues. A. Pinchon employed a mixture of tungsten-blue and yellow tungstic acid as a non-poisonous green pigment in place of the arsenical copper greens. J. J. Berzelius observed that when dry hydrogen is passed over gently warmed tungsten trioxide, a blue oxide is formed—F. J. Malaguti used the flame of a spirit-lamp as a source of heat; and A. Riche recommended working at 250°. F. Göbel, and L. Gmelin obtained the blue oxide by passing carbon monoxide over tungsten trioxide at a red-heat. F. J. Malaguti, and L. von Uslar obtained the blue oxide by igniting ammonium tungstate in a covered crucible; and E. F. Anthon, by heating the ammonium tungstate in a current of hydrogen—*vide infra*, the 5 : 14, 4 : 11, and 3 : 8 oxides; and also the analogous blue molybdenum oxides.

There are some hydrated forms of the blue oxide—thus, A. Riche observed that when tungstic acid under water is exposed to sunlight, it acquires a blue colour; and R. E. Liesegang, that tungstic acid in contact with paper, becomes blue in sunlight. R. Bunsen said that paper moistened with sodium tungstate soln. becomes blue or green when treated with stannous chloride, or ammonium sulphide. H. E. Roscoe observed that when tungsten pentachloride or pentabromide is hydrolyzed, the blue oxide is formed, and this is easily oxidized by permanganate to tungstic acid. P. Burckhard obtained the blue product by the electrolysis of fused sodium tungstate; and E. F. Smith, by the electrolysis of fused sodium tungstate, and by the electrolysis of a soln. of a tungstate in boiling hydrochloric acid. C. Scheibler added that when a soln. of metatungstic acid is sat. with hydrogen sulphide, and then treated with ammonia or ammonium sulphide, sulphur separates out, and the mixture acquires an intense blue coloration. W. Biltz found that the blue colloidal soln. so prepared dyes silk a pale blue—the result is less satisfactory with cotton or wool. W. Biltz dialyzed the colloidal soln. and found that some of the blue substance passes through the membrane. The dialyzed soln. is deep sky-blue. M. Kröger obtained colloidal soln. of the blue tungsten oxide by electrolyzing a 2 per cent. soln. of sodium tungstate with an excess of acid; if an excess of acid be not used, a dark brown soln. is formed. The colloid is reversible, and the colloid is negative so that it collects about the anode as a dark blue liquid when an electric current is passed through the liquid contained in A. Coehn's apparatus. The liquid about the cathode becomes clear. The colloid is precipitated from the soln. by positively charged colloids—*e.g.* the hydrated oxides of iron, aluminium, chromium, thorium, zirconium, and cerium. W. Biltz and W. Geibel found that a freshly-prepared colloidal soln. of the blue oxide is optically empty, older preparations are more or less cloudy in Tyndall's cone of light. N. R. Dhar and co-workers studied the coagulation of the colloidal soln.

According to E. T. Allen and V. H. Gottschalk, *tungsten pentitatetradecoxide*, $W_5O_{14}.H_2O$, is formed when tungsten trioxide is reduced by heating it with soln. of stannous chloride in hydrochloric acid on a water-bath, or by heating it to 200° with hydriodic acid in a sealed tube. The *pentitatetradecoxide* forms a dark blue powder with a purplish lustre; it is insoluble in water acidified with hydrochloric acid, but in pure water it seems to form a colloidal soln. It is readily oxidized by exposure to the air or by oxidizing agents, and is instantly converted into the trioxide by the action of heat. When heated with a soln. of an alkali hydroxide, hydrogen is evolved and a tungstate is produced, whilst by the action of ammonia, ammonium tungstate and a brown residue are formed, but no gas is evolved. According to E. D. Desi, when sulphurous acid acts on tungsten, W_5O_{14} is formed. J. Eltzbacher found that when freshly precipitated tungsten trioxide is dissolved in a boiling soln. of oxalic acid, and the liquid electrolyzed in a compartment cell, the cathode liquid becomes clear, and a deposit of the dark blue oxide forms on the cathode. H. Leiser stated that if an acidic soln. of tungstic acid is electrolyzed, using a platinum or nickel cathode, a blue soln. of *tungsten tetritahenoxide*, W_4O_{11}, the anhydride of metatungstic acid, is formed. L. von Uslar reported *tungsten pentitaoctoxide*, W_5O_8. As indicated above, when the pentitatetradecoxide is treated with aq. ammonia, a brown mass is produced which E. T. Allen and V. H. Gottschalk found to have the composition of *tungsten tritaoctoxide*, $W_3O_8.H_2O$, when it has been washed and dried. The deep purple oxide has a bronze lustre, and its chemical behaviour is like that of the pentitatetradecoxide. E. D. Desi said that the tritaoctoxide, W_3O_8, is obtained by heating ammonium metatungstate to a bright red-heat, or by fusing tungstic acid with potassium iodide. The purple product has a yellow metallic lustre, and it is insoluble in acids, and alkali-lye. O. F. von der Pfordten also prepared this oxide.

L. Wöhler and O. Balz measured the equilibrium constants of the systems in which tungsten trioxide and dioxide are reduced by hydrogen; and in which tungsten is oxidized by steam. The equilibrium constant is represented by the ratio of the concentrations of steam, C_{H_2O}, and of hydrogen, C_{H_2}, in equilibrium with the solid phase. Only the bluish-violet **tungsten hemipentoxide,** W_2O_5, and brown tungsten dioxide, WO_2, were found as stable solid phases. The blue oxides with a composition between that of the trioxide and of the hemipentoxide are mixtures. These results were confirmed by G. Chaudron—*vide supra*, Fig. 2. L. Wöhler and O. Balz found that the equilibrium constants were $K_1=16$ for $WO_3 : W_2O_5$ at 800° ; $K_2=5{\cdot}1$ for $W_2O_5 : WO_2$ at 800° ; and $K_3=1{\cdot}0$ for $WO_2 : W$ at 950°. L. Wöhler and W. Prager gave :

	733°	828°	863°	868°	941°	1036°
K_3 . .	0·45	0·65	0·75	0·82	0·99	1·29

J. A. M. van Liempt showed that the conditions of equilibrium indicate that if hydrogen be passed through water at 95°, and the mixture of hydrogen and water vapour be passed over tungsten trioxide at 900°, tungsten hemipentoxide is formed. The blue oxide obtained by W. Reinders and A. W. Vervloet varied in composition between $WO_{2{\cdot}20}$ to $WO_{2{\cdot}95}$. G. A. Meerson found that in hydrogen, the hemipentoxide sublimes above 900°. L. Wöhler and R. Günther calculated for the dissociation press., p_2 atm., for $W_2O_5 \rightarrow WO_2$, $\log p_2=-28000T^{-1}+8{\cdot}496$; and for the heat of the reaction, 128·0 Cals. H. Alterthum and F. Koref calculated values for the dissociation press., and gave for the heat of vaporization 43·36 Cals. at 1800° K. For the equilibrium constant in the reaction $4WO_2+O_2=2W_2O_5+237$ Cals., $K_2=[WO_2]^4[O_2]/[W_2O_5]^2$, where the bracketed terms denote partial press., $\log K_2=-237000T^{-1}/4{\cdot}57+3\times1{\cdot}75\log T+9$. W. Fränkel found for the reaction $2WO_3+CO \rightleftharpoons CO_2+W_2O_5$, for $K=[CO_2]/[CO]$ between 750° and 1050°, $K=17{\cdot}2$ to 21·1—*vide infra*, tungsten trioxide. Z. Shibata gave $2WO_2+\frac{1}{2}O_2=W_2O_5+62{\cdot}9$ Cals. P. Sabatier and J. B. Senderens said that tungsten dioxide at 450°–500° is oxidized by nitrous or nitric oxide to tungsten hemipentoxide. The various intermediate oxides, prepared in the dry-way as indicated above, must be regarded as mixtures containing blue hemipentoxide. E. Friederich and L. Sittig obtained the dark violet hemipentoxide by heating at 1000° for an hour a mixture of 4·77 grms. of powdered tungsten and 29 grms. of tungsten trioxide. H. Leiser obtained a blue oxide approximating W_4O_{11} by the electrolysis of metatungstic acid with a platinum cathode, and with a lead cathode the dioxide is formed. J. A. M. van Liempt gave for the heat of formation $4WO_2+O_2=2W_2O_5+125{\cdot}2$ Cals. ; or $2(2W,5O)=318{\cdot}4$ Cals. E. Friederich gave 4·56 ohm. per sq. mm. for the electrical resistance. The blue oxide has been obtained only in an impure state as an amorphous powder ranging in colour from a greenish-blue to deep blue. The X-ray diffraction pattern obtained by C. J. Smithells and H. P. Rooksby is shown by Fig. 14. E. Friederich and L. Sittig gave $4{\cdot}5\times10^4$ ohms for the sp. resistance at 100°, and found it to be less than the resistance of the dioxide. E. Wedekind and C. Horst gave $0{\cdot}755\times10^{-6}$ for the magnetic susceptibility. The blue oxide is converted into the trioxide when heated in air or oxygen ; and when prepared in the wet way, it is readily oxidized by nitric acid or aqua regia, but when prepared in the dry way it resists attack by these reagents. V. I. Spitzin and L. Kaschtanoff observed that when the hemipentoxide is heated in hydrogen chloride, the dioxydichloride is formed, leaving a residue of tungsten ; and he represented the composition : $W(WO_3)_5$, *i.e.* $3W_2O_5$. P. Sabatier and A. Mailhe said that above 170°, the blue oxide acts catalytically in decomposing formic acid into carbon monoxide and water. The catalytic properties of the blue oxide in forming ethyl alcohol, etc., were studied by P. Sabatier and A. Mailhe, and J. N. Pearce and A. M. Alvarado. A. Charriou demonstrated the increased catalytic activity of alumina containing the adsorbed blue oxide.

J. J. Berzelius[2] obtained **tungsten dioxide,** WO_2, by passing hydrogen over tungsten trioxide, free from alkali, and feebly ignited in a glass tube. A. Riche added that if the temp. be too low, the blue oxide is formed, and if too high the metal is formed. In the formation of the dioxide as an intermediate stage in the reduction of tungsten trioxide by hydrogen, J. A. M. van Liempt showed that the conditions of equilibrium indicate that if hydrogen be passed through water at 85°, and the mixture of hydrogen and water vapour be passed over tungsten trioxide at 900°, tungsten dioxide is formed—*vide supra.* W. Fränkel made similar observations in connection with the reduction of carbon monoxide—*vide infra,* tungsten trioxide. C. F. Bucholz heated a mixture of tungsten trioxide and carbon in a covered crucible at a dull red-heat; the Westinghouse Metal Filament Lamp Co. added that better results are obtained with a mixture of tungsten trioxide, free from alkali, and one-tenth to one-fifth its weight of glycerol, or ethylene glycol. The dried mass is heated in a closed vessel at a bright red-heat for some hours. F. Wöhler allowed dil. hydrochloric acid and zinc to act on tungsten trioxide, if necessary renewing the acid, and zinc, until all trioxide had been converted into copper-red scales. The product is washed with water while protected from air, and preserved under water. O. F. von der Pfordten used hydrated tungsten trioxide. A. Riche added that the tungsten trioxide is only superficially reduced by this process, and he recommended the use of an alkali tungstate in place of tungsten trioxide, and washing the product with water saturated with hydrogen, and afterwards drying it in an atm. of hydrogen. F. Wöhler heated an intimate mixture of potassium tungstate and ammonium chloride until the ammonium salt was all expelled; washed out the potassium chloride with water, and the undecomposed acid tungstate with a boiling dil. soln. of potassium hydroxide; and finally washed the product with water. F. Wöhler, and H. E. Roscoe decomposed tungsten tetrachloride with water and obtained a precipitate of the dioxide and a greenish-brown soln. which gradually deposited the dioxide; tungsten dichloride is also hydrolyzed by water slowly giving off hydrogen and forming the dioxide. E. Defacqz heated tungsten diiodide to 500° in a current of carbon dioxide. E. D. Desi obtained the dioxide by evaporating sulphuric acid along with tungsten monoxide. L. A. Hallopeau heated lithium paratungstate for nearly an hour in a current of hydrogen, and washed the product successively with boiling water, conc. hydrochloric acid, a 20 per cent. boiling soln. of lithium hydroxide, and finally with hot water. E. Friederich and L. Sittig obtained the dioxide by heating a mol of the triiodide and a gram atom of carbon; and also by heating to 1000° for an hour, an intimate mixture of a gram-atom of tungsten powder and 2 mols of tungsten trioxide. H. Leiser observed that a soln. of a metatungstic acid when electrolyzed with a lead cathode furnishes tungsten dioxide, and with a platinum cathode, a blue oxide approximating W_4O_{11}. W. Meissner, and A. Schulze discussed the supraconductivity of the dioxide; and J. S. Donal, the emission of electrons by tungstous oxide. J. Vrede observed that the oxide is no use as a radio-detector.

R. F. Bernhardi-Grisson said the electrolytic reduction of soln. of tungsten trioxide in hydrofluoric or hydrochloric acid furnishes the *dihydrate,* $WO_2.2H_2O$, **tungsten tetrahydroxide,** H_4WO_4, or $W(OH)_4$. It is a brown powder soluble in hydrochloric acid forming a greenish soln. which rapidly becomes blue owing to the oxidation of quadrivalent to quinquevalent tungsten. It is insoluble in soda-lye, sulphuric acid, and acetic acid.

J. J. Berzelius described tungsten dioxide as a brown powder with a tinge of copper-red; and A. Riche found his preparation to be dark yellow. F. Wöhler said that it forms copper-red scales with a metallic lustre; and L. A. Hallopeau, a brown powder, with a copper-red lustre, consisting of microscopic, opaque, regular, octahedral crystals. V. M. Goldschmidt and co-workers discussed the crystal structure. L. Pauling discussed the crystal structure. C. J. B. Karsten gave 12·11 for the sp. gr. W. Biltz studied the mol. vol. E. Friederich and L. Sittig gave 5·0 to 5·5 for the hardness. L. Wöhler and R. Günther calculated for the dissociation press. p_3 atm., for $WO_2 \rightarrow W$, $\log p_3 = -29808T^{-1} + 9{\cdot}168$; and for the heat of the reaction: $W + O_2 = WO_2 + 136{\cdot}2$ Cals. N. Parravano and G. Malquori gave for the dissociation press., $\log p_{O_2} = -24{\cdot}993$ at 600°. H. Alterthum and F. Koref calculated values for the equilibrium constant in the equation $W + O_2 = WO_2 + 82{\cdot}6$ Cals., $K_1 = [WO_2]/[O_2]$, where the bracketed terms denote partial press., and log

$K_1=82600T^{-1}\div 4{\cdot}57$. They gave for the heat of vaporization, 48·86 Cals. at 2000° K. Z. Shibata gave 138·2 cals. per gram. E. Friederich and L. Sittig gave 1500°–1600° for the m.p. J. A. M. van Liempt gave for the heat of formation $(W,O_2)=127{\cdot}9$ Cals.; and for the heats of oxidation, $(4WO_2,O_2)=2W_2O_5+125{\cdot}2$ Cals.; and $(2W_2O_5,O_2)=4WO_3+140{\cdot}4$ Cals. The X-ray diffraction pattern, obtained by C. J. Smithells and H. P. Rooksby, is shown in Fig. 14. H. von Wartenberg and H. Moehl observed that the heat of formation of WO_2 is 131 Cals., and the heat of vaporization −31 cals. E. Friederich found the electrical resistance to be $9{\cdot}8\times10^4$ ohms at 1000°. When the dioxide is heated in **hydrogen,** F. Wöhler said that it is reduced to the metal—*vide supra,* the action of water-vapour on tungsten: $W+2H_2O\rightleftharpoons WO_2+2H_2$. The powder obtained by the hydrogen reduction process is pyrophoric, but, according to A. Riche, after it has stood 24 hrs. in hydrogen, it is stable in **air.** When the dioxide is heated in air, it burns like tinder to form the trioxide. The dioxide, freshly prepared by the wet-process, rapidly oxidizes in air, acquiring a blue colour; if the powder has been dried, it may be kept in contact with air without change. The dioxide burns to the trioxide when heated in **oxygen;** and the same product is obtained when the dioxide is heated with **mercuric oxide.** If **water** be in contact with the dioxide for some months, it acquires a blue colour. S. M. Délepine and L. A. Hallopeau found that the dioxide readily decomposes water containing a little alkali in consequence of the formation of an alkali tungstate. J. J. Berzelius said that a conc. boiling soln. of **potassium hydroxide** decomposes the dioxide forming the alkali tungstate, and giving off a little hydrogen; and A. Riche, and E. F. Smith and O. L. Shinn added that the soln. in alkali-lye becomes intensely red, it gives off hydrogen, and then acquires a blue colour. L. A. Hallopeau's preparation was not attacked by conc. alkali-lye. H. E. Roscoe observed that the dioxydichloride is formed when dry **chlorine** acts on the dioxide; and A. Riche, and E. F. Smith and O. L. Shinn added that chlorine-water oxidizes the dioxide to the trioxide. V. I. Spitzin and L. Kaschtanoff found **hydrogen chloride** converts it into the dioxydichloride and tungsten; and they wrote the formula $W(WO_3)_2$, *i.e.* $3WO_2$. L. A. Hallopeau found that the dioxide is attacked neither by **hydrochloric acid** nor by **sulphuric acid.** A. Riche, and E. F. Smith and O. L. Shinn added that a little of the dioxide prepared by the wet process dissolves in cold hydrochloric or sulphuric acid forming a reddish soln. which becomes purple when heated; the soln. remains red for a long time, but it slowly decomposes forming the blue oxide. The change occurs rapidly if the soln. is heated. E. F. Smith and H. Fleck found that **sulphur monochloride** converts the dioxide into the oxytetrachloride. According to F. Wöhler, when gently warmed in dry **ammonia,** the dioxide forms a brownish-black substance containing hydrogen and nitrogen, mixed with unchanged dioxide, and at a higher temp., tungsten is formed. A. Riche, and E. F. Smith and O. L. Shinn found that boiling, aq. ammonia does not dissolve the dioxide. According to P. Sabatier and J. B. Senderens, if the dioxide is heated to 450° or 500° in **nitrous oxide,** the blue hemipentoxide is formed—neither nitric oxide nor nitrous fumes were observed, the nitrous oxide is reduced to nitrogen. At about 500°, tungsten dioxide reacts vigorously with **nitric oxide** forming the blue hemipentoxide; and at about 300°, **nitrogen peroxide** forms a mixture of tungsten hemipentoxide and trioxide. A. Riche, E. F. Smith and O. L. Shinn, and L. A. Hallopeau observed that cold **nitric acid** slowly oxidizes the dioxide to the trioxide; and A. Riche found that **aqua regia** forms a similar product. H. C. Greenwood found that the dioxide is reduced to the metal when it is heated with **carbon** to about 1020°. O. Brunner showed that when tungsten dioxide is heated with **carbon dioxide** it is oxidized: $WO_2+CO_2=WO_3+CO$. A. Riche, and E. F. Smith and O. L. Shinn found that the dioxide reduces an ammoniacal soln. of **silver nitrate** to silver; and **cupric and mercuric chlorides** are reduced to cuprous and mercurous chlorides respectively. H. von Wartenberg and H. Moehl found that there is a balanced reaction at high temp. With **aluminium, zirconium,** and **thorium** and tungsten dioxide, *vide* *supra*, the chemical properties of tungsten. F. Wöhler found that when a mixture of the dioxide and **sodium carbonate** is heated out of contact with air, tungsten and sodium tungstate are formed.

F. Wöhler[3] observed that when acid sodium tungstate is reduced by hydrogen, a bronze-coloured powder is obtained. The product is a member of a series of reduction products of the alkali and alkaline earth tungstates which have been designated **tungsten-bronzes** because, owing to their intense and vivid colours, and their remarkable chemical inactivity, they can be used as substitutes for *bronze-powders.* This term is applied to finely-divided or powdered metals—*e.g.* brass, bronze, aluminium, and copper—which, when mixed with a suitable binding material—*e.g.* varnish, or amyl acetate—can be used as paints for ornamental and decorative purposes, and for protecting iron, etc., against corrosion.

The tungsten-bronzes appear to contain several sexivalent tungsten atoms, and one quadrivalent tungsten atom. Their composition can be represented by $mR_2O.nWO_3.WO_2$, although in the majority of them m is unity, and the general formula is then $R_2O.nWO_3.WO_2$, or simply $R_2(WO_3)_{n+1}$. The chemical nature of the tungsten-bronzes has not been worked out. Many of them are probably solid soln. of different individuals. Different formulæ have been applied to the products of apparently similar reactions. Thus, G. von Knorre heated equimolar proportions of sodium and potassium tungstates to redness in hydrogen and obtained on one occasion a purple-red bronze, $2Na_4W_5O_{15}.5K_2W_4O_{12}$, and on another occasion a dark red bronze, $2Na_2W_3O_9.3K_2W_4O_{12}$. Different products have probably been given the same formula. Each new investigation furnishes new products, but rarely are the reports of previous workers completely confirmed. There are difficulties (i) in the analytical determination of the ratio of the total tungsten to that present in the quadrivalent form (ii) in recognizing whether the products are chemical individuals or mixtures because of their general insolubility, and resistance to attack by ordinary reagents. When heated in hydrogen chloride, V. I. Spitzin and L. Kaschtanoff found that the dioxydichloride is formed, sodium chloride, and tungsten are formed, and they think that their results agree with the formula $(Na_2W_2O_6)_3$, or $Na_6[(WO_4)_3W(WO_3)_2]$, for the yellow bronzes; and $(Na_2W_3O_9)_3$, or $Na_6[(WO_4)_3(WO_3)_3W(WO_3)_2]$, for the red bronzes. (iii) In repeating the work of previous investigators because of unrecognized but essential conditions for producing particular results. In some cases, arrested reactions are involved—*vide* **4**. 31, 33. Thus, O. Brunner showed that the reaction with the yellow sodium tungsten bronze: $3Na_2W_2O_6 \rightleftharpoons Na_2WO_4+2Na_2W_2O_7+W$, is reversible, and if it be slow, or if the temp. be variable, it will be difficult to obtain a definite product.

The tungsten-bronzes are obtained: (1) by the reduction of an acid tungstate with hydrogen, coal gas, or tin, zinc, or iron at a high temp.—F. Wöhler, and H. Wright; (2) by the electrolytic reduction of a fused polytungstate—C. Scheibler, A. Stavenhagen, E. Engels, L. and H. H. Kahlenberg, and E. Zettnow; and (3) by melting mixtures of normal or acid tungstates with tungsten dioxide, out of contact with air—O. Brunner. According to V. I. Spitzin, the tungstates are reduced by hydrogen at 650° to 700° to a constant weight; and the products from the ditungstate, $Na_2W_2O_7$, paratungstate, $Na_{10}W_{12}O_{41}$, tetratungstate, $Na_2W_4O_{13}$, and pentatungstate, $Na_2W_5O_{16}$, are, in every case, mixtures of sodium tungstate, Na_2WO_4, and tungsten. Above 700°, a further loss in weight takes place, and at 900°, each of the above acid tungstates and also sodium tungstate are reduced to tungsten. The various tungsten bronzes are also reduced to sodium tungstate and tungsten at 650°–700°. The blue bronze, $Na_2W_5O_{15}$, is reduced successively to the violet, $Na_2W_4O_{12}$, the red, $Na_2W_3O_9$, and the yellow bronzes, $Na_2W_2O_6$; this reduction takes place comparatively slowly at 550° and rapidly at 650°, but at no temperature does reduction cease at any intermediate stage. The formation of bronzes by the reduction of acid tungstates is believed to take place according to equations of the type: $Na_2W_4O_{13}+H_2=Na_2W_4O_{12}+H_2O$; $Na_2W_4O_{12}+3H_2=Na_2W_3O_9+W+3H_2O$. In this case, the molecule of bronze could never contain more atoms of tungsten than that of the tungstate from which it was prepared. This, however, is sometimes the case, but is ascribed to impurities in the tungstate; thus, sodium tetratungstate yields a blue bronze, but the metatungstate, $Na_2W_4O_{13},10H_2O$, which can be purified by crystallization from water, yields the violet bronze.

The colour of the tungsten bronzes ranges from golden-yellow, reddish-yellow, purple-red, violet, blue, to bluish-black. As the proportion of tungsten increases, the colour changes in the order indicated. In thin layers, the bronzes are more or less translucent, and the colour by transmitted light may be complementary to that by reflected light. These bronzes are usually crystalline—generally as cubes or needles. Their sp. gr. is high ranging from 6·5 to 7·5. For the luminescence of the tungsten-bronzes, *vide infra*, calcium tungstate. They are good conductors of electricity. They are insoluble in water; and with the exception of hydrofluoric acid are not attacked by the usual acids. Hot aqua regia acts on some of the tungsten bronzes. They are not acted on by alkali-lye, but they are decomposed by fusion with alkali hydroxide, sulphur, and ammonium hydrosulphate or persulphate. Some of the bronzes were shown by O. Brunner to be oxidized when heated with carbon dioxide to form carbon monoxide. They are oxidized to tungstates when heated in air or oxygen, or when heated with mercuric oxide. When boiled with an ammoniacal soln. of silver nitrate, silver is precipitated. O. Brunner showed that the tungsten-bronzes with a relatively small proportion of tungsten decompose when heated, forming tungsten, normal tungstate, and a tungsten-bronze with a higher proportion of tungsten, *e.g.* $3Na_2W_2O_6 \rightleftharpoons W + Na_2WO_4 + 2(Na_2WO_4.WO_3)$.

Lithium-tungsten-bronzes were prepared by O. Brunner, W. Feit, L. A. Hallopeau, G. von Knorre, and C. Scheibler. Thus, $Li_2W_4O_{12}$ furnishes steel-blue, microscopic plates of sp. gr. 7·50; $Li_2W_5O_{15}$ appears in deep blue, microscopic prisms when lithium paratungstate is fused with tin, or fused paratungstate is electrolyzed; $Li_2W_7O_{21}$ is steel-blue; and $Li_2W_5O_{15}.3K_2W_4O_{12}$ appears in violet needles when a fused mixture of equimolar proportions of lithium and potassium tungstates is reduced with tin.

Sodium-tungsten-bronzes were prepared by E. F. Anthon, O. Brunner, L. and H. H. Kahlenberg, F. J. Malaguti, F. Margueritte, H. Schnitzler, J. Philipp, J. Philipp and P. H. Schwebel, C. Scheibler, F. Wöhler, and H. Wright. Thus, $Na_2W_2O_6$ furnishes golden-yellow cubes of sp. gr. 7·28; $Na_2W_3O_9$, purple-red octahedra of sp. gr. 7·22; $Na_2W_4O_{12}$, violet needles of sp. gr. 7·195; and $Na_2W_5O_{15}$, blue cubes with a copper-red lustre. W. Feit, and G. von Knorre prepared $3K_2W_4O_{12}.2Na_2W_3O_9$, and $5K_2W_4O_{12}.2Na_2W_5O_{15}$ as indicated above. Both are dark red; the latter has a sp. gr. 7·117, and when powdered, becomes blue.

Potassium-tungsten-bronzes were prepared by O. Brunner, L. A. Hallopeau, G. von Knorre, A. Laurent, E. Schaefer, and E. Zettnow. The $K_2W_4O_{12}$ bronze furnishes reddish-violet prisms of sp. gr. 7·1. A suspension appears blue by transmitted and green by reflected light. G. von Knorre and E. Schaefer were of the opinion that this is the only potassium-tungsten-bronze known, but others have been reported—*e.g.* O. Brunner obtained reddish-violet $K_2W_3O_9$; a blue mixture $K_2W_4O_{12}+K_2W_5O_{15}$; and blue mixtures of the ultimate composition $K_2W_5O_{15}$, $K_2W_6O_{18}$, and $K_2W_8O_{24}$.

Alkali-alkaline earth-tungsten-bronzes were prepared by E. Engels by the electrolysis of fused mixtures of potassium or sodium tungstate with the calculated amount of alkaline earth carbonate. He reported the following products: $CaW_4O_{12}.5Na_2W_5O_{15}$, in blue pyramids; $CaW_4O_{12}.10Na_2W_3O_9$, in purple-red cubes or pyramids; $CaW_4O_{12}.5K_2W_4O_{12}$, in glistening red needles; $SrW_4O_{12}.5Na_2W_5O_{15}$, in violet pyramids; $SrW_4O_{12}.12Na_2W_5O_{15}$, in carmine-red pyramids; $SrW_4O_{12}.5K_2W_4O_{12}$, in red needles: $2BaW_4O_{12}.3Na_2W_5O_{15}$, in dark blue crystals; $BaW_4O_{12}.5Na_2W_3O_9$, in yellowish-red cubes; and $Ba_4O_{12}.5K_2W_4O_{12}$, in violet-red prisms.

Thorium-tungsten-bronzes.—C. J. Smithells inferred that the coloured thoria residues from dissolved thoriated tungsten filaments, which have been heated to a high temp., contain thorium-tungsten-bronzes.

§ 10. Tungsten Trioxide

B. Silliman[1] observed the occurrence of a bright yellow, or yellowish-green, pulverulent earthy mineral which he called *tungstic ochre* at Monroe, Connecticut; it was called *oxide of tungsten* by W. Phillips; *acide tungstique*, by F. S. Beudant; *Wolframocker*, by C. C. von Leonhard; Wolframsäure, by F. von Kobell; Scheelsäure, and *Scheelocher*, by E. F. Glocker; *wolframine*, by R. P. Greg and W. G. Lettsom; and **tungstite,** by J. D. Dana. Its composition approximates **tungsten trioxide,** WO_3. R. P. Greg and W. G. Lettsom, and J. H. Collins found tungsten ochre in Callington and Gwennap, Cornwall; and in Carrock Fells, Cumberland. J. H. Collins called the ochre wolframite, and wolframite he called wolfram. F. S. Beudant referred to an occurrence as a yellow deposit on wolframite at Zinnwald, Bohemia, but J. J. Berzelius found no tungsten in the deposit, and V. R. von Zepharovich does not mention it. A. Lacroix observed its occurrence at La Vilate, Haupte-Vienne; and Vaubry, Pury-les-Vignes; and at Meymac, Corrèze; while P. A. Dufrénoy found it near Limoges. In addition to the occurrence at Monroe, Connecticut, J. D. Dana obtained the ochre from Cabarrus, Carolina; and F. D. Smith, from Osceola, Nevada. W. F. Petterd observed its occurrence at Ben Lomond, Tasmania. J. B. Scrivenor and J. C. Shenton observed a honey-yellow, crystalline mineral in the Kramat Pulai mine in the Federated Malay States. The crystals were rhombic; the sp. gr. 5·55; and the composition approximated $(ThO_2,Ce_2O_3,ZrO_2)H_2O+2WO_3.H_2O$, and the mineral was called **thorotungstite.**

The extraction of tungsten trioxide or tungstates from wolframite, scheelite, hübnerite, etc., has been previously discussed; so also has the purification of the tungsten trioxide. The trioxide is formed by the oxidation of the metal; I. Langmuir[2] observed that tungsten wires heated in oxygen at a low press. form the trioxide at about 530°, and above this temp. the oxide volatilizes. The trioxide is also obtained by roasting the lower oxides, or the oxynitrogen compounds, the hydrated tungsten oxides, ammonium tungstate, ammonium oxyfluotungstates, or tungsten sulphide. As previously indicated, hydrated tungsten trioxide is precipitated by adding an acid to a soln. of a tungstate. J. A. M. van Liempt studied the influence of temp. and the conc. of the acid on precipitated tungsten trioxide. The precipitate consists of a mixture of the white and the yellow forms of the trioxide, together with an adsorption compound with water. Temp. has little effect on the precipitation, but in order to obtain the precipitate in a granular and easily manipulated form, it is advisable to use an excess of highly conc. hydrochloric or nitric acid. The rate of precipitation depends on the method of mixing the soln. When the sodium tungstate soln. is added drop by drop to the acid, the rate of precipitation depends on the degree of ionization of the acid. Thus, 0·25*N*-nitric, perchloric, and hydrochloric acids showed very nearly identical precipitation curves, whilst 0·25*N*-sulphuric acid showed a much more extended period of induction, before precipitation started. This last curve, however, was very similar to that given by 0·18N-hydrochloric acid, the dissociation of which is about equal to that of 0·25N-sulphuric acid. When the acid was added to the tungstate soln., the slower the addition of the acid (up to the limit of twelve minutes) the slower was the subsequent precipitation of the tungstic acid. Y. Nakazawa and T. Okada prepared tungstic acid (i) by evaporating a soln. of the trioxide in conc. hydrochloric acid and obtained crystals of $WO_3.H_2O$; (ii) by passing steam into the soln. of the trioxide in conc. hydrochloric acid and obtained crystals of $WO_3.H_2O$; and (iii) by diluting the conc. hydrochloric acid at ordinary temp. and obtained a white acid, $WO_3.7H_2O$, difficult to filter. According to F. A. Bernoulli, and A. Safarik, the lemon-yellow, amorphous tungsten trioxide obtained by these methods can be converted into the crystalline form by strongly heating the product; according to A. E. Nordenskjöld, by fusing the hydrated trioxide with borax and washing the cold mass with hydrochloric acid, and aq. ammonia ; and, according to H. Debray, by passing a current of hydrogen chloride over the trioxide, or over a red-hot mixture of sodium tungstate and carbonate. E. Zettnow, and J. Waddell noticed the formation of some crystals when the trioxide is heated in hydrogen. A. Pinagel found a sample of commercial tungsten trioxide with 1·35 per cent. silica, 0·13 per cent. molybdenum trioxide, and traces of vanadium, iron, manganese, and sodium.

For α- and β-forms of tungsten trioxide, *vide supra*, the oxidation of tungsten. The **crystals** obtained by A. E. Nordenskjöld were small, bright yellow, transparent, rhombic prisms with the axial ratios $a:b:c=0·7002:1:0·3991$, or 0·6966 : 1 : 0·4026 ; and those obtained by H. Debray were octahedral—some were yellow and translucent, others dark green and opaque. P. Niggli studied the electronic structure. The crystals are sometimes thin, dark blue or green needles. H. C. Burger added that the X-radiograms of both the yellow and green forms are the same. H. E. Roscoe attributed the discoloration to the presence of small traces of sodium salts ; this was confirmed by N. H. Smith and H. S. Lukens. J. A. M. van Liempt attributed it to the reducing action of the dust particles in the air, a reaction which is favoured by exposure to light. L. Gmelin attributed the green coloration to the presence of reducing gases during the ignition of the oxide. N. H. Smith and H. S. Lukens showed that these hypotheses are not likely because, as shown by J. B. A. Dumas, and F. A. Bernoulli, the green oxide cannot be converted into the yellow oxide by ignition in a current of oxygen or nitrous oxides. J. J. and F. de Elhuyar gave 6·13 for the **specific gravity** of the amorphous, yellow oxide ; W. Herapath gave 5·274 at 16·5° ; A. E. Nordenskjöld, 6·302 to 6·384 ; and C. J. B. Karsten, 7·1306 ; while E. Zettnow gave 7·16 at 17° for the amorphous oxide, and 7·232 at 17° for the crystals. E. F. Smith and F. F. Exner gave 7·157 for the sp. gr. of the trioxide obtained by heating the hydrate to bright redness. H. P. Walmsley gave 7·146 for the sp. gr. of the dispersed oxide. The sp. gr. of tungsten ochre is 6·3 to 7·2.

The mol. vols. were studied by H. Schröder, C. del Fresno, W. Biltz, and D. Balareff. O. Ruff and A. Riebeth discussed the **plasticity** of mixtures of the oxide with water, etc. H. V. Regnault gave 0·0798 for the **specific heat,** and H. Kopp, 0·0894. According to A. S. Russell, the sp. ht. between −189° and −80·9° is 0·0442 ; between −75·8° and 0°, 0·0678 ; and between 2·3° and 46·6°, 0·0783 ; the corresponding **molecular heats** are 10·25, 15·73, and 18·16. F. M. Jäger and E. Rosenbohm gave $c_p=0·0503755+0·13644\times10^{-3}\theta-0·0490476\times10^{-6}\theta^2$ for the sp. ht. up to 1300° of the crystalline, yellowish-green oxide formed by heating tungsten to 1300°. J. Maydal discussed the sp. ht. When heated, the colour of tungsten trioxide deepens to a dark orange, but on cooling, the lemon-yellow colour is restored. E. D. Clark found that the yellow oxide is decomposed in the oxy-hydrogen flame—presumably by hot reducing gases. A. Riche said that the trioxide can be fused in the gas blowpipe flame, and the mass, on cooling, furnishes tabular crystals. W. D. Bancroft and H. B. Weiser found that when tungsten trioxide is introduced into the oxyhydrogen flame, the flame deposits a bright, lustrous, metallic mirror on a cold surface. F. M. Jäger and H. C. Germs gave 1473° for the **melting point ;** but C. Matignon said that it does not melt at 2130°. A. A. Read observed no change in the composition of the oxide after it had been heated to 1750°. W. R. Mott studied the volatilization of the oxide in the electric arc ; and I. Langmuir found that in an atm. of oxygen under reduced press., the trioxide formed on the surface of wire volatilizes above 530°, and the heated wire at about 930°. H. Copaux found that at a moderate red-heat tungsten trioxide is stable, but volatilization occurs at a bright red-heat so much so that 500 mgrms. lost 3 mgrms. in 5 min. G. A. Meerson also found that the trioxide volatilizes in moist hydrogen above 850°. L. Wöhler and R. Günther calculated for the **dissociation pressure,** p_1 atm., for the reaction $WO_3 \rightarrow W_2O_3$, log $p_1 = -28750T^{-1} + 10{\cdot}53$, and for the heat of the reaction, 131·4 Cals. If p_2 likewise denotes the dissociation press. of $W_2O_5 \rightarrow WO_2$ (*q.v.*), and p_3, that of $WO_2 \rightarrow W$ (*q.v.*), then,

T° K. .	873°	1073°	1273°	1473°	1673°	2800°	3200°	3300°
p_1 .	$10^{-24{\cdot}4}$	$10^{-18{\cdot}3}$	$10^{-14{\cdot}2}$	$10^{-11{\cdot}1}$	$10^{-8{\cdot}7}$	1·0	—	—
p_2 .	$10^{-25{\cdot}6}$	$10^{-19{\cdot}7}$	$10^{-15{\cdot}6}$	$10^{-12{\cdot}6}$	$10^{-10{\cdot}3}$	—	—	1·0
p_3 .	$10^{-26{\cdot}9}$	$10^{-20{\cdot}7}$	$10^{-16{\cdot}4}$	$10^{-13{\cdot}2}$	$10^{-10{\cdot}7}$	—	1·0	—

F. Born discussed this subject. H. Alterthum and F. Koref also calculated values for the dissociation press. ; and they found the **heat of vaporization** to be 40·64 Cals. at 1700° K. For the equilibrium condition in the reaction $2W_2O_5 + O_2 = 4WO_3 + 56{\cdot}7$ Cals., $K_3 = [W_2O_5]^2[O_2]/[WO_3]^2$ when the bracketed symbols denote partial press., log $K_3 = -56700T^{-1}/4{\cdot}57 - 1{\cdot}75 \log T^{-3}$. S. M. Delépine and L. A. Hallopeau gave for the **heat of formation** (W,3O)=195·41 Cals. at constant vol., and 196·3 Cals. at constant press. ; J. E. Moose and S. W. Parr, 194·9 Cals. ; Z. Shibata, 199·9 Cals. ; W. G. Mixter, 196·3 Cals. ; and L. Weiss, 192·648 to 196·146 at constant vol. S. M. Delépine and L. A. Hallopeau gave (WO_2,O)=64·63 Cals. at constant vol., and 64·9 Cals. at constant press. A. Berkenheim discussed the heat of formation. J. J. and F. de Elhuyar, and H. E. Roscoe said that tungsten trioxide turns green when exposed to direct sunlight, probably, added L. Gmelin, because the organic particles and dust diffused in air may exert a reducing action, so that a small portion of the blue oxide becomes mixed with the yellow trioxide. A. F. Wasiléeff found that tungstic acid in the presence of certain reducing agents —*e.g.* cellulose—is reduced by exposure to light. A. Riche observed that if the purified trioxide be confined under purified water for 14 days while exposed to direct sunlight, no green coloration appears. J. A. M. van Liempt also said that light discolours yellow tungsten trioxide ; but N. H. Smith and H. S. Lukens added that any change in colour is only slight, and is superficial. H. M. P. Brinton and A. N. Lohmann added that the effect of sodium salts is negligibly small ; the colour is probably due to traces of impurities like dust. If the ignited trioxide be protected from dust, the light of the mercury vapour lamp has no action, but if it be exposed to the atm., a green colour is developed, and similarly if the trioxide was treated with redistilled ammonia before the ignition. The effect of daylight is negligible in comparison with ultra-violet. A. Karl said that the crystals exhibit **triboluminescence ;** J. Ewles, cathodo-luminescence ; but no ultra-violet fluorescence in X-rays was observed by J. O. Perrine. E. Wrede used tungsten trioxide as a target indicator to determine magnetic separation in a stream of unimolecular hydrogen. C. J. Smithells and H. P. Rooksby's X-ray diffraction pattern is shown in Fig. 14. P. Krishnamurti, and H. Nisi studied the **Raman effect ;** and J. S. Donal, the emission of electrons. J. Vrede observed that the oxide is of no use as a radio-detector.

F. Beijerinck stated that tungstite shows no evidence of **electrical conductivity.** E. Friederich gave $1{\cdot}8 \times 10^9$ ohm per sq. mm. for the resistance. W. Meyer examined the electrical conductivity of compressed rods of the powdered trioxide, and for a rod $0{\cdot}2 \times 0{\cdot}18$ cm. section, and 0·37 cm. long, he gave at room temp. :

Volts .	0·033	0·100	0·200	0·300	0·400	0·666	1·000
Ampères .	$0{\cdot}0_5275$	$0{\cdot}0_5825$	$0{\cdot}0_4166$	$0{\cdot}0_4245$	$0{\cdot}0_4330$	$0{\cdot}0_4541$	$0{\cdot}0_4815$

The **electrolysis** of fused tungstates, and of soln. of tungsten trioxide in various solvents has been discussed in connection with the electrodeposition of tungsten. L. Andrieux electrolyzed a soln. of the oxide in fused boric acid. O. Collenburg and J. Backer found that at a platinum cathode, soln. of alkali tungstates in conc. hydrochloric acid (containing the oxychloride WO_2Cl_2) are reduced quantitatively to derivatives of quinquevalent tungsten, whereas reduction proceeds further at a mercury, lead, or tin cathode. Above 16°, sodium tungstate gives quantitative yields of tervalent tungsten derivatives at the base metal cathode, but below 16°, reduction is not so complete; potassium tungstate is completely reduced only at a lead cathode. During reduction, the colour of the soln. changes first to blue when the tungsten is in the quinquevalent form, and this colour slowly fades on further reduction, yielding eventually a yellowish-green or red soln. of tervalent tungsten. The yellowish-green soln. is always obtained above 35°; it contains compounds of the type $R'_3W_2Cl_9$. The red soln. is obtained at 16° and contains compounds of the type $R'_2(WCl_5.H_2O)$ which are unstable, changing on keeping or warming to compounds of the first-named type. According to O. Collenburg and K. Wilson, electrolysis of soln. containing 11·2 grms. of potassium tungstate and 16 grms. of oxalic acid in 100 c.c. at a current density of 0·01–0·03 amp. per sq. dm. and a temp. of not less than 70° with lead or tin cathodes leads to a complete reduction of tungsten to the quinquevalent stage and no further. The method is well adapted to the preparation of quinquevalent tungsten compounds. K. Fischbeck and E. Einecke found that when used as anode in the electrolysis of 2 per cent. sulphuric acid, tungsten trioxide is reduced to the blue oxide. A. M. Iléeff studied the **thermoelectric force** of powdered tungsten trioxide. E. Wedekind and C. Horst found the **magnetic susceptibility** to be $0·808 \times 10^{-6}$ mass units at 15°; S. Berkman and H. Zocher gave $0·20 \times 10^{-6}$ mass units. S. Freed and C. Kesper studied the subject.

G. C. Gmelin[3] discussed the physiological action of salts of tungstic acid. Tungsten trioxide is more stable and less readily reduced than the corresponding trioxide of molybdenum or chromium. It is an acid anhydride forming tungstic acid with water. The acid and its anhydride were shown by O. W. Gibbs, and J. C. G. de Marignac to have a tendency to form complexes with phosphoric, silicic, boric, and other acids; and by C. Friedheim, to have a tendency to form condensation products. In illustration, the oxides of phosphorus, arsenic, antimony, and bismuth unite with tungsten to form complex salts; aluminium, manganese, iron, chromium, nickel, cobalt, praseodymium, neodymium, lanthanum, and cerium also form a series of tungstates. T. G. y Arnal discussed the reactions of tungstates with various salts.

J. J. Berzelius[4] observed that **hydrogen** reduces heated tungsten trioxide in stages, forming first a blue oxide, then a brown oxide, and then the metal. The observations of G. Chaudron and of L. Wöhler and W. Prager, L. Wöhler and O. Balz, L. Wöhler and R. Günther, W. Reinders and A. W. Vervloet, and H. Altherthum and F. Koref, on this reaction have been discussed in connection with the blue oxide, and with the metal. E. W. Engle said that reduction commences at 620° and is rapid at 950°. C. W. Davis said that the mixture of brown oxides is obtained at 800°–900°, and at 1080°, the metal itself is formed. The reaction was studied by Z. Shibata. J. N. Pearce and M. J. Rice studied the adsorption of water vapour by the oxide. C. Reichard observed that nascent hydrogen, from zinc and dil. hydrochloric or sulphuric acid with tungsten trioxide in suspension, gives a pale blue coloration which gradually becomes darker. F. Wöhler said that the reduction under these conditions proceeds to the blue or violet oxide, and finally to copper-red tungsten dioxide; and O. F. van der Pfordten also gave the dioxide as the end-stage of the reduction by zinc and acid. E. T. Allen and V. H. Gottschalk found that the reduction does not occur with aluminium in alkaline soln. J. J. and F. de Elhuyar found that the oxide is insoluble in **water;** and A. Riche, that it can be exposed to direct sunlight while under water without losing its colour. If rubbed to a fine powder with water, part of it passes through filter-paper as a turbid liquid—*vide infra*, colloidal tungsten trioxide. Tungsten trioxide is tasteless, and if it has been ignited, it does not redden blue litmus. The hydrates are discussed below. T. Fairley found that tungsten trioxide is converted into a higher oxide by **hydrogen dioxide.** B. Kellner said that the freshly-precipitated trioxide is easily soluble in hydrogen dioxide, but when dried it is only partially soluble ; and after ignition, it is insoluble—*vide infra*, pertungstic acid. A. Lottermoser said that hydrogen dioxide is catalytically decomposed in the presence of tungstic acid in accord with the equation $dx/dt=kx(a-x)$. This is due to the rapid formation of *tungsten trioxide hydroperoxide*, $WO_3.H_2O_2$. The photochemical decomposition of the dioxide and dextrose with tungstic acid as a catalyst was studied by J. C. Ghosh and J. Mukherjee.

According to A. Riche, when the trioxide is heated with **chlorine,** a yellow dioxydichloride is formed ; but an analogous reaction with **bromine,** or with **iodine** does not occur. R. Wasmuht studied the reaction with chlorine and the heated trioxide. K. Fredenhagen and G. Cadenbach said that the trioxide is not dissolved or changed by liquid **hydrogen fluoride.** A. Michael and A. Murphy found that a soln. of chlorine in carbon tetrachloride attacks the trioxide at 240°, forming $WOCl_4$, and at 280°, WCl_6. O. Ruff and H. Krug found that the trioxide is attacked with incandescence by **chlorine trifluoride.** H. Copaux found that some tungsten is lost by volatilization when the trioxide is heated in **hydrogen chloride** at 500°, and V. I. Spitzin and L. Kaschtanoff said that the dioxychloride commences to form at 300°. J. J. Berzelius observed that tungsten trioxide which has been ignited is sparingly soluble in **hydrofluoric acid ;** and A. Riche found that it dissolves in conc. hydrofluoric acid at 50° to 60°, forming an oxyfluoride. W. K. van Haagen and E. F. Smith said that hydrofluoric acid has scarcely any action on the trioxide. The ignited trioxide is insoluble in **hydrochloric acid.** A. Pinagel found that no tungsten is lost by volatilization when the trioxide is heated with a mixture of hydrofluoric and hydrochloric acids. E. T. Allen and V. H. Gottschalk found that the trioxide is reduced when it is heated with fuming **hydriodic acid** in a sealed tube at 200°. According to H. O. Schulze, almost all **chlorides** are decomposed when heated with tungsten trioxide in the presence of oxygen, tungstates are formed, and chlorine is evolved. If heated with calcium chloride in the absence of air, the reaction is symbolized : $CaCl_2+2WO_3=CaWO_4+WO_2Cl_2$. The chlorides of magnesium, iron, cobalt, and nickel behave similarly, but not the alkali chlorides. The chlorides of lead and silver are decomposed. L. and H. H. Kahlenberg found that tungsten trioxide and tungstic acid are soluble in fused alkali chlorides ; 100 grms. of fused sodium chloride will dissolve 21·3 grms. of the trioxide ; some chlorine is evolved during the reaction, and when the mass is cooled, most of it dissolves in water, but a little white powder remains undissolved. The reaction is symbolized : $2WO_3+2NaCl=Na_2O.W_2O_5+Cl_2$. If the hydrated trioxide be employed, 100 grms. of fused sodium chloride dissolve 95·7 grms. H_2WO_4 with the evolution of hydrogen chloride, forming $Na_2O.4WO_3$, or $Na_2O.5WO_3$. Tungsten trioxide is also dissolved by other fused **alkali halides.** H. O. Schulze found that potassium iodide is decomposed by tungsten trioxide ; and if an excess of the trioxide be employed, in air, all the iodine is expelled and a tungstate is formed. According to W. R. E. Hodgkinson and F. K. S. Lowndes, if a little tungsten trioxide be placed on molten **potassium chlorate,** oxygen mixed with so much chlorine is evolved that the gas is yellow. G. J. Fowler and J. Grant added that the trioxide lowers the temp. of decomposition of the chlorate, the oxygen is accompanied by chlorine, and some potassium tungstate is formed. G. Bredig discussed tungsten trioxide as a catalytic agent.

J. J. and F. de Elhuyar found that when a mixture of tungsten trioxide and **sulphur** is heated, the blue oxide is formed, or, according to A. Riche, tungsten sulphide, and if alkalies are present, an alkali sulphotungstate is produced. J. J. Berzelius said that the conversion of the heated trioxide by sulphur vapour into sulphide is incomplete ; **hydrogen sulphide** also converts the heated trioxide into sulphide ; and, according to A. Riche, **carbon disulphide** also forms the sulphide. J. J. Berzelius found that the sulphide is formed when the trioxide is heated with **mercuric sulphide.** According to E. F. Smith and H. Fleck, tungsten trioxide, wolframite, or scheelite, forms a red soln. of the oxytetrachloride when treated with **sulphur monochloride.** The trioxide obtained by heating ammonium tungstate, or the trioxide which has been heated for some time in the air, is not completely acted on by sulphur chloride, whereas the trioxide obtained by heating the oxychloride is practically all dissolved by it. This difference is not due to the presence of a nitride or oxynitride. R. D. Hall found that the vapour of sulphur monochloride passed over the heated trioxide forms the volatile oxychloride ; and F. Bourion, that a mixture of chlorine with sulphur chloride transforms the trioxide at 230°–250° completely into a mixture of tungsten oxytetrachloride and dioxydichloride, but not into the hexachloride. G. Darzens and F. Bourion found that **thionyl chloride** attacks tungsten trioxide at 150°, forming the oxytetrachloride, and as the temp. rises the proportion of the accompanying dioxydichloride increases—the hexachloride is not formed. P. Berthier found that **sulphurous acid** has no action, and E. T. Allen and V. H. Gottschalk found that it is not reduced by sulphurous acid in a sealed tube at 200°. E. D. Desi observed that tungsten trioxide is not dissolved even by cold or boiling dil. or conc. **sulphuric acid,** under conditions where molybdenum trioxide is rapidly dissolved. P. Berthier observed that when the trioxide is melted with **potassium hydrosulphate,** and the cold product is leached with water, the undecomposed hydrosulphate is first removed, and normal potassium tungstate then passes into soln. F. J. Faktor observed that when the trioxide is triturated with anhydrous **sodium thiosulphate,** the mixture becomes greenish-yellow, and when heated, tungsten disulphide is formed. O. Brunck found that in acid soln., the trioxide is reduced by **sodium hyposulphite.**

According to A. Riche, aq. **ammonia,** especially in conc. soln., dissolves tungsten trioxide forming a tungstate. A. Rosenheim and F. Jacobsohn found that liquid ammonia does not dissolve a perceptible amount of the trioxide either at ordinary temp. or at 108°–109°. According to F. Wöhler, ammonia converts tungsten trioxide at a dull red-heat into a complex oxynitride, and at a higher temp., into the metal. C. H. Ehrenfeld also observed that complex oxynitrides are formed by the action of ammonia. E. D. Desi also found that **ammonium chloride** mixed with tungsten trioxide, and strongly heated out of contact with air, forms the metal, but at a lower temp. a complex oxynitride is formed. E. T. Allen and V. H. Gottschalk observed that **hydroxylamine** in alkaline soln. does not reduce tungsten trioxide ; and T. Curtius and F. Schrader, that **hydrazine hydrate** forms an indigo-blue mass with the evolution of very little oxygen. P. Sabatier and J. B. Senderens found that the trioxide at 500° is not attacked by **nitric oxide ;** and J. J. Berzelius, that the trioxide is insoluble in **nitric acid,** and in **aqua regia.** C. H. Ehrenfeld observed that the trioxide is reduced to the blue oxide by phosphine at 125°–150°. A. Michaelis found that **phosphorus trichloride** at 200° colours the trioxide superficially green, but no other change was observed ; N. Teclu, C. F. Gerhardt, H. Schiff and A. Piutti, J. Persoz, and C. H. Ehrenfeld observed that **phosphorus pentachloride** furnishes tungsten hexachloride and some complex products. J. Persoz and N. Bloch obtained *tungsten trioxyphosphopentachloride,* $WO_3.PCl_3$—*vide* phosphorus pentachloride, **8**. 50, 32. C. H. Ehrenfeld said that **arsine** acts like phosphine but more sluggishly. L. Gugliamelli studied the complexes of tungstic acid with **arsenic acid ;** and A. Wolff, the complexes with **arsenious, antimonious,** and **phosphorous acids.**

H. N. Warren found that the trioxide is easily reduced by **silicon,** but L. Kahlenberg and W. J. Trautmann were unable to confirm this—any reduction is very local. The reduction of tungsten trioxide to the metal by heating it with **carbon** was observed by J. J. and F. de Elhuyar, A. Riche, C. F. Bucholz, E. G. A. Street, etc. and has been discussed in connection with the metal. H. Moissan said that a carbide is formed. C. Matignon noted the formation of a carbide at about 2000°. H. N. Warren found that **calcium carbide** reduces the trioxide to the metal. As in the case of hydrogen, W. Fränkel found that the reduction of tungsten trioxide by **carbon monoxide** takes place in stages: $2WO_3+CO=CO_2+W_2O_5$, has an equilibrium constant $K=[CO_2]/[CO]$ has between 17·2 and 21·1 between 750° and 1050°; and for the stage $W_2O_5+CO\rightleftharpoons 2WO_2+CO_2$ at 800°, $K=5{\cdot}08$; the last stage $WO_2+2CO\rightleftharpoons W+2CO_2$ could not be measured because of the formation of carbide. Z. Shibata also studied the reaction; he found that $\log K_p=1555{\cdot}5T^{-1}-1{\cdot}1427$ for the reaction $2WO_3+CO=W_2O_5+CO_2$; $\log K_p=1029{\cdot}8T^{-1}-0{\cdot}7884$ for the reaction $W_2O_5+CO=2WO_2+CO_2$; and $\log K_p=321{\cdot}6T^{-1}-0{\cdot}0647$ for $\frac{1}{2}WO_2+CO=\frac{1}{2}W+CO_2$. According to C. H. Ehrenfeld, **methane** does not reduce the trioxide heated by a bunsen burner, but at a higher temp. the dioxide is formed; no reduction occurred with **ethane,** but at a red-heat, **ethylene** furnishes the blue oxide; and **acetylene,** the blue and brown oxides. E. D. Desi also observed the formation of the blue oxide with ethylene, and he found that with cyanogen, a complex oxynitride is formed; and that fused **potassium cyanide** forms a complex oxynitride, and at a very high temp., silver-white globules of tungsten. F. Göbel found that **carbon monoxide** reduces the heated trioxide to the blue oxide. P. Camboulives observed that when the trioxide is heated to 560° in the vapour of **carbon tetrachloride,** an oxychloride is formed, and A. Michael and A. Murphy said that no reaction occurs at 240°, but at 280°, the hexachloride is produced—in the presence of chlorine, the oxychloride is formed at 240°, and the hexachloride at 280°. P. Sabatier and A. Mailhe, and J. N. Pearce and A. M. Alvarado studied the catalytic action of the trioxide on **alcohol** vapour whereby the alcohol is reduced to ethylene. J. N. Pearce and M. J. Rice studied the adsorption of the vapour of ethyl alcohol, ethyl acetate, and of acetic acid at 99·4°; and S. Ghosh and A. K. Bhattacharya, the photochemical reduction of tungstic acid by ethyl alcohol; and J. C. Ghosh and S. K. Nandy, of formaldehyde. J. C. Ghosh and J. Mukherjee, and E. T. Allen and V. H. Gottschalk found that the trioxide is not reduced by alcohol or **oxalic acid** with hot conc. hydrochloric acid; nor is it reduced by **grape-sugar.** The trioxide is reduced to the blue oxide by boiling **acetic acid** and other **organic compounds.** L. Fernandes studied the compounds formed with gallic acid; R. F. Weinland and co-workers, the action of the phenols, and phenolic acids; A. V. Dumansky and S. I. Dyachkovsky studied the action of tartaric acid. According to A. C. Neish, *m*-nitrobenzoic acid does not give a precipitate with soln. of ammonium tungstate; according to G. von Knorre, benzidine hydrochloride precipitates the tungsten quantitatively from cold soln. of the tungstates; and, according to M. Tschilikin, α-naphthylamine gives a quantitative precipitation. E. F. Smith studied the action of organic bases.

J. L. Gay Lussac and L. J. Thénard found that **potassium** or **sodium** when heated reduces tungsten trioxide vigorously with *une lumière vive.* E. D. Desi also reduced the trioxide with sodium; and with magnesium he obtained an alloy of tungsten. The reducing action of these and other **metals** has been discussed in connection with the preparation of tungsten (*q.v.*). O. Freih found that zinc reduces tungstic acid to the dioxide. K. Someya reduced tungsten trioxide to the quadrivalent stage by bismuth amalgam, and to the tervalent stage by lead, cadmium, and zinc amalgams. For the action of various basic oxides, *vide infra,* the tungstates. A. Riche found that conc. soln. of the **alkali hydroxides or carbonates** readily dissolve the trioxide, forming soln. of the tungstates; similarly also with the fused alkalies. E. J. Mills and D. Wilson measured what they called the chemical effect of tungsten trioxide when it is fused with potassium carbonate. This was expressed in terms of the units, a, of carbon dioxide evolved per unit of the trioxide acting for an hour at 750°. They found for tungsten trioxide, $a=0{\cdot}99597$; for silicon dioxide, $a=0{\cdot}83$; and for titanic oxide, $a=0{\cdot}71917$, showing that the action of titanic oxide is more sluggish than silica, and silica is more sluggish than tungsten trioxide. The blue colour obtained by the action of warm **stannous**

chloride on tungsten trioxide has been previously described. K. Someya described the reduction of tungstic acid or its salts with the amalgams of calcium, zinc, and lead.

§ 11. The Hydrates of Tungsten Trioxide—The Tungstic Acids

According to E. Zettnow,[1] and C. D. Braun, when sodium tungstate is treated with hot sulphuric acid, the hydrated tungstic acid which separates contains, after drying at a low temp., variable quantities of water. Thus, when dried at 50°, it has 3·68 per cent. of water—or $2WO_3.H_2O$; at 120° to 130°, 2·46 per cent.—or $3WO_3.H_2O$; and at 200°, 1·74 per cent.—or $4WO_3.H_2O$. The dihydrate dried at 100° to 110° was found by C. D. Braun to correspond with the *hemihydrate*, $2WO_3.H_2O$; and it has been called *pyrotungstic acid*, $H_2W_2O_7$, but there is no evidence to show that this composition is other than an arbitrarily selected stage in the continuation desiccation of an indefinite hydrate, $WO_3.nH_2O$—*vide infra*, Fig. 23.

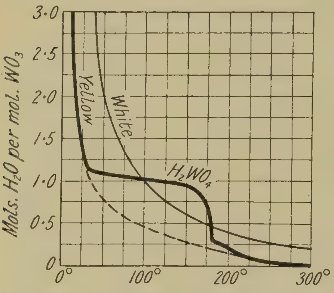

Fig. 23.—Dehydration Curves of the White and Yellow Hydrates of Tungsten Trioxide.

A. Laurent, A. Riche, and V. Forcher decomposed an aq. soln. of a tungstate or metatungstate with an excess of *hot* acid, and dried the product in air, or, according to C. D. Braun, over conc. sulphuric acid. The yellow hydrate was considered to be the *monohydrate*, $WO_3.H_2O$, **tungstic acid.** It was also obtained by decomposing wolframite with aqua regia; and C. D. Braun obtained it by drying the dihydrate over conc. sulphuric acid until its weight was constant. A. Laurent added that the yellow hydrate is stable at 200°; and L. Pissarjewsky, that its heat of neutralization is 13·698 Cals. per mol. The effects produced by acids of different concentration, etc., are discussed in connection with the extraction of tungsten. G. F. Hüttig and B. Kurre recommended the following method for preparing the *yellow tungstic acid*:

Add 20 grms. of purified calcium tungstate to a boiling mixture of 50 c.c. of water, 40 c.c. of conc. hydrochloric acid, and 40 c.c. of conc. nitric acid; wash the yellow precipitate by decantation 8 times with water feebly acidulated with hydrochloric acid; dissolve the precipitate in 50 c.c. of conc. aq. ammonia; and filter. Pour the boiling filtrate into a mixture of 60 c.c. of water, 50 c.c. of nitric acid, and 10 c.c. of hydrochloric acid; wash the yellow tungstic acid many times by decantation with water; filter through Zsigmondy's filter; and stir up the product with water. After the mixture has stood for about 14 days, passing now and again an electric current through the liquid—using platinum electrodes—the tungstic acid will have settled as an emulsion. The excess of water is syphoned off, the emulsion is concentrated on a water-bath. The product is then dried over solid sodium hydroxide. The composition approximates $WO_3.1·13H_2O$.

J. Eltzbacher used a similar process. A. Pinagel transformed sodium tungstate into barium tungstate, by adding barium chloride to a soln. of the sodium salt, and flocculating the precipitate with ammonium nitrate. The product was then decomposed by hot aqua regia, and the yellow hydrate washed with hot water. A. Riche said that if a soln. of the hydrated trioxide in conc. hydrofluoric acid at 50° or 60°, be evaporated in air, the oxyfluoride which first separates is decomposed forming crystals of yellow tungstic acid. A. M. Morely examined the products obtained by different modes of preparation, and found that the X-radiograms indicate the existence of the *monohydrate*, $WO_3.H_2O$, or H_2WO_4, and the *dihydrate*, $WO_3.2H_2O$, or $H_2WO_4.H_2O$. The other products are either condensed compounds or impure substances either non-crystalline or imperfectly crystalline. G. Jander and T. Aden observed the change in the visible and ultra-violet absorption spectra with aggregation in alkaline and acid soln. The yellow hydrate dissolves in water, for R. C. Wells found the sp. conductivity of the aq. soln. to be $10·3\times10^{-6}$ at 25°; he observed very little change when the soln. were left to stand for a long time, hence it is inferred that no large quantity of a polymerized acid is formed under these conditions. J. W. Mallet gave for the solubility in 38 per cent. hydrochloric acid, 0·36 and 0·75 grm. WO_3 per 100 grms. of soln. respectively at 50° and 80°; and R. F. Bernhardi-Grisson, for the solubility in 40 per cent. hydrochloric acid, 44·75 and 53·7 grms. per 100 grms. of soln. respectively at 25° and 50°. The yellow hydrate is readily soluble in alkali-lye.

According to A. Riche, J. J. and F. de Elhuyar, and J. J. Berzelius, if a soln. of a tungstate be treated with *cold* dil. acid, some soluble or metatungstic acid passes into soln., and there is formed a white luminous precipitate which tastes at first sweet and afterwards bitter; reddens litmus; and dissolves in water especially when hot, but scarcely at all in water containing acid. The white product forms yellow tungstic acid when it is boiled with sulphuric, hydrochloric, or nitric acid. When ignited in closed vessels it forms a blue oxide, and in open vessels, yellow tungsten trioxide. E. F. Anthon said that the white precipitate is amorphous, but, according to A. Riche, it becomes crystalline after two or three washings. The white product is very liable to pass through the filter-paper when it is washed. C. W. Scheele regarded the precipitate as pure tungstic acid, but J. J. Berzelius showed that it is always contaminated with some of the acid used as the precipitant; and J. J. and F. de Elhuyar, and J. C. G. de Marignac, with some of the alkali with which the tungstic acid was previously combined. The analyses of A. Riche, E. F. Anthon, C. D. Braun, and V. Forcher, show that the product is a *dihydrate*, $WO_3.2H_2O$. G. F. Hüttig and B. Kurre obtained *white tungstic acid* by the following procedure:

Ten grams of calcium tungstate are treated with acid as indicated above in connection with the yellow acid, and the product mixed with enough conc. aq. ammonia to dissolve nearly all the precipitate. The filtered soln. is cooled by ice, and 70 c.c. of conc. hydrochloric acid added drop by drop. The tungstic acid is filtered off, and again dissolved in conc. aq. ammonia. It is cooled and treated with hydrochloric acid as before, but with the exclusion of light. The mixture is filtered, and the precipitate washed six times with 25 c.c. of water. The white tungstic acid so formed still retains traces of ammonia and hydrochloric acid; and it has a tendency gradually to pass into the yellow variety. The analysis of a sample so prepared contained WO_3, 13·6 per cent.; H_2O, 86·05; NH_4Cl, 0·2; free HCl, 0·15 per cent. It showed no yellow tinge after being kept 14 days.

The white hydrate was also obtained by A. Riche, H. E. Roscoe, and V. Forcher by the action of moist air on tungsten hexachloride, pentachloride, oxytetrachloride, or dioxydichloride. E. F. Anthon, and V. Forcher also said that the white dihydrate is formed when the anhydrous trioxide is rubbed up with water and filtered—the dihydrate passes through the filter-paper forming a turbid filtrate.

According to G. F. Hüttig and B. Kurre, the white acid is to be regarded as hydrated tungsten trioxide because the composition-temp. curve, Fig. 23, shows that the adsorbed water is gradually lost as the temp. is raised, and the curve shows no signs of a break corresponding with the formation of a definite hydrate. The decomposition press., p mm., the decomposition temp., θ°, and the number n mols. of water per mol. of WO_3 were found to be:

p .	10·4	16·6	13·7	15·5	12·0	14·6	12·0	7·6	11·5
θ .	16°	21°	20°	36°	85°	129°	180°	305°	>500°
n .	60·61	44·90	16·0	2·44	0·95	0·64	0·39	0·24	0

The case is different with the yellow hydrate for it shows a definite break, Fig. 23, corresponding with the formation of a monohydrate, $WO_3.H_2O$, or tungstic acid, H_2WO_4. The following is a selection from the observed values of p, θ, and n:

p .	20·5	12·2	8·9	12	8·8	9·8	8·7	8·9	7·6
θ .	16°	17°	13°	20°	22°	94°	120°	218·5	278
n .	12·62	6·61	2·52	1·35	1·21	1·05	1·00	0·07	0·04

At temp. above 188° and below 76°, the white hydrate is the more stable, whereas between 76° and 188°, the yellow variety is the more stable. The subject was investigated by J. A. M. van Liempt. G. F. Hüttig found that yellow tungstic acid, $WO_3.H_2O$, has an X-radiogram showing that the chemically combined water molecules occupy fixed positions in the crystal-lattice ; with zeolites, on the contrary, the greater portion of the water is free to move in the crystal lattice. H. C. Burger found that the X-radiogram of tungsten trioxide is different from that of the monohydrate which has a definite and characteristic crystalline form, and it is on this account to be regarded as a definite compound. A definite compound was also indicated in the case of the dihydrate. Hence, if $W(OH)_6$ be *orthotungstic* acid, H_6WO_6 ; $WO(OH)_4$, is *paratungstic acid*, H_4WO_4, or $WO_3.2H_2O$; and $WO_2(OH)_2$, *metatungstic acid*, H_2WO_4, or $WO_3.H_2O$. This is in accord with the nomenclature in use for iodic and many other acids, but in the case of tungsten the terms metatungstic acid, and paratungstic acid have been employed with a different connotation—*vide infra*—namely, for the parent *paratungstic acid* of the salt with the formula $3Na_2O.7WO_3.21H_2O$, or the alternative $5Na_2O.12WO_3.28H_2O$; and of the parent *metatungstic acid*, of the salt $Na_2O.4WO_3.nH_2O$. For the so-called *isotungstic acid*, *vide supra*, the history of tungsten. M. E. Chevreul, and J. J. and F. de Elhuyar said that tungstic acid possesses a real acidity, for it reddens blue litmus. According to H. T. S. Britton, and H. T. S. Britton and W. L. German, when 100 c.c. of a 0·0678N-NaOH, and 0·0250M-WO_3 are titrated with 0·1020N-HCl, the electrometric curve is that shown in Fig. 24. A sharp diminution in hydrogen-ion concentration occurred when the amount of hydrochloric acid necessary to react with the alkali in excess of that required to form the normal sodium tungstate (Na_2WO_4) was added. This explains the successful use of phenolphthalein as an indicator for the titration of the oxide—observed by O. Hertig, A. Lottermoser and co-workers, D. Mojert, D. D. Peirce and L. F. Yntema, A. Rosenheim and A. Wolff, G. Jander and W. Heukeshoven, S. L. Dyachkovsky, M. L. Holt and L. Kahlenberg, F. Hundeshagen, and S. C. Lind and B. C. Trueblood. Sodium paratungstate with either 2·33 or 2·4 mols of Na_2O per mol of WO_3, respectively in accord with the 3 : 7-formula or the 5 : 12-formula, corresponds with a $H^{\cdot}$-ion conc. of $p_H = 6{\cdot}0$ respectively, and in agreement with H. Schmidt's observation that a soln. of the 2·4 salt is acidic to rosolic acid, and alkaline to cochineal. The metatungstate, $Na_2W_4O_{13}$, is formed when the $H^{\cdot}$-ion conc. is 10^{-4}. The inflexion in the hydrogen-ion concentration curve indicates that tungstic acid is not an ordinary dibasic acid —*vide infra*, sodium tungstate. W. Jander and A. Winkel found that the normal tungstate exists in soln. when the $[H^{\cdot}]$-concentration is between 10^{-14} and $10^{-6\cdot5}$; and the paratungstate when the $[H^{\cdot}]$-concentration is between $10^{-6\cdot5}$ and $10^{-1\cdot5}$. Meta- and para-tungstates are assumed to contain tungstic acid either in a polymerized form or in a semi-colloidal form. G. Jander also studied the tungstates from this point of view. W. V. Bhagwat and N. R. Dhar studied the ionization constants ; and S. Kato, the absorption spectra in the ultra-red, and the visible spectrum. L. Pissarjewsky found the heat of neutralization of tungstic acid, H_2WO_4, in 0·5N-NaOH, to be 13·698 Cals.

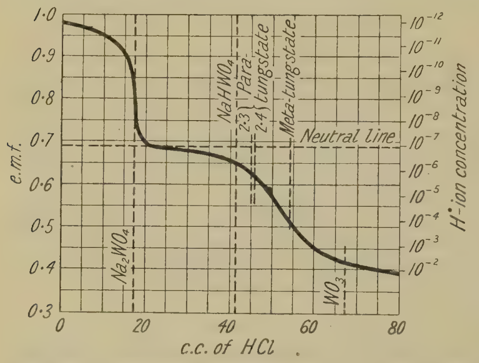

Fig. 24.—Electrometric Titration of Tungstic Acid.

A. Carnot [2] observed a hydrated form of tungsten trioxide associated with the scheelite of Meymac, Corrèze, France, and he accordingly called it **meymacite.** It is a yellow or greenish-yellow, friable earth sometimes having the general form of scheelite. Its composition approximates $WO_3.2H_2O$. G. C. Hoffmann also reported a pale yellow ochre associated with the scheelite of Marlow, Quebec, Canada.

According to T. Graham,[3] when dil. hydrochloric acid is added to a soln. of sodium tungstate until the liquid becomes slightly acid, a **colloidal solution of tungstic acid** is formed. A. P. Sabanéeff added that if the proportion of tungstate and acid is $2Na_2WO_4 : 3HCl$, and the mixture is dialyzed, the colloid is really sodium tungstate, $Na_2O.4WO_3$. T. Graham said that the colloid is tungstic acid from which all the sodium cannot be removed by dialysis. W. Biltz and A. von Vegesack said that the soln. remaining in the dialyzer contains $2Na_2O.11WO_3$, but considered that some colloidal tungstic acid is present. N. Pappada added that when moderately conc. hydrochloric acid is added drop by drop to a 5 per cent. soln. of sodium tungstate, a white gelatinous precipitate is formed when the liquids meet, but it quickly goes into soln., forming an acid liquor. The soln. contains colloidal tungstic acid, and he regards A. P. Sabanéeff's hypothesis, that it is $Na_2O.4WO_3$, as incorrect. According to A. Lottermoser, hydrochloric acid gives a voluminous, gelatinous, white precipitate with conc. soln. of sodium tungstate ; more dil. soln. remain clear at first, and afterwards slowly deposit the white precipitate in a more voluminous form. If the precipitate formed from the very dil. soln. is repeatedly decanted with distilled water, a clear hydrosol may be obtained, which, however, is unstable, as it gradually becomes cloudy, and changes to a hydrosol which is yellow in reflected light. When more conc. soln. are used, the voluminous, white precipitate gradually decreases in bulk, at the same time turning yellow ; finally, the same yellow hydrosol is obtained as previously. If this yellow hydrosol is shaken, a silky lustre is noticeable in reflected light, although it appears clear in transmitted light ; it is a suspension of relatively large particles, and gradually clears on keeping. L. Wöhler and W. Engels found that colloidal tungstic acid mixed with gelatin in the presence of ammonium chloride gives a flocculent precipitate which is peptized by an excess of ammonium chloride. W. A. Patrick mixed 3 to 8 per cent. soln. of a soluble salt, with vigorous stirring, with such a quantity of acid that the $H^{\cdot}$-ion conc. of the mixture is 0·1 to 0·5 mol per litre. The mixture is allowed to stand quietly for 2 to 5 hrs., until the soln. sets to a firm hydrogel. This is broken up, washed to remove salts and excess acid, and dried in a current of air at 75° to 120°, or heated to 300°–400° if a hard gel is desired. N. Pappada recommended preparing the colloid by the following process :

> Hydrochloric acid is added to a conc. soln. of sodium tungstate until the liquid has an acidic reaction. The white, gelatinous precipitate is washed several times by decantation at a low temp., 0° to 5°, while protecting the precipitate from currents of air which produce a change in the colloid. 15 parts of the tungstic acid are then dissolved by gently warming with a conc. soln. of one part of oxalic acid and the liquid dialyzed. If the outer water is frequently changed, the oxalic acid is completely removed, leaving a colloidal soln. of tungstic acid which may be concentrated in vacuo over sulphuric acid at ordinary temp. until it contains as much as 1·25 per cent. WO_3.

L. Moser and J. Ehrlich added hydrochloric acid of sp. gr. 1·19, drop by drop, to a soln. containing 32·89 grms. of normal sodium tungstate per litre. The precipitate at first formed was redissolved on continuing the addition of acid. The resulting soln. is colloidal, and can be coagulated by boiling. If nitric acid be used in place of hydrochloric acid, the precipitate does not redissolve with either cold or hot soln. The washed tungstic acid precipitated by hydrochloric acid, however, is partly soluble in hot nitric acid, while washed tungstic acid precipitated by nitric acid is no longer so easily soluble in hydrochloric acid. Sulphuric acid stands between hydrochloric and nitric acid in that the precipitate at first formed with this acid is partly redissolved on adding more acid. Consequently, although the tungstic acid precipitated by all the mineral acids is chemically the same, its physical condition depends on the nature of the acid. When the hydrochloric acid is added to the boiling soln. of sodium tungstate, at first a white precipitate forms which turns yellow, and passes into soln. with the exception of a few white particles which remain at the bottom of the vessel. If increasing amounts of acetic acid are added to the sodium tungstate soln., before adding the hydrochloric acid, the initial precipitation does not take place until greater amounts of hydrochloric acid are added, and this precipitate redissolves more quickly on adding more hydrochloric acid. However, the addition of 5 c.c. acetic acid to 2 c.c. of sodium tungstate soln. gives a precipitate which is not soluble in hydrochloric acid. If tungstic acid is precipitated from sodium tungstate soln. by hydrochloric acid and allowed to stand, the precipitate, at first white, becomes yellow and insoluble on adding more hydrochloric acid. If acetic acid is added, then hydrochloric acid, and the soln. heated, the precipitate again dissolves. The tungstic acid in all cases is positively charged. E. B. Miller and G. C. Connolly, and W. A. Patrick and E. H. Barclay prepared tungstic acid gels.

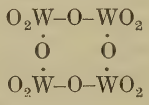
A. Müller prepared a colloidal soln. by dissolving 5 grms. of tungsten tetrachloride in 50 c.c. of a mixture of equal vols. of ethyl alcohol and ether, and the filtered soln. is then diluted to 250 c.c. with ethyl alcohol. If this soln. is mixed with an equal vol. of water, a colloidal soln. of tungstic acid is obtained, which can be kept for some days without any appreciable opalescence being observed. With larger quantities of water, coagulation takes place much more quickly. On adding small quantities of neutral salts or of hydroxides, coagulation occurs immediately; strong acids produce a similar effect after some minutes, but weak organic acids appear to exert no influence on the stability of the colloidal soln. A rise of temp. is also without influence, but coagulation takes place if the vol. is reduced to about a fourth of the original by evaporation. When an electric current is passed through the colloidal soln., a deep blue precipitate is formed at the cathode. This is attributed to reduction of the positively charged colloidal particles by the discharged hydrogen. The behaviour of the colloidal soln. towards electrolytes is consistent with the supposition that the tungstic acid is a positive colloid, and the spontaneous coagulation of the soln. is probably due to the presence of chlorine ions in the soln. According to M. Kröger the electrolysis of a 2 per cent. soln. of sodium tungstate between a mercury cathode and a silver anode produces the hydrosol of tungstic acid. The removal of alkali may be hastened by the cautious addition from time to time of a little hydrochloric acid, but in no circumstances may the neutral point be passed. Should the soln. become acid, blue tungsten compounds are produced. The tungsten hydroxide hydrosols are clear and transparent, but possess a deep brown colour, which in dil. soln. is yellowish-brown. They are coagulated by potassium chloride to form a black powder which resembles the lower oxides of tungsten. The coagulation of the colloid was studied by S. Ghosh and N. R. Dhar, A. Kargin, W. V. Bhagwat and N. R. Dhar, S. I. Diatschowsky, and K. Jacobsohn.

J. Duclaux said that colloidal soln. can be conc. by filtering out the solvent under press. through collodion. An increasing press. will remove more and more solvent, until a limit is attained where the colloid solidifies. This limiting press. is termed the " maximum osmotic pressure " of the colloid, and the limiting conc. the " solubility " of the colloid. In this sense, colloidal tungstic acid may be said to have a 60 per cent. solubility. N. Pappada prepared a soln. with 1·25 per cent. of WO_3, and it did not freeze at 0°. D. Klein said that when dried at 200°, the colloid has the composition $3WO_3.H_2O$. According to A. P. Sabanéeff, when colloidal tungstic acid is dried at 200°, it contains about 2·57 per cent. of H_2O and corresponds with $H_2W_3O_{10}$—mol. wt. 714; the mol. wt. calculated from the observed f.p. of the soln. is between 677 and 995. G. E. Linebarger measured the osmotic press. of soln. containing 0·02467 grm. and 0·0100 grm. of tungstic acid per c.c., and the values calculated for the mol. wt. of the colloidal tungstic acid averaged 1700, or nearly seven times 250, the number corresponding with the simple molecule H_2WO_4. The colloid mol. would therefore consist of seven simple mol. in the case of tungstic acid, and this is in keeping with the ordinary assumption that the mols. of colloids are very large. W. Biltz and A. von Vegesack made some observations on the osmotic press. A. V. Dumansky and co-workers discussed the formation of complexes as an intermediate stage in the formation of colloidal tungstic acid—*vide* colloidal molybdic acid. A. V. Dumansky and A. P. Buntin said that the electrical properties of the soln. indicate that the reaction takes place in stages: $Na_2WO_4+2HCl=H_2WO_4+2NaCl$ and $H_2WO_4+Na_2WO_4=Na_2O.2WO_3+H_2O$. This process is repeated, until a colloidal particle of the composition $Na_2O.nWO_3$, or $H_2[WO_4.nWO_3]$, is obtained. Numerous complexes of tungstic acid are known which confirm this view. They also measured the viscosity of tungstic acid sols. The hydrosol of tungstic acid, said T. Graham, has a bitter, astringent taste, and at 19°, the sp. gr. of a soln. with 5 per cent. WO_3 is 1·0475; with 10 per cent., 1·2168; 50 per cent., 1·6011; 66·5 per cent., 2·396; and 79·8 per cent., 3·243. C. E. Fawsitt found that the viscosity of the soln. is a linear function of the concentration: soln. with 2·8 and 4·4 per cent. of tungstic acid had viscosities 1·028 and 1·044 (water unity) respectively at 25°. N. R. Dhar and co-workers also measured the viscosity of the sol. S. Ghosh and N. R. Dhar measured the viscosity of the colloidal sol.; H. Pallman, and A. J. Rabinowitsch and V. A. Kargin, the $H^{\cdot}$-ion concentration of the hydrosol; and W. Riedal, the change in the electric conductivity with the age of the hydrosol.

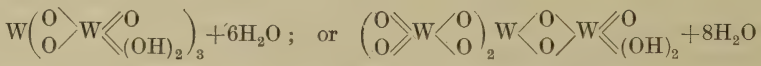
According to A. F. Wasiliewa-Sinzowa, when a colloidal soln. of tungstic acid in the presence of an organic reducing agent—*e.g.* dextrose, sucrose, dextrin, cellulose, or formaldehyde—is exposed to sunlight, it becomes blue. The soln. gradually loses this property at a speed which corresponds with a reaction of the first order. The reverse change occurs when the soln. is heated. It is assumed that colloidal tungstic acid exists in two modifications; the variety sensitive to the action of light is assumed to be converted into the other by the absorption of water; or the compound which is sensitive to light may be tungsten trioxide which on adsorbing a mol. of sodium tungstate forms the colloid which is not sensitive to light. According to A. F. Wasiliewa-Sinzova, when $0{\cdot}5N$-$Na_2WO_4.2H_2O$ is allowed to stand for t min. with an equal vol. of xN-HCl, and then mixed with 2 vols. of $0{\cdot}5N$-glucose, exposed for 5 min. to an arc-lamp, and the blue reduction product titrated with potassium permanganate, the latter result can be regarded as a measure of the sensitivity of the tungstic acid to light. The relation between the light sensitivity of the tungstic acid and the concentration, x, corresponded with the formula for a monomolecular reaction in which the constant k—using ordinary logarithms—decreased from 0·006 with $x=0{\cdot}43$ to 0·0003 with $x=0{\cdot}50$, and became constant when $x=0{\cdot}54$. The light sensitivity increases with x up to 0·47, then decreases—perhaps because the number of mols. of tungstic acid sensitive to light increases—and is then followed by a coagulating action of the acid. The decrease in the velocity constant with increasing values of x is attributed to the simultaneous decrease in the conc. of the WO_4''-ions which exert a catalytic effect. The conc. of this ion becomes zero when for every eq. of sodium tungstate an eq. of acid is present. The phenomena do not depend on the Cl'-ions of the acid because similar results are obtained with sulphuric acid. L. Wöhler and W. Engels showed that the precipitation which occurs when soln. of molybdates are acidified is due to the presence of tungstates. The readiness with which precipitation takes place is dependent on the proportion of tungstic acid present, and when this is present in very small amount, the temp. may be raised to nearly 100° before a precipitate is obtained. The precipitation is primarily due to the tungstic acid in the soln., and when this separates out, molybdic acid is simultaneously removed from the soln. S. Glixelli studied the electroösmosis or cataphoresis. T. Graham found that the gelatilization of silicic acid is retarded by the presence of colloidal tungstic acid; M. Kröger measured the time required for the complete gelatinization of silicic acid with different conc. of tungstic acid and found that the time-conc. curve passes first through a minimum with the addition of tungstic acid soln., it then passes through a maximum, and finally falls continuously with increasing proportions of tungstic acid. E. Wedekind and H. Fischer said that hydrated tungstic acid does not adsorb prussian blue. The stability of the colloid was studied by S. I. Diatschowsky. The adsorption of water, ethyl alcohol, ethylacetate, and acetic acid vapours was studied by J. N. Pearce and M. J. Rice.

F. Margueritte[4] obtained the ammonium salt of an acid which A. Laurent called **metatungstic acid ;** the former represented it by $(NH_4)_2O.3WO_3.5H_2O$, and the latter by $5(NH_4)_2O.18WO_3.31H_2O$. W. Lotz showed that the ratio of base to acid, $R_2O : WO_3$ is more nearly 1 : 4, and this is in accord with the observations of A. Riche, W. Lotz, R. Scheibler, and J. C. G. de Marignac on these salts. The corresponding acid was obtained by A. Laurent by treating a soln. of the ammonium salt with hydrochloroplatinic acid, filtering off the ammonium chloroplatinate, and evaporating the filtrate for crystallization. The colourless crystals of the metatungstic acid, $H_2O.4WO_3.9H_2O$, are readily soluble in water and alcohol. C. Scheibler treated the barium salt with the calculated amount of dil. sulphuric acid, and evaporated the filtrate over sulphuric acid in vacuo. A similar process was employed by E. Péchard, and M. Soboleff. V. Forcher treated the lead salt with hydrogen sulphide, expelled the excess of that gas by a current of carbon dioxide, concentrated the soln. on a water-bath, and finished the evaporation for crystallization over sulphuric acid, in vacuo. J. Lefort treated a conc. soln. of sodium ditungstate with arsenic acid and warmed the mixture. A. Rosenheim and F. Kohn obtained metatungstic acid by treating a conc. aq. soln. of ammonium metatungstate with ether and conc. hydrochloric or sulphuric acid. Three layers of liquid are formed; the lower layer contains free metatungstic acid, together with ether and the mineral acids. The required acid is obtained by evaporating this layer in air. The soluble tungstic acid described by J. Persoz was probably metatungstic acid.

Analyses by M. Soboleff, etc. agree with the formula $H_2W_4O_{13}.8H_2O$, or $H_2W_4O_{13}.6H_2O$. A. Rosenheim and F. Kohn gave $H_2W_4O_{13}.8H_2O$ and $H_2W_4O_{13}.6H_2O$. According to D. I. Mendeléeff, the same transformation is accomplished in the passage of ordinary tungstates into the metatungstates as takes place in the passage of tungstic acid itself from an insoluble into a soluble state—the hydrosol. A. Michaelis represented ordinary tungstic acid by H_2WO_4, and he regarded metatungstic acid as a condensation product of this acid, $H_2W_4O_{13}.nH_2O$, derived from the anhydride, W_4O_{12}, or, with tungsten sexivalent,



The question is not so easily decided. The complex heteropoly-acids of tungsten have been discussed by A. Rosenheim and co-workers, as well as by W. Prandtl and co-workers, A. Rogers and E. F. Smith, P. Pfeiffer, H. Copaux, etc. C. Scheibler showed that all the metatungstates are dehydrated with difficulty, and that after all the water has been expelled, the residue no longer dissolves in water. This makes it probable that part at least of the water is constitutional. A. Geuther represented metatungstic acid by formulæ which assumed that all the tungsten atoms are sexivalent, and that one mol. or three mols. of water are constitutional:



$$W\Big(\begin{smallmatrix}O\\O\end{smallmatrix}\!>\!W\!\ll\!\begin{smallmatrix}O\\(OH)_2\end{smallmatrix}\Big)_3+6H_2O\,; \quad \text{or} \quad \Big(\begin{smallmatrix}O\\O\end{smallmatrix}\!\gg\!W\!<\!\begin{smallmatrix}O\\O\end{smallmatrix}\Big)_2W\!<\!\begin{smallmatrix}O\\O\end{smallmatrix}\!>\!W\!\ll\!\begin{smallmatrix}O\\(OH)_2\end{smallmatrix}+8H_2O$$

C. Friedheim found that the ammonium and potassium salts lose all but one mol. of water at 100°, whilst the sodium, barium, cadmium, lead and manganese salts retain 3 mols. at 100°, and, with the exception of the lead salt, they retain one mol. up to 220°. This makes it appear as if at least one and possibly 3 mols. of water are constitutional. H. Copaux argued that metatungstic acid is isomorphous with the complex heteropoly acids—*e.g.* boro-, phosphato-, and silico-tungstic acids—and that some of the salts—those of ammonium, potassium, and barium—are also isomorphous, and consequently, these compounds have probably a similar constitution; and if the mol. wt. be increased six times, the potassium salts can be represented: $6K_2O.(3H_2O.24WO_3).36H_2O$, $5K_2O.(B_2O_3.24WO_3).36H_2O$, and $4K_2O.(2SiO_2.24WO_3).36H_2O$; and the barium salts: $6BaO(3H_2O.24WO_3).54H_2O$, and $5BaO(B_2O_3.24WO_3).54H_2O$. The mol. proportion of acid and base is not the same in the isomorphous compounds, but if 3 mols. of water are assumed to be constitutional in metatungstic acid, the proportions of water of crystallization are the same. There are also several points of resemblance in the properties of the salts of these heteropolyacids. It is therefore assumed that the 3 mols. of constitutional water are acidic, and the free acids can be represented by the formulæ: $6H_2O(3H_2O.24WO_3).48H_2O$; $5H_2O.(B_2O_3.24WO_3).48H_2O$; $4H_2O.(2SiO_2.24WO_3).48H_2O$; and $3H_2O.(P_2O_5.24WO_3).48H_2O$.

A. Rosenheim and F. Kohn tried to find how much water is constitutional by preparing insoluble salts which usually do not contain water of crystallization, and showed that in the silver salt 2 or 3 mols. are firmly combined with the molecule, while in the thallium and guanidinium salts, only one mol. is firmly combined. They also showed that the ratio of fixed water to the WO_3 group is at least 1 : 4 and probably 3 : 4, whereas H. Copaux's hypothesis requires this ratio to be 1 : 8. A. Rosenheim and F. Kohn concluded that the constitution is best represented by a formula of the co-ordination type with 3 mols. of constitutional water: $R_2[WO(WO_4)_3(H_2O)_3]$, or possibly $R_2[WO(WO_4)_3(H_2O)]$. When the constitutional water is expelled, the salts are decomposed. H. Copaux then modified this hypothesis, and represented the salts as derivatives of the acid (hypothetical):

Metatungstic acid	$H_{10}[H_2(W_2O_7)_6]$
Borotungstic acid	$H_9[B(W_2O_7)_6]$
Silicotungstic acid	$H_8[Si(W_2O_7)_6]$
Phosphotungstic acid	$H_7[P(W_2O_7)_6]$

where the basicity is determined by the difference between the valency of the central element and the combined valency of associated six radicles. Metatungstic acid can thus be referred to water $H_{10}[H_2O_6]$ in which the six oxygen atoms are replaced by six bivalent W_2O_7-radicles. The acid is thus assumed to be decabasic, whereas, with the exception of the mercury salt, only hexabasic salts of the type $M_6H_4[H_2(W_2O_7)_6]$ have been prepared. An ill-defined mercurous salt, $Hg^{\cdot}{}_8H_2[H_2(W_2O_7)_6]$, has been reported—*vide infra*. Actually the basicity of the acid is unknown.

The crystals of metatungstic acid were described by V. Forcher as octahedra, while C. Scheibler called them tetragonal bipyramids. H. Copaux found that the crystals are isomorphous with those of the silico- and phospho-tungstic acids. C. Scheibler found that the sp. gr. is 3·93. The sp. gr. of the aq. soln. with 41·46, 88·57, and 111·87 grms. of $H_2W_4O_{13}.9H_2O$ were found by M. Soboleff to be respectively 1·6025 at 0°; 2·5239 at 22°; and 3·6503 at 43·5°; and he gave for soln. with p per cent. of WO_3 at 17·5°, the sp. gr. $=1+0{\cdot}00903p+0{\cdot}0000633p^2+0{\cdot}00000141p^3$. The crystals, said A. Rosenheim and F. Kohn, readily effloresce in air. M. Soboleff added that when heated to 50°, the crystals lose 8·34 per cent. or $4{\cdot}5H_2O$, and they then become virtually insoluble in water, this means that the acid is decomposed. The loss at 100° is 10·1 per cent. or $6{\cdot}1H_2O$; at 150°, 12·94 per cent. or $7{\cdot}5H_2O$; at 180°, 13·5 per cent. or $8{\cdot}1\ H_2O$, and at 180°, 13·48 or $8H_2O$. C. Scheibler gave 11·4 per cent. or $7H_2O$ for the loss at 100°. According to M. Soboleff, the lowering of the f.p. of soln. of the acid with 0·3489, 2·8724, and 25·9447 grms. of $H_2W_4O_{13}$ per 100 c.c. of water are respectively 0·05165°, 0·04076°, and 0·03393°, corresponding with the respective mol. wts. 365·2, 464·7, and 557·9—theory 926—so that the factors i are respectively 2·53, 1·99, and 1·66. The mol. electrical conductivities, μ, of the aq. soln. with 926 grms. in v litres, at 25°, are:

v .	32	64	128	256	512	1024
μ .	159·9	219·1	261·8	305·1	348·6	390·9

A. Rosenheim and F. Kohn said that in aq. soln., metatungstic acid behaves as a normal electrolyte, and acts as a dibasic acid. For the electrometric titration, *vide supra*, Fig. 24. The solubilities of $H_2W_4O_{13}.9H_2O$ at 0°, 22°, and 43·5° are respectively 41·46, 88·57, and 111·87 grms. per 100 c.c. of water. The aq. soln. is colourless, or, according to V. Forcher, pale yellow. The soln. has a strong acid and bitter taste, and does not appear to be poisonous. A. Rosenheim and E. Brauer found the $H^{\cdot}$-ion conc. of 0·005N-soln. of $H_{10}[H_2(W_2O_7)_6].22H_2O$, to be $[H^{\cdot}]=0{\cdot}0035$, or $p_H=2{\cdot}45$, when the values for 0·01N-HCl are $[H^{\cdot}]=0{\cdot}0095$, or $p_H=2{\cdot}022$; and for N-$CH_3.COOH$, $[H^{\cdot}]=0{\cdot}0043$, or $p_H=2{\cdot}366$. H. Leiser found that while no change occurred in the electrolysis of a tungstate, a soln. of metatungstic acid is reduced to a blue soln. which is readily oxidized by exposure to air, and from which no crystalline product could be obtained. Using a platinum basin as cathode, and a nickel gauze anode, the blue compound formed approximates W_4O_{11}, and if a lead cathode be employed the reduction goes further forming black tungsten dioxide. According to C. Scheibler, the aq. soln. can be boiled for a long time without decomposition, and at 100°, the soln. can be evaporated to a certain point when it forms a white gummy mass of white tungstic acid which suddenly cracks, and finally yellow tungstic acid is formed. Dil. soln. can be kept for a long time in closed vessels without change, but conc. soln. slowly form white tungstic acid. If the soln. is not too dil., sulphuric acid gives a white precipitate which passes into soln. if more water is added. V. Forcher, and C. Scheibler added that with hydrochloric acid and zinc, metatungstic acid becomes blue; the soln. gives no precipitate with hydrogen sulphide; and with ammonium sulphide, sulphur separates out, and after a time, the soln. deposits bluish-black cubes of ammonium sulphotungstate. J. C. Ghosh and J. Mukherjee studied tungstic acid as a photocatalyst in the decomposition of hydrogen dioxide. A. Rosenheim and F. Kohn said that in alcoholic soln., metatungstic acid acts as a colloid; when a mineral acid is present, it is possible that a mol. compound of metatungstic acid and ether is formed. No esters of metatungstic acid could be prepared. M. Soboleff said that at 0°, 7·8°, 18·2° and 24·2°, ether dissolves respectively 83·456, 88·389, 99·66, and 110·76 grms. $H_2W_4O_{13}.9H_2O$ per 100 c.c. If the acid has lost some water it does not dissolve. In extracting the acid from aq. soln. by means of ether, a liquid with 3 layers is formed. G. Jander and co-workers regard the metatungstates as hexatungstates, possibly $R_6H_4[H_2(W_2O_7)_6].nH_2O$. They found that when aq. soln. of alkali tungstates are gradually acidified, amorphous precipitates of hydrated forms of tungsten trioxide are finally obtained. Before the precipitate is actually formed, however, polymerization changes occur in the dissolved tungstic acid, and these changes have been investigated by the two methods already used in the case of stannates, *viz.*, by means of measurements of diffusion coefficients and of absorption coefficients of visible and ultra-violet light. The gradual addition of hydrochloric acid to a soln. of an alkali tungstate produces first a polymerization to hexatungstic acid, without the formation of any intermediate acid, as follows: $6WO_4''+6H^{\cdot}\rightleftharpoons W_6O_{21}''''''+3H_2O$. With the addition of more acid there is a further polymerization to metatungstic acid, which is probably a diparatungstic acid, and in presence of other acids, such as arsenic or phosphoric acids, heteropolytungstic acids are formed.

According to J. Lefort, if a very conc., cold soln. of one part of arsenic acid is mixed with a similar soln. of four parts of normal sodium tungstate, a complex arsenatotungstate is formed, but if one part of arsenic acid be mixed with two parts of sodium ditungstate, and the soln. evaporated, metatungstic acid is obtained in very fine yellow leaflets. To this acid, the name **metaluteotungstic acid,** $WO_3.7H_2O$, is given—luteus, yellow. This acid is also obtained if phosphoric acid is used instead of arsenic acid. The properties resemble those of ordinary metatungstic acid. The yellow colour may be due to impurities; E. Péchard could not confirm J. Lefort's results.

In 1847, A. Laurent[5] prepared salts of a **paratungstic acid.** He called them paratungstates, and represented them by the formula $5R_2O.12WO_3$, while W. Lotz, and C. Scheibler suggested $3R_2O.7WO_3$. J. C. G. de Marignac concluded that the majority of the paratungstates contained $5R_2O.12WO_3$, but a few contained $3R_2O.7WO_3$. G. von Knorre, and C. Gonzalez were unable to decide in favour of either formula. The degree of purity of the salts, and the limits of the analytical errors do not enable a distinction to be made between these formulæ. H. Copaux studied the dehydration of the salts, and concluded that they are hydrohexatungstates with the general formula $R_5[H(W_2O_7)_3].nH_2O$. He preferred this to a formula with the WO''_4-radicle because like the metatungstates the paratungstates absorb ultra-violet light, whereas the normal tungstates do not do so. A. Rosenheim regarded the paratungstates as salts of the acid $H_{10}[H_2(WO_4)_6]$. There is no evidence proving the basicity of the acid, but the salts are usually representable by the formula $R_5H_5[H_2(WO_4)_6]$. G. von Knorre found that the paratungstates gradually decompose in aq. soln., forming normal tungstates and metatungstates; hence, while a freshly prepared soln. is neutral to phenolphthalein, it gradually becomes acidic. The change proceeds rapidly when the soln. is boiled. R. C. Wells also found that the electrical conductivities of aq. soln. slowly increase when allowed to stand for some time.

L. A. Hallopeau found that free paratungstic acid is not easily obtained by the action of hydrogen sulphide on the lead salt, or of hydrochloric acid on the silver salt, because the resulting silver chloride is difficult to separate. The best method is to mix the barium salt with not quite enough dil. sulphuric acid for the complete decomposition of the salt. Dil. soln. of paratungstic acid are not decomposed by heat, but prolonged boiling partially converts the paratungstic into metatungstic acid. When the soln. is evaporated, even in vacuo, at the ordinary temp., some ordinary tungstic acid is formed. Alkali-lye neutralizes the soln. and yields paratungstates. Hydrochloric, nitric, and sulphuric acids decompose dil. soln. of paratungstic acid; hydrogen sulphide reduces them with formation of the blue or the green oxide; acetic, phosphoric, and carbonic acids have no action. Organic substances, including filter-paper, reduce the acid with formation of the blue oxide, and a soln. mixed with alcohol is similarly reduced when exposed to light. For the electrometric titration, *vide supra*, Fig. 24.

§ 12. The Monotungstates—Normal Tungstates

The great variety of compounds of tungsten trioxide with the bases has introduced difficulties in their classification. Some consider that they are best regarded as normal tungstates of the type, $M_2WO_4.nH_2O$; paratungstates of the type $3M_2O.7WO_3.nH_2O$, or $5M_2O.12WO_3.nH_2O$; and metatungstates of the type $M_2W_4O_{13}.nH_2O$; there are, however, other relations which make this system inadequate—*vide supra,* tungstic acid. As in the case of the higher molybdates (*q.v.*), many of the complex tungstates can be regarded as

Hexa-tungstates	Ditungstates or Tetrahydrohexatungstates . . .	$R_6H_4[H_2(WO_4)_6]$
	Paratungstates or Pentahydrotungstates . . .	$R_5H_5[H_2(WO_4)_6]$
	Tritungstates or Hexahydrohexatungstates . . .	$R_4H_6[H_2(WO_4)_6]$
Dodeca-tungstates	Metatungstates or Tetrahydrododecatungstates . .	$R_6H_4[H_2(W_2O_7)_6]$
	Hexatungstates or Hexahydrododecatungstates . .	$R_4H_6[H_2(W_2O_7)_6]$
	Octotungstates or Heptahydrododecatungstates . .	$R_3H_7[H_2(W_2O_7)_6]$

Hydrated tungsten trioxide readily dissolves in aq. ammonia, but neither E. F. Anthon,[1] nor J. C. G. de Marignac were able to isolate normal **ammonium tungstate,** $(NH_4)_2WO_4.nH_2O$, from the soln. because when the soln. is concentrated, ammonia is lost, and an acid salt remains. The corresponding sulpho-salt, $(NH_4)_2WS_4$, has been obtained. It is assumed that an aq. soln. of the salt exists because, as shown by E. F. Anthon, a soln. of calcium chloride precipitates normal calcium tungstate. A. Rosenheim and F. Jacobsohn, however, did obtain the normal salt as a white mass by the action of hydrated tungstic acid on liquid ammonia. Likewise the salt was prepared by T. H. Tsao, and by E. Kunau. For the so-called *ammonium isotungstate, vide supra,* the history of tungsten. Ammonium tungstate is very soluble in water, and readily loses ammonia. According to C. E. Guignet, the aq. soln. readily dissolves prussian blue; and, according to R. E. Liesegang, paper treated first with ammonium tungstate, and then with hydrochloric acid, becomes grey when exposed to light. According to K. A. Hofmann and V. Kohlschütter, when 25 grms. of powdered sodium paratungstate are added to a soln. of 10 grms. of hydroxylamine hydrochloride in 20 c.c. of water, the product dissolved in 50 c.c. of 15 per cent. ammonia, and the soln. allowed to evaporate over potassium hydroxide, thick tablets of **ammonium hydroxylamine tungstate,** $(NH_3OH).WO_4.(NH_4)$, are formed. The salt reduces Fehling's soln., and an ammoniacal soln. of silver nitrate.

G. C. Gmelin[2] obtained **lithium tungstate,** Li_2WO_4, by dissolving tungsten trioxide in a boiling soln. of lithium carbonate, and evaporating the liquid for crystallization; and E. F. Anthon obtained it by dissolving the tungsten trioxide in molten lithium carbonate, and allowing an aq. soln. of the cold product to crystallize. J. A. M. van Liempt found that lithium tungstate melts at 742° and shows no transition point. F. Hoermann gave 742° for the m.p. The f.p. of mixtures with tungsten trioxide are shown in Fig. 25, as far as about $Li_2O : WO_3 = 1 : 2{\cdot}5$; the molten tungstate does not dissolve more trioxide. A compound lithium ditungstate is formed melting at 745°, and with a transition point at 687°. The curve Fig. 25 is by F. Hoermann. *Vide infra,* for mixtures of lithium tungstate with sodium and potassium tungstates. According to W. Zachariasen, the X-radiogram shows that lithium tungstate is isomorphous with the molybdate (*q.v.*); the elementary trigonal cell has *a* about 8·20 A., and *c*, about 9·45 A. The rhombic columns, or octahedral crystals, are stable in air; they have a sweet, yet bitter, taste; they are readily soluble in water; and the aq. soln. has an alkaline reaction.

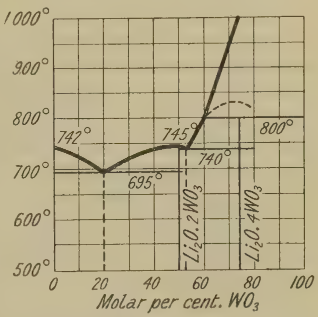

Fig. 25.—Freezing Points of the System: Li_2WO_4–WO_3.

A. Rosenheim and W. Reglin found the hydrate to be $Li_2WO_4.H_2O$, and that the salt in aq. soln. is strongly hydrolyzed. With atm. carbon dioxide, lithium carbonate and tungstic acid are formed. The salt is soluble in a soln. of lithium hydroxide, and on evaporating the soln., a non-crystallizable syrup is obtained.

Anhydrous **sodium tungstate,** Na_2WO_4, was obtained by E. F. Anthon,[3] E. Zettnow, and F. Ullik by fusing together eq. proportions of tungsten trioxide and the alkali hydroxide or carbonate. It was also produced by B. von Pawlewsky, by allowing the hydrate to stand for a long time over conc. sulphuric acid; by A. Riche, by allowing it to stand in vacuo; and by A. Riche, V. Forcher, B. von Pawlewsky, and R. Funk, by heating the hydrate over 100°. The preparation of the salt from wolframite, etc., has been discussed in connection with the extraction of tungsten (*q.v.*). It separates from its aq. soln. in the hydrated form. W. Jander and A. Winkel observed that the normal alkali tungstate is formed in aq. soln. when the $[H^{\cdot}]$-concentration lies between 10^{-14} and $10^{-6\cdot5}$; and the paratungstate $R_5(HW_6O_{21})$ when the conc. is between 10^{-65} and $10^{-6\cdot5}$.

The relations of sodium tungstate to water closely resemble those of sodium molybdate. The percentage solubility, S, found by R. Funk, was:

	−5°	0°	5°	6°	10°	20°	40°	80°	100°
S .	30·6	36·5	41·0	41·8	41·9	42·2	43·8	47·4	49·2
Solid phase	$10H_2O$			$2H_2O$					

There is an unstable form of the dihydrate with S=41·7 at −3·5°. The results are plotted in Fig. 26, where the dotted curve refers to sodium molybdate, the continuous curve to sodium tungstate. The anhydrous tungstate does not appear as a stable phase in the system below 100°. A. Riche obtained the *dihydrate,* $NaWO_4.2H_2O$, from a soln. of tungsten trioxide and sodium carbonate; and E. F. Anthon from a soln. of that oxide and sodium hydroxide, or from an aq. soln. of a previously melted mixture of wolframite and sodium carbonate. The dihydrate can be recrystallized from water. The conditions of stability are indicated in Fig. 26. R. Funk showed that below 6°, the aq. soln. furnishes crystals of the decahydrate: $Na_2WO_4.10H_2O$. Analyses of the dihydrate were made by E. F. Anthon, V. Forcher, R. Funk, E. Wegelin, J. C. G. de Marignac, A. Riche, and E. Zettnow.

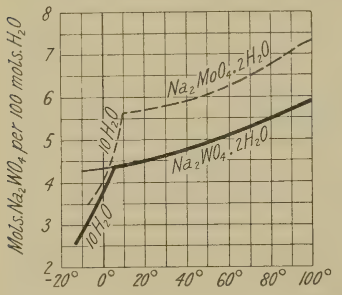

FIG. 26.—The Solubility of Sodium Tungstate in Water.

Anhydrous sodium tungstate furnishes white crystals; and when heated, the salt undergoes two transformations. H. E. Boeke showed that the changes are reversible. The molten liquid freezes at about 700°—f.p. Fig. 27. For reasons which will appear, H. E. Boeke called the salt in this state β-Na_2WO_4, and he observed that there is a **transition point** at 588°, involving the reversible change: $\beta\text{-}Na_2WO_4 \rightleftharpoons \gamma\text{-}Na_2WO_4$; and at 564°, γ-Na_2WO_4 passes into δ-Na_2WO_4 by a reversible process: $\gamma\text{-}Na_2WO_4 \rightleftharpoons \delta\text{-}Na_2WO_4$. The δ-form is stable at ordinary temp. According to N. Parravano, the transition points on the cooling curve for the $\beta \rightleftharpoons \gamma$ and the $\gamma \rightleftharpoons \delta$ transformations are respectively 585° and 568°; H. S. van Klooster gave respectively 589° and 572°; F. Hoermann, 590° and 583°; and K. Hüttner and G. Tammann found the $\gamma \rightleftharpoons \delta$ transition to occur at 570°—J. A. M. van Liempt gave 577°; and A. Hare, 579°. H. S. van Klooster and H. C. Germs found on the heating curve, 587° for the $\delta \rightleftharpoons \gamma$ transition point—J. A. M. van Liempt gave 588°—and 591° for the $\gamma \rightleftharpoons \beta$ transition point. The thermal value of the $\delta \rightleftharpoons \gamma$-transformation is much greater than that of the $\gamma \rightleftharpoons \beta$-transformation. Sodium sulphate shows a transition point at 239° in which what H. E. Boeke called α-Na_2SO_4 passes into ϵ-Na_2SO_4, the form stable at ordinary temp.

The reason the β-prefix is not here employed turns on the fact that on comparing the results with sodium sulphate with those obtained with the molybdate and tungstate, other forms may be subsequently discovered. The results with sodium sulphate, molybdate, and tungstate are summarized in Fig. 27, and in the following table showing the range of stability of the different forms, as well as their birefringence, b:

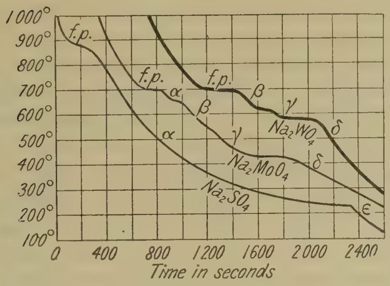

FIG. 27.—Cooling Curves of Sodium Sulphate, Molybdate, and Tungstate.

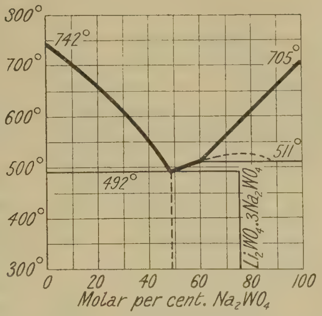

FIG. 28.—Freezing-point Curves of the System: Li_2WO_4–Na_2WO_4.

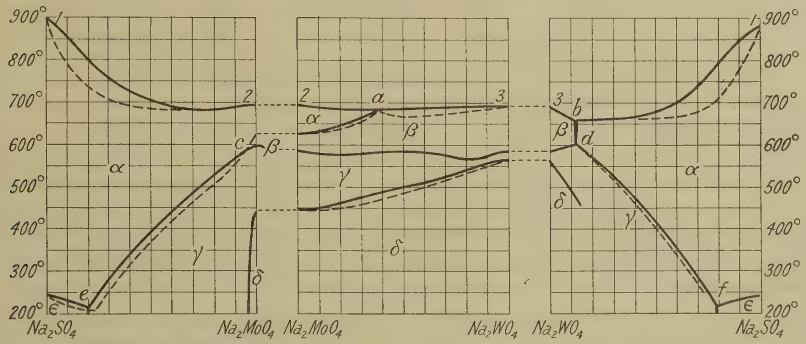
	Melting-point	α-crystals (b feeble)	β-crystals (b strong)	γ-crystals (b very strong)	δ-crystals (isotropic)	δ-crystals (b very strong)
Na_2SO_4 .	888°	888°–239°	,,	,,	,,	239°– . . .
Na_2MoO_4.	698°	—	698°–588°	588°–564°	564°– . . .	,,
Na_2WO_4.	692°	692°–619°	619°–587°	587°–431°	431°– . . .	,,

R. Lorenz and W. Herz made some observations on the transition temp. of sodium tungstate. The f.p. curve of the system, Li_2WO_4–Na_2WO_4, by J. A. M. van Liempt, is shown in Fig. 28. There is a simple eutectic at 491° and 45 molar per cent. of sodium tungstate. F. Hoermann's observations are summarized in Fig. 28. A compound of the two salts is formed with an incongruent m.p. at 511°. H. S. van Klooster and H. C. Germs' observations on the behaviour of each of the three salts—Na_2WO_4, Na_2MoO_4, and Na_2SO_4—in binary systems is illustrated by Figs. 29 to 31; and these diagrams are combined in Fig. 32 to represent the ternary system—Na_2SO_4–Na_2MoO_4–Na_2WO_4. H. E. Boeke, and P. Kordes also studied the system Na_2MoO_4–Na_2WO_4.



FIGS. 29, 30, and 31.—The Binary Systems Na_2SO_4–Na_2MoO_4, Na_2MoO_4–Na_2WO_4, and Na_2WO_4–Na_2SO_4.

The ordinary commercial salt is the dihydrate, and the white or transparent, nacreous, scaly **crystals** were described by L. N. Vauquelin and L. Hecht as four-sided plates, and by E. F. Anthon, A. Riche, and V. Forcher as rhombic plates. According to J. C. G. de Marignac, the rhombic bipyramids have the axial ratios $a:b:c=0{\cdot}8002:1:0{\cdot}6470$. F. Zambonini gave $0{\cdot}8013:1:0{\cdot}6524$, and for the optic axial angle, $2E=35°\ 20'$ for $\lambda=667$; 39° 30′ for Na-light; and 43° 40′ for $\lambda=533$. The crystals were also described by C. F. Rammelsberg, and E. Herlinger. According to F. W. Clarke and J. L. Davis, the **specific gravity** of the anhydrous salt is 4·1833 at 18·5° and 4·1743 at 20·5°; and that of the dihydrate is 3·2588 at 17·5° and 3·2314 at 18·5°. F. Zambonini gave 3·50 at 15°/15°. F. M. Jäger's values for the molten salt are indicated below; and he represented the sp. gr., D, at $\theta°/4°$ between 930° and 1595° by $D=3{\cdot}673-0{\cdot}0009275$, $(\theta-930)+0{\cdot}0_6337(\theta-930)^2$. The sp. gr. at 917° was 3·685; at 1128°, 3·502; and at 1330°, 3·356. W. Herz, and R. Lorenz and W. Herz made some observations on this subject. The sp. gr., D, of aq. soln. of the dihydrate with the following percentage proportion of Na_2WO_4, were measured by B. von Pawlewsky, who found:

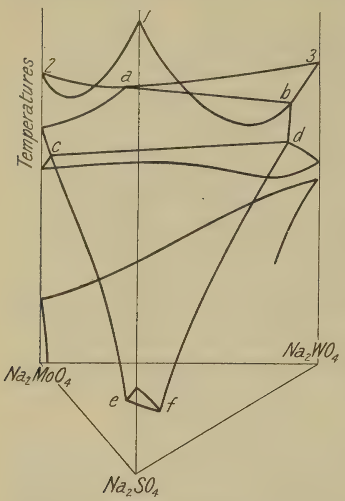


FIG. 32.—The Ternary System: Na_2SO_4–Na_2MoO_4–Na_2WO_4 at different Temperatures.

Na_2WO_4		2·21	6·25	10·08	14·44	20·59	25·46	32·68	38·43
D	20°/20°	1·02016	1·05831	1·09687	1·14392	1·21720	1·28143	1·38826	1·48595
	20°/4°	1·01837	1·05641	1·09486	1·14177	1·21483	1·27887	1·38539	1·48279

Observations were also made by I. Traube, and B. Franz. I. Traube found the drop-weight of the molten salt to be 259 referred to water 100 at 0°. F. M. Jäger gave the following values for the sp. gr. D, the **specific cohesion,** a^2 mgrm. per mm.; the **surface tension** σ dynes per cm.; and the **surface energy,** χ ergs per sq. cm. of the molten salt:

	710°	788°	1038·5°	1181·4°	1231·5°	1331·5°	1450°	1595°
D_2	3·893	3·812	3·576	3·461	3·424	3·355	3·282	3·208
a	10·65	10·60	10·34	10·15	10·00	9·76	9·44	9·02
σ	203·3	198·2	181·4	172·4	168·0	160·6	152·0	142·6
χ	3632	3591	3430	3332	3270	3168	3043	2899

R. Lorenz and W. Herz discovered some relations of the surface tension. J. J. Coleman found that the **diffusion** of 28, 25, and 17 per cent. of normal soln. of sodium molybdate, chromate, and tungstate respectively occurred in 30 days at 12·5°. H. Schulz and G. Jander observed that the diffusion coeff. of the tungstate ion in aq. soln. of sodium tungstate decreases considerably with increasing acidity of the soln., which is probably due to an increase in complexity of the ions according to some such scheme as $7WO_4''+8H^{\cdot}\rightleftharpoons W(WO_4)_6''''''+4H_2O$. In soln. $0{\cdot}1N$ in respect of a mineral acid and containing neutral salts, the degree of aggregation of the tungstate ion is 5 to 7 times that of the ion in alkaline soln. In soln. which contain no neutral salts, but are $0{\cdot}1N$ in respect of a mineral acid and have been boiled, the degree of aggregation is 9 to 11. G. Tammann found the **vapour pressure** of soln. with 19·62, 56·06, and 111·13 grms. of sodium tungstate in 100 grms. of water at 100° was 24·6, 85·3, and 197·1 mm. less than the value for water alone. E. F. Anthon, and V. Forcher observed that the salt melts at a red-heat, forming a clear liquid which, on cooling, solidifies to a crystalline mass. K. Hüttner and G. Tammann, H. E. Boeke, and N. Parravano gave 698° for the **melting point** of sodium tungstate; H. S. van Klooster, 700°; F. Hoermann, and J. A. M. van Liempt, 705°; and H. S. van Klooster and H. C. Germs, 694°. E. F. Smith gave for the m.p. of

$Na_2O.WO_3$, 665°; $5Na_2O.12WO_3$, 705·8°; $4Na_2O.10WO_3$, 680·8°; $9Na_2O.22WO_3$, 683·3°; and $Na_2O.4WO_3$, 706°. N. Parravano measured the f.p. curve of mixtures of sodium tungstate and tungsten trioxide, so far as the solubility of the trioxide allows—namely, $Na_2O : WO_3 = 1 : 2·5$; according to J. A. M. van Liempt, and N. Parravano, transformations—*vide supra*—occur at 588°, and 564°. The m.p. of sodium tungstate falls steadily with increasing additions of tungsten trioxide until it reaches the eutectic at 626°. It then rises to a maximum at 731°, corresponding with the pyrotungstate $Na_2W_2O_7$. From 626° to 588°, the mixtures are composed of α-Na_2WO_4 and $Na_2W_2O_7$; from 588° to 564°, they are composed of β-Na_2WO_4 and $Na_2W_2O_7$; and below 564°, of mixtures of γ-Na_2WO_4 and $Na_2W_2O_7$. The subsequent course of the curve indicates the possible existence of $Na_2W_5O_{16}$, but excludes the tritungstate $Na_2W_3O_{10}$. The results of F. Hoermann are summarized in Fig. 33. J. A. M. van Liempt gave 738° for the m.p. of sodium ditungstate, and 628° for the eutectic with normal tungstate; he also noted the lowering of the transition temp. of sodium tungstate by tungsten trioxide. E. Wegelin found that 0·5196 grm. of the dihydrate in 20 c.c. of water lowered the f.p. of water at 0·3°. This corresponds with a mol. wt. of 112·3. Other determinations gave analogous results. The theoretical mol. wt. for Na_2WO_4 is 294·1, hence the salt in aq. soln. probably furnishes three ions. W. G. Mixter gave for the **heat of formation** with powdered tungsten: $W+3Na_2O_2=Na_2WO_4+2Na_2O+231·2$ Cals.; $W+Na_2O+3O=Na_2WO_4+291$ Cals.; and $WO_3+Na_2O=Na_2WO_4+94·1$ Cals.; and L. Pissarjewsky gave H_2WO_4aq.$+2NaOH$aq.$=Na_2WO_4$aq.$+H_2O+13·694$ Cals. A. Hare gave 9·51 Cals. per mol for the energy of the transformation at 579°.

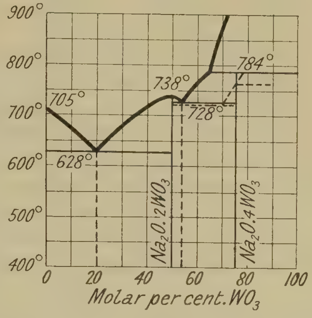

FIG. 33.—Equilibrium Curves of Mixtures of Sodium Tungstate and Tungsten Trioxide.

B. von Pawlewsky found the **index of refraction,** μ, of soln., at 20°, with the following percentage proportions of sodium tungstate, to be:

Na_2WO_4	2·21	6·25	10·08	14·44	20·59	25·46	32·68	38·43
μ	1·33586	1·34065	1·34516	1·35064	1·35933	1·36648	1·37306	1·38890

H. Schulz and G. Jander found that with increasing acidity, the optical absorption limit of the soln. moves towards the region of longer wave-lengths. This is taken to indicate an aggregation of the anions. O. H. Wagner found for the index of refraction, μ, of the molten salt for wave-lengths λ at $\theta°$: $\mu=a-b(\theta-750)$, so that

λ	0·670	0·610	0·589	0·579	0·546	0·436
a	1·574	1·580	1·588	1·589	1·595	1·615
b	0·00021	0·00024	0·00026	0·00021	0·00020	0·00011

or $\mu=2·6531+1·0562\lambda/\{\lambda^2-(1·777)^2\}$. For the luminescence in **X-rays,** *vide infra*, calcium tungstate. P. Krishnamurti examined the **Raman effect.**

P. Walden, J. Eltzbacher, and H. Grossmann and H. Krämer measured the **electrical conductivity** of soln. of sodium tungstate; and C. Watkins and H. C. Jones gave for the conductivity, μ mhos, of soln. with a mol of the salt in v litres of water:

	v	4	8	16	32	128	512	1024
μ	0°	63·5	74·4	88·2	93·3	105	114	116
	15°	107	120	135	143	162	175	178
	25°	—	151	169	180	203	221	225
	35°	—	183	206	219	249	271	272

W. V. Bhagwat and N. R. Dhar gave for the eq. conductivity, λ, of a soln. with a mol of the salt in v litres at 21°:

v	8	16	32	64	128	256	512	1024
λ	77·6	82·9	87·3	91·3	95·3	99·1	101·3	103·9

so that $\mu_{1024}-\mu_{32}=16{\cdot}6$; and P. Walden gave $\mu_{1024}-\mu_{32}=21{\cdot}5$. F. M. Jäger and B. Kapma represented the mol. conductivity of the fused salt at $\theta°$ between 750° and 501° by $\mu=83{\cdot}50+0{\cdot}185(\theta-750)$; and the resistance, R ohms, and sp. gr. D, are :

	752·5°	958°	1066°	1209°	1361·5°	1412°	1501°
D .	3·843	3·648	3·554	3·443	3·339	3·308	3·258
R .	0·1706	0·1194	0·0996	0·0804	0·0702	0·0650	0·0628

The subject was discussed by W. Biltz and W. Klemm. G. Gore obtained black matter at the cathode during the **electrolysis** of fused sodium tungstate, and a gas was given off at the anode. E. Schaefer, and M. Kröger obtained colloidal tungstic acid (*q.v.*) by the electrolysis of soln. of sodium tungstate ; and A. Lottermoser obtained paratungstate and other complex tungstates. P. Burckhard found that the molten salt conducts the electric current, forming oxygen at the anode, and at the cathode, a mass of tungsten hemipentoxide—*vide supra*, the extraction of tungsten. According to E. F. Smith, neutral soln. of the tungstates are not affected by the electric current, but J. Eltzbacher, E. Schaefer, and E. F. Smith made observations on the electrolysis of acidified soln. of sodium tungstate, and found that tungstic acid, at the cathode, is reduced to the blue oxide. R. G. Wells said that the conductivity of the aq. soln. does not change with time.

F. Wöhler said that the salt is not decomposed when it is heated in **hydrogen ;** and E. Bouchhaus studied the reaction. V. Spitzin observed that neutral sodium tungstate is reduced by hydrogen at 900° in accord with $Na_2WO_4+4H_2=2Na+W+4H_2O$; and J. A. M. van Liempt said that the reduction at 1100° proceeds: $Na_2WO_4+3H_2=W+2NaOH+2H_2O$. R. Funk said that the dihydrate is stable in **air,** but V. Forcher observed that efflorescence occurs in dry air. According to L. N. Vauquelin and L. Hecht, 100 parts of **water** dissolve 25 parts of the salt in the cold, and 50 parts when boiling; and E. F. Anthon gave, respectively, 100 and 200. A. Riche reported that 100 parts of water dissolve 40·98 parts of salt at 0° ; 55·25 parts at 15° ; and 123·4 parts at the b.p. ; and R. Funk, that 100 parts of water dissolve 90·09 parts of salt at 21°, and 123·4 at the b.p.—*vide supra*. E. F. Anthon said that the soln. has a bitter, rough, saline taste, and an alkaline reaction. B. Kellner observed that the salt dissolves more easily in **hydrogen dioxide** than it does in water, and the soln. is yellow, and reacts acid. W. K. van Haagen and E. F. Smith found that the heated tungstate is attacked with difficulty by **hydrogen fluoride.** V. I. Spitsin and L. Kaschtanoff said that with **hydrogen chloride,** volatile tungsten dioxydichloride and sodium chloride are formed. According to A. Riche, and E. Zettnow, a soln. of the salt is decomposed by strong **acids** as well as by boric, sulphurous, carbonic, oxalic, and acetic acids, and, added V. Forcher, by carbon dioxide. The action of phosphoric acid has been discussed by C. Scheibler, J. Lefort, etc.—*vide infra*, phosphotungstates—H. Rose said that with a soln. of a tungstate, phosphoric acid gives a white precipitate, soluble in excess ; and E. Zettnow added that the normal alkali tungstates do not precipitate orthophosphoric acid, and by quickly transforming that acid into metaphosphoric acid, hinder the precipitation of tungstic acid by other acids. F. J. Factor found that when the soln. is warmed with **sodium thiosulphate,** a mixture of tungsten dioxide, trioxide, and the lower oxides is precipitated ; and **alkali sulphites** give no blue coloration with the hot soln., but if a little hydrochloric acid be present, a feeble blue colour may appear. A. Rosenheim observed that the tungstates seem to form unstable complex salts when treated with **sulphur dioxide.** F. Bourion said that chlorine mixed with the vapour of **sulphur dichloride** drives out all the tungsten as volatile chloride from sodium tungstate at 180°–450°. W. I. Baragiola showed that when a soln. of sodium tungstate is treated with **ammonium chloride,** various acid tungstates are formed—namely, $3(NH_4)_2O.2Na_2O.15WO_3.25H_2O$; $4(NH_4)_2O.2Na_2O.15WO_3.21H_2O$; and $6(NH_4)_2O.2Na_2O.20WO_3.24H_2O$. F. Wöhler, and E. F. Anthon supposed that ammonium salts with conc. soln. of sodium tungstate give the ammonium salt, but A. Laurent, and W. Lotz said that a double salt is produced—*vide infra*. H. Traube obtained trigonal, bipyramidal crystals of probably an isomorphous mixture **lithium sodium 1 : 3-tungstate,** $Li_2WO_4.3Na_2WO_4.12H_2O$, from a soln. of equimolar proportions of the two salts. The axial ratios are $a : c = 1 : 0{\cdot}8947$, and $\alpha = 100° 34'$. The optical character is negative. L. Kahlenberg and W. J. Trautmann found that sodium tungstate reacts with silicon with difficulty, forming no free metal or silicide. H. S. van Klooster examined fused mixtures of sodium metasilicate and tungstate. The two salts are practically immiscible in the liquid state, and quite immiscible in the solid condition. The fragment of the equilibrium diagram which was explored is shown in Fig. 34. J. A. M. van Liempt examined the sp. gr., D, the viscosity, η, and the sp. electrical conductivity, K, of soln. of mixtures of sodium orthosilicate, Na_4SiO_4, and sodium tungstate, Na_2WO_4, and found that the curves show no maxima or minima at 30°. The results were :

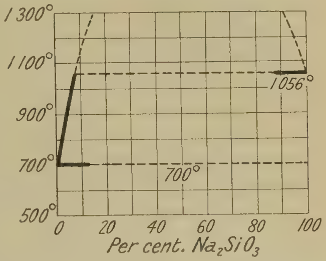

FIG. 34.—Equilibrium Diagram of the System : Na_2WO_4–Na_2SiO_3.

Na_2WO_4 .	0	2	4	6	8	10 vol. per cent.
D . .	1·193	1·206	1·218	1·230	1·242	1·225
η . .	2·888	2·579	2·389	2·062	1·881	1·671
K . .	0·1517	0·1317	0·1241	0·1154	0·1057	0·0910

The action of many reagents on aq. soln. has been discussed in connection with the analytical reactions of tungsten. P. Hautefeuille and A. Perrey, and H. Corimboeuf discussed its use as *un agent mineralisateur*—**6**. 40, 17 and 22—in the synthesis of silicate minerals, and in the conversion of **silica.** H. S. van Klooster found that sodium tungstate and sodium silicate, Na_2SiO_3, are practically immiscible below 1100° ; and they are completely immiscible in the crystalline state. A. Riche, and V. Forcher found that alcohol precipitates crystals of the salt from its aq. soln., and that the salt is insoluble in **alcohol.** O. Maschke showed that strongly alkaline soln. are coloured blue by **organic compounds** owing to reduction ; and R. E. Liesegang found that a mixture of sodium tungstate with a soln. of citric acid is sensitive to light, and on isolation, acquires a blue colour. The coloration is not produced by sodium tungstate alone nor in the presence of acetic acid, sodium oxalate, stannous chloride, or ammonium thiocyanate. According to J. H. Long, the optical rotation of a soln. of potassium antimonyl tartrate is raised by the addition of sodium tungstate, very little tungstic acid is precipitated. D. Gernez also observed that the optical activity of several organic substances is raised by sodium tungstate, itself optically inactive. A. V. Dumansky and S. I. Diatschkovsky observed its action on the activity of tartaric acid. J. Lefort studied the action of quinine on normal alkali tungstate. C. N. Fenner, and C. J. van Nieuwenburg and C. N. G. de Nooijer discussed its catalytic action on the transformations of silica (*q.v.*). F. Mauro and R. R. Panebianco discussed the reduction of tungstic acid or tungstates in hydrofluoric acid soln. by metals. F. Hoermann's observations, Fig. 28, show that a compound **lithium sodium tungstate,** $Li_2WO_4.3Na_2WO_4$, is formed with an incongruent m.p. of 511°.

E. F. Anthon prepared anhydrous **potassium tungstate,** K_2WO_4, by crystallization from a filtered soln. of tungstic acid in soln. of potassium hydroxide or carbonate. J. C. G. de Marignac said that the anhydrous salt is always obtained when the hot, sat. soln. is cooled, or evaporated hot. F. Ullik added that if the alkali-lye contains sodium, a mixed sodium potassium tungstate is formed. E. F. Anthon, E. Zettnow, and F. Ullik melted equimolar proportions of potassium carbonate and tungsten trioxide at a red-heat. The mass on cooling disintegrates to a powder, indicating that polymorphic transformations are involved. J. C. G. de Marignac found that if the aq. soln. be evaporated over sulphuric acid, below 10°, monoclinic prisms and plates of the dihydrate, $K_2WO_4.2H_2O$, are formed ; they have the axial ratios

$a:b:c=0{\cdot}9998:1:0{\cdot}7830$, and $\beta=110°\ 57'$; and they effloresce in dry air particularly if warmed, and deliquesce rapidly in moist air. A. Riche reported a *monohydrate*, $K_2WO_4.H_2O$, but he probably mistook a partially effloresced dihydrate for the monohydrate. E. F. Anthon's hexagonal *pentahydrate*, $K_2WO_4.5H_2O$, was, according to F. Ullik, a mixed sodium potassium tungstate. As stated by S. Surawicz, the assumption of water produces no change in the crystal system, for J. C. G. de Marignac showed that the acicular crystals of the anhydrous salt are monoclinic prisms with the axial ratios $a:b:c=1{\cdot}9702:1:1{\cdot}2341$, and $\beta=113°\ 15'$. Twinning occurs about the (001)-plane. J. W. Retgers found that the crystals are isomorphous with those of potassium sulphate, selenate, and molybdate. J. W. Retgers found that two kinds of crystals are formed during the evaporation of aq. soln. —(i) slender needles which exhibit feeble polarization, and are coloured green by potassium manganate with which they are isomorphous; and (ii) prisms which exhibit strong polarization and are not coloured by potassium manganate. J. W. Retgers considered that the first kind of crystals are rhombic and are pseudohexagonal; and the second kind are probably monoclinic. It is not improbable that anhydrous and dihydrated crystals are here in question. F. M. Jäger found the sp. gr. of the molten salt at $\theta°/4°$, between 925° and 1520·3°, to be best represented by $D=3{\cdot}113-0{\cdot}00082(\theta-1000)+0{\cdot}0_6162(\theta-1000)^2$—*vide infra* for data. F. M. Jäger and J. Kahn, and W. Herz made observations on this subject. I. Traube found the sp. gr. of soln. with 2·42, 6·57, 8·72, and 16·19 per cent. of the salt to be respectively 1·0202, 1·0575, 1·0781, and 1·1518, at 15°. I. Traube found the drop-weight of the molten salt at its m.p. to be 170 when that of water at 0° is 100. F. M. Jäger found the sp. gr., D, referred to water at 4°, the specific cohesion, a^2 mgrm. per mm.; the surface tension, σ dynes per cm.; and the surface energy, χ ergs per sq. cm., of the molten salt to be:

D_1	925·0°	1051·5°	1183·2°	1284·0°	1408·5°	1520·3°
a .	10·34	9·69	9·21	8·78	8·30	7·89
σ .	161·0	145·9	134·1	124·6	114·3	105·6
χ .	3531	3275	3076	2908	2723	2560

R. Lorenz and W. Herz discussed some relations of the surface tension. G. Tammann found the vapour pressure of soln. 19·71, 51·63, 81·77, and 156·52 grms. of the normal salt in 100 grms. of water at 100° to be respectively 17·6, 52·0, 96·9, and 215·4 mm. below that of water at 100°. F. Ullik, and J. C. G. de Marignac observed that when the salt is heated, there is a violent decrepitation attended by the loss of 0·25 to 0·50 per cent. of included water; the salt readily fuses at a red-heat without suffering any further loss. As indicated above, the shattering of the cooling solid indicates a transformation from one form to another. K. Hüttner and G. Tammann observed a transformation on the cooling curve occurs between 200° and 300°; and M. Amadori gave 575°, F. Hoermann, 338°; while H. S. van Klooster obtained 388° on the heating curve. K. Hüttner and G. Tammann gave 926° for the m.p.; J. A. M. van Liempt, 926° in one case and 933° in another; M. Amadori, 894°; F. Hoermann, 921°; and H. S. van Klooster, 921°. J. A. M. van Liempt found that potassium tungstate is not reduced by hydrogen at 1100°, but it volatilizes unchanged. For the luminescence in X-rays, *vide infra*, calcium tungstate. J. A. M. van Liempt measured the f.p. of mixtures of potassium tungstate and tungsten trioxide so far as the solubility of the trioxide allows—namely $K_2O:WO_3=1:2{\cdot}5WO_3$. There is a eutectic at 584° with 50 per cent. WO_3. F. Hoermann's results are shown in Fig. 35. J. A. M. van Liempt found that with the system

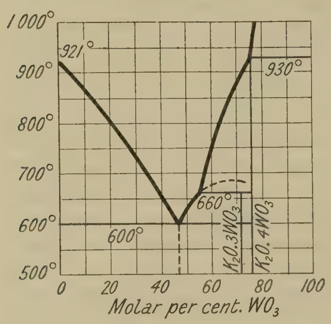

FIG. 35.—Freezing-point Curve of the System: K_2WO_4–WO_3.

Li_2WO_4–K_2WO_4, there is formed a compound **lithium potassium tungstate,** $Li_2WO_4.K_2WO_4$, melting at 632°, Fig. 36. It gives a simple eutectic with 70 per cent. of lithium tungstate at 579°, and with 40 per cent. lithium tungstate at 607°. J. A. M. van Liempt's curve for mixtures of sodium and potassium tungstates is shown in Fig. 37. There is a minimum in the curve with 20 per cent. of the potassium salt. According to M. Amadori, the f.p. curve of the binary system

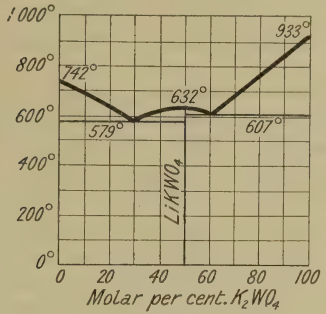

FIG. 36.—Freezing-point Curve of the System: Li_2WO_4–K_2WO_4.

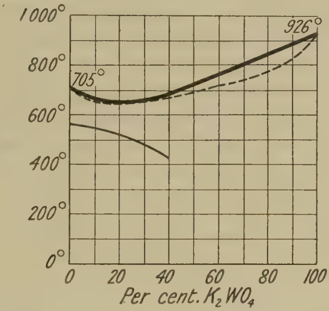

FIG. 37.—Freezing-point Curve of the System: Na_2WO_4–K_2WO_4.

K_2SO_4–K_2WO_4, Fig. 38, is continuous with a slight minimum 10° below the m.p. of the tungstate. The transformation point of the tungstate is not visible with mixtures containing over 15 molar per cent. of sulphate. The transformation of the sulphate follows a curve descending to 482° for mixtures containing 50 molar per cent. below which point it can no longer be followed. The f.p. curve is also continuous in the system K_2CrO_4–K_2WO_4, Fig. 39, and it is intermediate between the m.p. of the two salts. The transformation points follow curves rising to the transformation points of the salts above, but were not detected with mixtures containing between 15 and 40 per cent. of chromate. The curve in the system

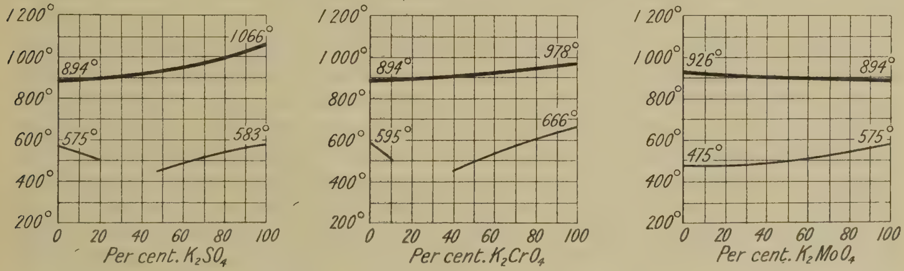

FIG. 38, 39, and 40.—Freezing-point Curve of Binary Mixtures of Potassium Tungstate with Potassium Sulphate, Chromate and Molybdate.

K_2MoO_4–K_2WO_4, Fig. 40, is almost a straight line between the m.p. of the two salts. The transformation point can be detected only with mixtures rich in one or other constituent. E. Blanc found that a 0·0162*N*-soln. of potassium tungstate is hydrolyzed 0·011 per cent. at 25°. J. A. M. van Liempt found the sp. gr. and viscosity curves of mixtures of potassium tungstate and potassium metasilicate, K_2SiO_3, gave similar results to those obtained with sodium tungstate and orthosilicate—*vide supra*. J. A. M. van Liempt observed that whilst sodium tungstate is reduced by hydrogen at 1100°, this is not the case with potassium tungstate. W. K. van Haagen and E. F. Smith found that potassium tungstate is attacked with difficulty by hydrofluoric acid. W. I. Baragiola treated soln. of potassium tungstate with ammonium chloride and obtained the salts $4\{\frac{1}{4}(NH)_4.\frac{3}{4}K\}_2O.11WO_3.10H_2O$; and

$2\{\frac{2}{3}(NH_4).\frac{1}{3}K\}_2O.5WO_3.8H_2O$. H. Traube obtained crystals of probably an isomorphous mixture of **sodium potassium 2 : 1-tungstate,** $K_2WO_4.2Na_2WO_4.14H_2O$.

Although **cuprous tungstate,** Cu_2WO_4, has not been prepared, H. Schultze[4] obtained what appeared to be a **cuprosic tungstate** by melting together a mixture of sodium tungstate, cuprous chloride, and sodium chloride (2 : 3 : 4) and extracting the cold mass with nitric acid. There remained white, and yellowish-brown, quadratic prisms. E. Zettnow obtained a pale brownish-red, crystalline powder of $Cu_2WO_4.2CuWO_4$, by fusing a mixture of equimolecular parts of copper sulphate and sodium tungstate, and leaching the cold product with water. The product was oxidized by nitric acid with the evolution of nitric oxide.

J. D. Whitney described a mineral from La Paz, California, which he called **cuproscheelite ;** M. Adam called it **cuprotungstate.** It occurred as a pistachio-green, olive-green, or leek-green, granular, crystalline mass, or in crusts. It was reported in the copper mines of Llamuco, Chili, by I. Domeyko ; in the Pot mine, S.W. Africa, by H. Traube ; and at Yeoral, N.S.W., by G. W. Card. The analyses by J. D. Whitney, and I. Domeyko show that it is a mixture of calcium and copper tungstates, and it can be represented by the formula $(Ca,Cu)WO_4$. According to L. Michel, and F. Fouqué and A. Michel-Lévy, the mineral can be synthesized by melting together a mixture of cupric chloride and sodium tungstate with an excess of sodium chloride. After washing the cold product with water, there remain pale green prisms and octahedra, which polarize light strongly.

G. Tammann observed that when a mixture of equimolecular proportions of cupric oxide and tungsten trioxide is heated, the formation of **copper tungstate,** $CuWO_4$, proceeds actively between 600° and 800°. According to E. F. Anthon, when a cupric salt is added to a soln. of normal potassium tungstate, a light green powder of copper tungstate is precipitated. When dried in air, its composition corresponds with the *dihydrate*, $CuWO_4.2H_2O$. When the dihydrate is heated, it turns yellowish-brown in colour ; fuses at a red-heat ; and, on cooling, it solidifies to a chocolate-coloured, crystalline mass containing cavities with crystalline geodes. The crystals are wine-yellow, transparent, six-sided prisms. G. Tammann gave 12·1 Cals. per mol for the heat of formation of the anhydrous salt, and 19·0 Cals. per mol for that of the dihydrate. R. E. Liesegang found that copper tungstate is not sensitive to light. For the luminescence in X-rays, *vide infra*, calcium tungstate. E. F. Anthon reported that the precipitated salt before ignition is insoluble in water, but after continued washing, it is peptized, and passes through the filter-paper rendering the filtrate turbid. Copper tungstate dissolves in phosphoric acid and acetic acids, and in aq. ammonia, but it is insoluble in oxalic acid. H. Schiff found that the soln. of copper tungstate in aq. ammonia is a corrosive liquid, which, when slowly evaporated, forms a dirty blue, crystalline crust of **copper diammino-tungstate,** $CuWO_4.2NH_3.H_2O$. Alcohol added to the ammoniacal soln. precipitates the salt as an amorphous powder. When dried over sulphuric acid, the salt loses its water without changing its form. S. H. C. Briggs prepared **copper tetrammino-tungstate,** $CuWO_4.4NH_3$, by precipitating a hot soln. of 7·5 grms. of copper sulphate with 10 grms. of dihydrated sodium tungstate, washing the precipitate by decantation, and dissolving it in 20 c.c. of cold, conc., aq. ammonia. A similar soln. was obtained by treating 13 grms. of dihydrated sodium tungstate with nitric acid, dissolving the washed tungstic acid in 20 c.c. of conc., aq. ammonia and adding it to an ammoniacal soln. of copper sulphate. Either of these soln. is filtered into a bottle, and a layer of alcohol allowed to diffuse slowly into the ammoniacal soln. during several weeks while the bottle is tightly closed. This prevents the escape of ammonia and avoids the formation of paratungstate. Blue crystals of the tetrammine slowly deposit. The blue crystals give off ammonia at ordinary temp. ; they dissolve in a small proportion of water ; and are easily dissolved by dil. aq. ammonia. No *ammonium copper tungstate* is formed however large an excess of ammonium tungstate is employed.

F. Wöhler and F. Rautenberg reported **silver subtungstate,** $Ag_4O.2WO_3$, to be formed by a method similar to that employed for silver submolybdate (*q.v.*); but W. Muthmann showed that in all probability the subtungstate is a mixture of silver and normal **silver tungstate,** Ag_2WO_4. E. Zettnow, and E. F. Smith and R. H. Bradbury prepared the normal salt by treating a soln. of the normal sodium salt with silver nitrate. The white precipitate soon becomes yellow. It can be washed without peptization. It should be prepared in darkness, and dried at 110° to 120°. It is not hygroscopic. It melts below redness to form a dark red liquid, which crystallizes on cooling. The salt is very sparingly soluble in water; and it is decomposed by nitric acid, and by a hot soln. of sodium chloride. The salt is decomposed by heat and is not a suitable form in which to precipitate tungstates for analytical work. A soln. of the normal salt in aq. ammonia, when evaporated over a mixture of quicklime and ammonium chloride, was found by O. Widman to furnish tabular crystals of **silver tetramminotungstate,** $Ag_2WO_4.4NH_3$. It is also obtained as a white powder by the action of ammonia gas on silver tungstate. When the tetrammine is heated over 60°, all the ammonia is expelled. The aq. soln. decomposes rapidly. P. Ray and J. Dasgupta prepared a complex with hexamethylenetetramine.

Normal **calcium tungstate,** $CaWO_4$, is represented by the mineral **scheelite**; and this played an important part in the history of our knowledge of tungsten. The observations of C. W. Scheele,[5] J. G. Wallerius, A. G. Werner, C. von Linnæus, A. Cronstedt, D. L. G. Karsten, R. J. Haüy, A. Breithaupt, and C. C. Leonhard have been previously described; the review of the occurrence of tungsten includes that of scheelite. For **powellite,** $Ca(W,Mo)O_4$, *vide* calcium molybdate. According to F. de Carli, when a mixture of tungsten trioxide and calcium oxide is heated, evidence of a thermal effect appears at 245°; and D. Balareff said that the maximum rise of temp. occurs at 750°. W. Jander said that the reaction with calcium carbonate begins at 600°. According to G. Tammann, the formation of calcium tungstate proceeds actively between 580° and 950°. When calcium carbonate is heated with tungsten trioxide, carbon dioxide comes off at temp. over 510°. E. F. Anthon, and J. Lefort obtained calcium tungstate as a precipitate by mixing soln. of normal potassium or sodium tungstate with a feebly acidified soln. of calcium chloride. A. de Schulten heated in a water-bath soln. of 10 grms. of anhydrous calcium chloride in 3 litres of water and 1 c.c. of conc. hydrochloric acid, and gradually added, drop by drop, a soln. of 3 grms. of ordinary sodium tungstate. Crystals of calcium tungstate gradually collect on the bottom of the vessel. The crystals are larger if more acid is used, but they are then coloured yellow. L. Weiss added a soln. of calcium chloride to an ammoniacal soln. of tungstic acid, almost neutralized with acid, so long as precipitation occurred; the liquid was then feebly acidified and the precipitated calcium tungstate washed and dried. E. Kunau used a similar process. N. S. Manross prepared the salt by melting a mixture of sodium tungstate and calcium chloride at a red-heat, and extracting the cold product with water. L. Michel found that if an excess of sodium chloride is also used with the mixture, larger crystals are obtained. H. Debray obtained crystals of scheelite by heating a mixture of amorphous calcium tungstate and quicklime in a current of hydrogen chloride; and A. Cossa imitated the crystals of the scheelite of Traversella by heating under sodium chloride a mixture of amorphous calcium tungstate and a little didymium salt. H. Traube obtained the crystals as a sublimate by heating to a high temp. a mixture of the tungstate with sodium and potassium chlorides. F. Zambonini found that the processes of A. Macé, and A. Drevermann, used for the synthesis of anglesite—7. 47, 30—give the best results in preparing crystals of scheelite. For the preparation of phosphorescent calcium tungstate, *vide infra.* Analyses were reported by A. Carnot, N. S. Manross, J. Lefort, A. Roemer, M. H. Klaproth, R. Brandes and C. F. Bucholz, B. Setlik, C. F. Rammelsberg, F. A. Bernoulli, G. T. Bowen, F. A. Genth, I. Domeyko, A. Delesse, M. Choubine, J. J. Berzelius, D. Lovisato, C. G. Hoffmann, L. Colomba, S. Traverso, C. Schmidt, W. Florence, J. Block, A. Lacroix, A. M. Findlayson, J. Eyerman, B. K. Almström, and G. Carobbi. Copper, manganese, iron, and tin oxides may be present, as well as some chlorine and fluorine. According to H. Traube, molybdenum is usually present in scheelite, and it replaces part of the tungsten. In the specimens he examined, up to 8·23 per cent. MoO_3 was observed. The amount varies with crystals from the same localities. The white and yellow varieties contained least, and the dark coloured varieties most. The proportion of molybdenum probably affects the angles of the crystals. L. G. Igelström also reported the presence of molybdenum in scheelite; A. Carnot found about 0·4 per cent. of tantalic oxide in scheelite from Meymac, Correze; and A. Cossa found didymium, cerium, and lanthanum oxides; the spectra showed strong absorption bands of these oxides; and C. de Rohden found the presence of samarium, erbium, terbium, europium, neodymium, and praseodymium salts in scheelite. G. T. Lindroth found copper, molybdenum, and bismuth; G. Carobbi, molybdenum, tantalum, columbium, and the rare earths. Precipitated calcium tungstate is an amorphous white powder; scheelite occurs in white, yellowish-white, pale yellow, brownish-yellow, greenish-yellow, reddish-yellow or orange-yellow granular masses, in reniform masses with a columnar structure, or in tetragonal, bipyramidal crystals which, according to H. Dauber, have the axial ratio $a:c=1:1·5356$; H. Traube gave 1 : 1·5315; H. Dauber, 1 : 1·5329 to 1·5355; G. vom Rath, 1 : 1·5364; V. R. von Zepharovich, 1 : 1·5349; L. Colomba, 1 : 1·53798; and F. Zambonini, 1 : 1·5300. There may be pyramidal hemihedrism. The habit may be octahedral or tabular. There may be contact and penetration twinning about the (100)-plane. The (001)-faces may be rough, and the (101)-faces striated. The faces of the twins may show feather-like striations meeting in a median line. The (111)-cleavage is most distinct; the (101)-cleavage is interrupted. E. Hugi studied the corrosion figures. The crystals were described by F. A. Genth, M. Bauer, H. Traube, C. F. Rammelsberg, C. Schmidt, G. Flink, L. Colomba, J. Block, C. Anderson, A. Serra, S. Koch, T. Hiortdahl, A. Russell, A. Roemer, A. de Schulten, E. Hugi, P. Berberich, etc. J. W. Retgers discussed the isomorphism of the alkaline earth molybdates, tungstates, sulphates, selenates, and chromates. R. G. Dickinson found that the X-radiogram corresponds with a face-centred lattice with the atoms so located as to give a diamond arrangement. The arrangement of the atoms is the same as in the case of lead molybdate (*q.v.*) with calcium in place of lead, and tungsten in place of molybdenum—Fig. 23, **11**. 61, 11. The calculated sp. gr. is 6·06, and the edge of the unit cell of 8 mols. is $a=22·80$ A. F. M. Jäger and H. Haga made some observations on the X-radiograms, and attributed the high degree of symmetry to twinning. L. Vegard gave for the lattice dimensions of scheelite, which is of the rutile type, $a=7·44$ A., and $c=11·35$ A., and for the ionic diameter 1·125 A. M. L. Huggins made some observations of the structure of the crystals. E. Tiede and A. Schleede also studied the X-radiogram. T. Barth said that the unit tetragonal cell contains four mols. of $CaWO_4$ and has $a=5·26$ A., $c=11·41$ A., and $a:c=1:2·17$; on the other hand, L. Vegard inferred that the unit cell has 8 mols. $CaWO_4$, $a=7·44$ A., $c=11·35$ A., and $a:c=1:1·537$; L. Vegard and A. Refsum gave $a=7·44$ A., $c=11·35$ A.; the radius of the oxygen atom is 1·125 A., of the metal in WO_4, 1·04 A., and of the positive ion, 1·11 A. N. S. Manross gave 6·076 for the sp. gr. of calcium tungstate; A. de Schulten, 5·542 at 15°; C. J. B. Karsten, 6·04; F. A. Bernoulli, 6·02; C. F. Rammelsberg, 6·03; and F. Zambonini, 6·0620. F. A. Henglein discussed the mol. vol. —47·53. H. Traube found that the sp. gr. of the samples of scheelite he examined ranged from 5·88 to 6·12. J. J. Saslawsky calculated a contraction of 0·51 to 0·54 in the formation of scheelite from its elements. The hardness ranges from 4·5 to 5·0. E. Cane gave 0·104 for the sp. ht. M. D. Draper, A. D. Cox, and J. J. Rubber devised methods for estimating the percentage amount of tungsten trioxide in scheelite ores from sp. gr. determinations. M. D. Draper found:

Sp. gr.	3·00	3·50	4·00	4·50	5·00	5·50	6·00
WO_3	15·40	31·20	44·80	56·20	65·40	72·00	78·20

E. Jannetaz found the ratio of the heat conductivities of scheelite a/γ to be 0·9. D. Vorländer and H. Hempel observed no transformation points on the heating curve of calcium tungstate. H. Kopp gave 0·0927 for the sp. ht. between 19° and 58°. G. Tammann gave 39·8 Cals. per mol for the heat of formation from its constituent oxides. A. des Cloizeaux gave for the indices of refraction for red-light, ω=1·918–1·919, and ϵ=1·934–1·935 ; the optical character is positive. F. Zambonini gave for the light of wave-length λ,

λ . .	667	C-line	623	D-line	570	533	E-line	475
ω . .	1·9107	1·9124	1·9159	1·9200	1·9208	1·9273	1·9298	1·9344
ϵ . .	1·9263	1·9281	1·9321	1·9365	1·9375	1·9442	1·9368	1·9525
ϵ—ω . .	0·0156	0·0157	0·0162	0·0165	0·0167	0·0169	0·0170	0·0181

Hence the dispersion increases regularly from the red to the violet ; and it is stronger for the ordinary than for the extraordinary ray. F. Zambonini also examined the optical constants of mixtures of calcium and cerous tungstates, and showed that the two salts furnish isomorphous mixtures. E. F. Anthon said that calcium tungstate is insoluble in water ; but J. Lefort found that 100 parts of water at 15° dissolve 0·2 part of calcium tungstate. E. F. Smith and R. H. Bradbury did not get good results when, for analytical purposes, the tungstates are precipitated in the form of calcium tungstate. E. F. Smith found that scheelite dissolves when it is heated with sulphur monochloride.

G. Ogden prepared calcium tungstate for use as screens which become luminous when exposed to X-rays. The luminescence was discussed by E. Kunau, T. H. Tsao, and F. R. van Horn. W. Arnold found that while the mineral scheelite exhibits a strong blue fluorescence when exposed to X-rays, the freshly-prepared and ignited calcium tungstate is only feebly luminescent, but it is more luminescent if it has been heated in the oxhydrogen flame. A solid soln. of copper tungstate in calcium tungstate is as luminous as scheelite ; manganese tungstate acts like the copper salt. The tungstates of sodium, potassium, strontium, barium, and zinc ; wolframite, ferberite, and the different tungstate-bronzes, are not luminous when exposed to the X-rays. K. Keilhack, F. Dreuschuch, R. J. Strutt, K. Endell, G. F. Kunz and C. Baskerville, P. Schuhknecht, F. E. Swindells, and C. H. Boissevain and W. F. Drea also studied the X-ray luminescence of the alkaline earth tungstates. W. Ducca, and W. Löwinthal studied the action of luminophores—*e.g.* traces of manganese, copper, or bismuth salts—in enhancing the fluorescence of calcium tungstate when exposed to X-rays. The presence of $\frac{1}{12,000}$th part of a bismuth salt gave the best results. The spectrum of the blue fluorescence of calcium tungstate containing a trace of a bismuth, manganese or copper salt shows feeble spectral bands in the blue violet ; and when the tungstate contains a trace of a silver, gold, nickel, cadmium, antimony, or lead salt, the fluorescence is green. Calcium tungstate exhibits no thermoluminescence at room temp. ; but when it is cooled to —192°, exposed to X-rays, and its temp. allowed to rise, it becomes luminescent, the glow is then extinguished, and as the temp. still continues to rise, a second luminescence appears. A small amount—say 0·1 grm.—shows only one thermoluminescence. The luminescence of calcium tungstate in cathode rays resembles that produced by X-rays. J. O. Perrine studied the ultra-violet spectrum excited by X-rays ; F. E. Swindells, and K. Becker and H. Becker-Rose, the fluorescence in the X-rays. W. Jander gave for the electrical conductivities, $11{\cdot}6\times10^{-6}$, $3{\cdot}2\times10^{-6}$, and $1{\cdot}3\times10^{-6}$, respectively at 1157°, 1072°, and 994°.

A. Radiguet used scheelite in making fluorescent screens for X-rays ; and M. G. Bogoslovsky and co-workers recommended adding 0·01 to 0·5 per cent. of tin oxide to calcium tungstate used for fluorescent screens ; and A. Schleede and T. H. Tsao showed that when commercial tungstic acid or ammonium tungstate is purified by alternate treatment with conc. hydrochloric acid, or aqua regia, and soda-lye or aq. ammonia, and then converted into calcium tungstate by treatment with calcium chloride and ignition at 1000°, the X-ray fluorescence is about equal to that of the best technical specimens, whilst phosphorescence is sometimes present, sometimes absent. The latter property is inhibited by addition of calcium molybdate, but the fluorescence is sensibly diminished. Similar preparations are obtained from ammonium tungstate and calcium chloride in very dil. soln. Calcium tungstate, prepared from repeatedly crystallized sodium tungstate and calcium chloride, still exhibited phosphorescence, but a non-phosphorescent material resulted when recrystallized ammonium tungstate was used as initial material. The residues obtained from the mother-liquors from the ammonium tungstate contained arsenic and molybdenum. The addition of ammonium arsenate to ammonium tungstate, previous to precipitation with calcium chloride, leads to preparations with good fluorescence but marked phosphorescence ; similar results are induced by ammonium antimonate. Ammonium molybdate does not induce phosphorescence. H. Hirschi, and K. Endell observed the luminescence of scheelite when the mineral is exposed to radium rays ; and A. Pochettino, when it is exposed to cathode rays. F. C. Henrici and J. F. L. Hausmann, and T. A. L. du Moncel said that scheelite is a conductor, and E. Wartmann, and F. Beijerinck, that it is a non-conductor of electricity. E. E. Fairbanks gave 7·7 (water 81) for the dielectric constant of scheelite ; and H. Saegusa studied this subject.

E. F. Anthon obtained normal **strontium tungstate,** $SrWO_4$, by mixing soln. of a strontium salt with normal potassium or sodium tungstate ; or by boiling freshly-precipitated strontium carbonate with tungstic acid and water. J. Lefort used soln. of strontium acetate and normal sodium tungstate. H. Schultze, and E. Zettnow prepared the crystals of the salt by melting mixtures of sodium tungstate, strontium chloride, and sodium chloride. L. Michel recommended an excess of the flux—sodium chloride. G. Tammann observed that when strontium carbonate is heated with tungsten trioxide, carbon dioxide is expelled, and strontium tungstate is formed. Strontium tungstate appears as a white, amorphous powder ; and A. Cossa described the crystals as tetragonal bipyramids with the axial ratio $a : c = 1 : 1·5582$. E. K. Broch calculated from the X-radiogram the space-lattice with $a = 5·405$ A., $c = 11·90$ A., $a : c = 1 : 2·202$; and density, 6·372. F. Zambonini gave 6·184 for the sp. gr. F. A. Henglein gave 54·27 for the mol. vol. When the voluminous powder is heated to redness, it becomes incandescent, and is afterwards compact. It remains white after being heated to redness. G. Tammann gave 56·4 Cals. for the heat of formation per mol. W. Jander gave for the electrical conductivities 107×10^{-6}, $62·5 \times 10^{-6}$, and $5·8 \times 10^{-6}$ respectively at 1040°, 900°, and 733°. E. F. Anthon said that strontium tungstate is insoluble in water, but J. Lefort found that 100 parts of water at 15° dissolve 0·14 part. E. F. Anthon found that strontium tungstate is soluble in a boiling soln. of oxalic acid, and, on cooling, the liquid becomes turbid. E. F. Smith and R. H. Bradbury found that the salt is easily decomposed when heated and is not therefore a suitable form in which to precipitate tungsten for analysis.

F. de Carli found that a mixture of barium and tungsten oxides when heated shows a thermal effect at 190° ; and G. Tammann observed that the two oxides unite to form **barium tungstate,** $BaWO_4$, between 300° and 550°. The subject was discussed by W. Jander. J. A. Hedvall and N. von Zweigbergk found that with a mixture of barium dioxide and tungsten trioxide, oxygen begins to come off at 250° ; and the greatest reaction velocity in forming tungstate is between 450° and 525°. The subject was studied by W. Jander, who found that the reaction with barium carbonate begins at 300°. E. F. Anthon, and A. Cossa obtained the salt by mixing soln. of a barium salt and of normal potassium or sodium tungstate, or by boiling barium carbonate with water and tungstic acid. J. Lefort obtained this tungstate by mixing aq. soln. of barium acetate and normal sodium tungstate, the washed product is heated to drive off the combined water. A. Geuther and E. Forsberg, and E. Zettnow obtained crystals of the salt by melting a mixture of normal sodium tungstate, barium chloride, and sodium chloride, slowly cooling the liquid, and washing out the soluble matters with water. L. Michel recommended using an excess of sodium chloride as a flux. A. Cossa found that the white, tetragonal, bipyramidal crystals have the axial ratio $a:c=1:1·6046$. I. I. Navano and J. Palacios' X-radiograms of this salt indicated the existence of 4 mols. in the elementary parallelopipedal cell. L. Vegard and A. Refsum gave $a=7·908$ A., $c=12·689$ A., $a:c=1:1·605$; the radius of the oxygen atom is 1·24; of the metal in WO_4, 1·03; and of the positive ion, 1·21 A. F. Zambonini gave 6·35 for the sp. gr., and F. W. Clarke and J. L. Davis, 5·0422 at 15°. F. A. Henglein gave 60·69 for the mol. vol. E. Zettnow found that the salt fuses with difficulty, and becomes incandescent at a red-heat. G. Tammann gave 73·5 Cals. for the heat of formation per mol.; J. A. Hevdall and N. von Zweigbergk gave 80 Cals. For the luminescence when exposed to X-rays, *vide supra*, calcium tungstate. W. Jander obtained for the electrical conductivity, $36·6\times10^{-6}$, $6·9\times10^{-6}$, and $1·8\times10^{-6}$ respectively at 1123°, 994°, and 815°. The salt is not changed by exposure to air, and J. Lefort found it to be sparingly soluble in water. E. F. Smith and R. H. Bradbury said that it is more soluble in ammonium nitrate soln. than it is in water; and that the salt is a suitable form in which to precipitate tungsten for analysis. E. Zettnow said that the salt is decomposed by fusion with sodium carbonate, and A. Geuther and E. Forsberg, by boiling it with nitric acid. C. Scheibler reported octahedral crystals of the *hemihydrate*, $BaWO_4.\frac{1}{2}H_2O$, to be formed when the mother-liquor obtained in the preparation of sodium barium tungstate is treated with baryta-water, and the precipitate filtered and washed; it is also formed by treating a soln. of barium metatungstate, or of metatungstic acid with baryta-water. E. Péchard reported the *dihydrate*, $BaWO_4.2H_2O$, to be formed by the action of an eq. of metatungstic acid on baryta water; he also obtained a *tetrahydrate*, $BaWO_4.4H_2O$, in a similar manner. E. Zettnow obtained a *hemipentahydrate*, $BaWO_4.2\frac{1}{2}H_2O$, by adding barium chloride to a soln. obtained by boiling sodium dodecatungstate with acetic acid and hydrochloric acid as long as precipitation occurs. The amorphous, voluminous precipitate is washed by decantation, and dried at 30° to 40°. L. Kahlenberg and W. J. Trautmann found that silicon reacts with difficulty with barium tungstate, yielding a slag and a few small globules of what is probably a silicide.

C. Scheibler reported a **beryllium tungstate** to be formed by crystallization from a syrupy soln. G. Tammann observed no singular point on the heating curve obtained from a mixture of beryllium oxide and tungsten trioxide. F. de Carli obtained no singular point on the heating curve of mixtures of magnesia and tungsten trioxide, but G. Tammann observed that **magnesium tungstate,** $MgWO_4$, is formed between 300° and 600°, and this is shown by a hump on the heating curve. A. Geuther and E. Forsberg obtained the anhydrous salt by a mixture of sodium tungstate, magnesium chloride, and sodium chloride. L. Michel recommended an excess of sodium chloride. The crystals were also prepared by N. S. Manross, and V. M. Goldschmidt. Octahedral and columnar crystals can be isolated by washing the product. The crystals were examined by F. Machatschky, and V. M. Goldschmidt. The monoclinic prisms have the axial ratios $a:b:c=0·8263:1:0·8703$, and $\beta=89°\ 40'$. From the X-radiograms, E. K. Broch found $a:b:c=4·67:5·66:4·92$, and $\beta=89°\ 35'$, or $a:b:c=0·828:1:0·871$—F. Machatschky gave $0·8263:1:0·8703$, and $\beta=89°\ 40'$. The monoclinic crystals have two $MgWO_4$ mols. per unit cell, and the sp. gr. is 5·66. The crystals are decomposed when heated with nitric acid. F. Ullik said that the salt does not melt at a bright red-heat. G. Tammann gave 3·4 Cals. for the heat of formation per mol from its constituent oxides. W. Jander obtained about $0·02\times10^{-6}$ for the electrical conductivity of the salt at 800°; and he obtained values for the diffusion coeff. J. Lefort reported a *trihydrate*, $MgWO_4.3H_2O$, to be formed by mixing soln. of normal sodium tungstate and magnesium acetate in eq. proportions in the presence of alcohol. The white, amorphous powder remains white when gradually heated; it is very soluble in water, and almost insoluble in alcohol. The aq. soln. forms a syrup when evaporated, but does not crystallize. F. Ullik obtained a *heptahydrate*, $MgWO_4.7H_2O$, by boiling tungstic acid and magnesium carbonate suspended in water. The clear, filtered soln. on cooling deposits lustrous prisms which dissolve a little in cold water, but freely in hot water. They lose water when heated. F. Rodolico obtained a complex $MgWO_4.X.10H_2O$ with hexamethylenetetramine. According to F. Ullik, if a conc. aq. soln. of the heptahydrate be mixed with a soln. of potassium tungstate, a white precipitate of **potassium magnesium tungstate** of variable composition is formed. If a soln. of eq. proportions of the two salts be evaporated, the product also has a variable composition, although on one occasion the composition approximated $K_2WO_4.MgWO_4.2H_2O$.

A. Geuther and E. Forsberg melted a mixture of sodium tungstate, zinc chloride, and sodium chloride, and leached the product with boiling water; there remained colourless crystals of **zinc tungstate,** $ZnWO_4$, considered to be isomorphous with calcium tungstate. E. Zettnow, and L. Michel also prepared the salt and supposed it to furnish rhombic crystals. E. K. Broch observed that the crystals are monoclinic like those of the magnesium salt. L. A. Hallopeau also obtained this salt by heating a mixture of sodium paratungstate and powdered zinc, and washing the cold product with water. E. K. Broch found that the X-radiograms corresponded with a space-lattice having $a=4·68$ A., $b=5·73$ A., $c=4·95$, and $\beta=89° 30'$, with the axial ratios $a:b:c=0·817:1:0·864$, and the calculated density 7·79. For the luminescence of zinc tungstate, *vide supra,* calcium tungstate. J. Lefort found that the *hydrate,* $ZnWO_4.H_2O$, is formed by double decomposition as in the case of calcium tungstate, and he added that the product is slightly soluble in water. W. Jander obtained $8·5\times10^{-6}$ for the electrical conductivity at 1000°, and $1·1\times10^{-6}$ at 850°; and he also calculated values for the diffusion coeff. S. H. C. Briggs obtained **zinc tetramminotungstate,** $ZnWO_4.4NH_3.3H_2O$, as in the case of the copper salt, by allowing a mixture of an ammoniacal soln. of zinc and ammonium tungstates gradually to diffuse into alcohol. The tetrahedral crystals gradually give off ammonia at ordinary temp. F. de Carli found that when a mixture of cadmium oxide and tungsten trioxide is heated, evidence of combination occurs at 250°; and W. Jander studied the action of solid cadmium and magnesium oxides on solid zinc tungstate, $MgO+ZnWO_4=ZnO+MgWO_4$, etc. A. Geuther and E. Forsberg, and L. Michel obtained **cadmium tungstate,** $CdWO_4$, by the method employed for the zinc salt. E. Zettnow also obtained the salt by a similar process, and described the product as a canary-yellow powder consisting of rhombic octahedra. E. F. Anthon obtained the *dihydrate,* $CdWO_4.2H_2O$, as a white powder, by treating a soln. of a cadmium salt with sodium or potassium tungstate. It loses its water when heated, and it is soluble in phosphoric, and oxalic acids, and in aq. ammonia, but not in water. E. F. Smith and R. H. Bradbury said that after the tungstate has been heated it is not soluble in acids; and they found the salt a suitable form in which to precipitate tungstates for the quantitative determination of tungsten. W. Jander obtained for the electrical conductivity of the cadmium salt 202×10^{-6}, $64·5\times10^{-6}$, and $2·8\times10^{-6}$ respectively at 1043°, 942°, and 761°. W. Jander studied the reaction: $MgO+CdWO_4=CdO+MgWO_4$. J. R. Partington discussed the fluorescence and phosphorescence of the salt. W. Jander studied the action of magnesium oxide on solid cadmium tungstate.

E. F. Anthon obtained **mercurous tungstate,** Hg_2WO_4, as a yellow precipitate by mixing a soln. of mercurous nitrate and sodium tungstate. When dried, it is dark yellow, and after calcination, tungsten trioxide remains. J. J. Berzelius examined the salt as a means of quantitatively determining tungsten. E. F. Anthon added that the yellow salt appears at first tasteless, but after a time it has a weak, metallic taste. J. Lefort found that **mercuric tungstate,** $HgWO_4$, is precipitated by adding a neutral soln. of mercuric acetate to a sat. soln. of sodium tungstate. The straw-yellow product becomes lemon-yellow when dried. It is not very stable, and is decomposed when washed for a long time with water; it is sparingly soluble in water. E. F. Anthon found that if ammonium ditungstate and neutral mercuric nitrate soln. be mixed, a white precipitate approximating **ammonium mercuric tungstate,** $(NH_4)_2WO_4.HgWO_4.H_2O$, is formed. It can be dried at 100°, but at

200°–250° it gives off water and ammonia, leaving a mixture of mercuric and tungsten oxides. It is insoluble in water, and is decomposed by alkali-lye, and acids.

The *borotungstates* were discussed in connection with the borates—**5.** 32, 15. G. Tammann [6] observed that when a mixture of alumina and tungsten trioxide is heated, no evidence of the formation of a compound is shown on the heating curve; but F. A. Bernoulli heated a mixture of a mol of alumina with 3 mols of tungsten trioxide in a porcelain oven for 18 hrs. and obtained a crystalline mass, presumably **aluminium tungstate,** $Al_2O_3.3WO_3$, or $Al_2(WO_4)_3$. E. F. Anthon obtained a precipitate of the hydrate by adding sodium tungstate to a soln. of an aluminium salt. W. Lotz found that the precipitate is insoluble in water, and in a soln. of sodium tungstate, but it is soluble in aq. ammonia, and in soln. of alum, sodium hydroxide, and phosphoric and oxalic acids. J. Lefort said that when a soln. of alum is poured into a soln. of normal sodium tungstate, the *octohydrate*, $Al_2(WO_4)_3.8H_2O$, is precipitated as a white, voluminous mass. 100 parts of water at 15° dissolve 0·0667 part of the octohydrate. Complex aluminophosphatotungstates, aluminoarsenatotungstates, and aluminoantimonatotungstates have been prepared; and also complex **aluminotungstates.** Thus, by boiling a mixture of aluminium hydroxide and a soln. of ammonium paratungstate, C. W. Balke and E. F. Smith obtained **ammonium aluminotungstate,** $3(NH_4)_2O.Al_2O_3.9WO_3.4H_2O$, as a dense, highly refractive syrup, which, on drying, leaves a translucent mass. The dry, powdered salt dissolved in conc. nitric acid; precipitation did not occur, even upon boiling. The salt was soluble also in conc. hydrochloric acid without the production, in the cold, of a precipitate, but when the soln. was vigorously boiled a yellow-coloured precipitate separated. Mercurous nitrate produced, in its aq. soln., a yellowish-white-coloured precipitate. The precipitate caused by barium chloride was almost insoluble in hot water. After drying, acids failed to dissolve it. In a slightly ammoniacal soln. of the salt, silver nitrate produced a yellowish-white precipitate, soluble in a large vol. of hot water. L. C. Daniels prepared **copper aluminotungstate,** $2CuO.Al_2O_3.9WO_3.16\frac{1}{2}H_2O$, by adding a conc. soln. of ammonium aluminotungstate to a 10 per cent. soln. of copper sulphate; or to an ammoniacal soln. of cupric hydroxide. C. W. Balke and E. F. Smith added silver nitrate to an ammoniacal soln. of ammonium aluminotungstate, and obtained a yellowish-white precipitate of **ammonium silver aluminotungstate,** $11Ag_2O.21(NH_4)_2O.4Al_2O_3.36WO_3$. The precipitate obtained by adding barium chloride to a soln. of ammonium aluminotungstate was found by L. C. Daniels to be **barium aluminotungstate,** $8BaO.Al_2O_3.9WO_3.7H_2O$; while a soln. of zinc oxide in aq. ammonia gives a white precipitate of **zinc aluminotungstate,** $ZnO.Al_2O_3.9WO_3.20H_2O$; and with mercurous nitrate, a pale yellow flocculent precipitate of **mercurous aluminotungstate,** $5Hg_2O.Al_2O_3.9WO_3$, was formed. A. Rogers and E. F. Smith treated a soln. of ammonium aluminotungstate with mercurous nitrate and obtained a yellowish-white precipitate supposed to be an **ammonium mercurous aluminotungstate.**

C. Renz [7] obtained **indium tungstate,** $In_2(WO_4)_3.8H_2O$, by adding a soln. of sodium tungstate to one of an indium salt. The white precipitate dries to a horny mass. H. Flemming obtained **thallous tungstate,** Tl_2WO_4, by mixing soln. of normal sodium tungstate and a thallous salt; or by boiling tungstic acid and thallous carbonate. The precipitate consists of microscopic, highly refracting, six-sided plates. P. S. Oettinger added that the precipitate is insoluble in water, sparingly soluble in aq. ammonia, but is soluble in hot soln. of alkali hydroxide or carbonate. E. Schaefer could not prepare normal thallous tungstate; **thallic tungstate** has not been reported.

G. Tammann [8] observed evidence of the formation of **cerous tungstate,** $Ce_2(WO_4)_3$, when a mixture of ceric oxide and tungsten trioxide is heated. The heating curve shows that an endothermic reaction occurs between 240° and 600°. According to A. Cossa and M. Zecchini, when a soln. of cerous sulphate is poured into one of sodium tungstate, an amorphous, pale yellow precipitate of cerous tungstate is formed. After heating to redness, the amorphous precipitate becomes crystalline. F. R. M. Hitchcock found that a soln. of sodium tungstate gives a precipitate with soln. of cerium salts, the precipitation is not complete, and the addition of alcohol precipitates other cerium salts along with the cerium tungstate in soln.

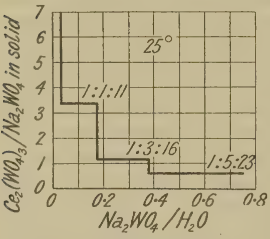

Fig. 41.—Equilibrium in the System : $Ce_2(WO_4)_3$–Na_2WO_4–H_2O.

P. Didier found that if ceric oxide be added in small portions at a time to fused sodium paratungstate, kept in excess, minute, yellow octahedra of normal cerous tungstate, resembling the crystals of scheelite, are formed. Larger crystals are produced by fusing precipitated cerous tungstate with sodium chloride out of contact with air. H. Traube obtained crystals of cerium tungstate as a sublimate by heating to a high temp. a mixture of the tungstate with sodium and potassium chlorides. F. Zambonini gave for the axial ratio of the crystals $a : c = 1 : 1{\cdot}5257$, and he examined the optical constants of isomorphous mixtures with cerous tungstate. F. Zambonini found the sp. gr. of $Ce_2(WO_4)_3$ to be 6·77 at 16·5°, and the mol. vol. 151·3. A. Cossa and M. Zecchini gave for the sp. gr. 6·514 at 12°; and for the sp. ht., 0·0821. F. Zambonini gave 1089° for the m.p. A. Rogers and E. F. Smith prepared **ammonium cerous tungstate,** $2(NH_4)_2O.Ce_2O_3.16WO_3.2H_2O$, as a red, transparent glass, insoluble in water, by boiling cerium hydroxide for 8 hrs. with a soln. of ammonium paratungstate, filtering the mixture, and evaporating it to dryness. By dissolving cerium oxide and tungsten trioxide in a fused mixture of sodium tungstate and chloride, A. J. Högbom obtained crystals of **sodium cerous tungstate,** $Na_8Ce_2(WO_4)_7$. P. Didier also obtained a complex tungstate, $Na_2Ce_2(WO_4)_4$, in sulphur-yellow, octahedral crystals, by dissolving precipitated cerous tungstate in normal sodium tungstate. G. Carobbi and G. Tancredi found that three crystalline compounds can exist in the system $Ce_2(WO_4)_3$–Na_2WO_4–H_2O, at 25°. The results are summarized in Fig. 41. These are $Ce_2(WO_4)_3.Na_2WO_4.11H_2O$; $Ce_2(WO_4)_3.3Na_2WO_4.16H_2O$; and $Ce_2(WO_4)_3.5Na_2WO_4.23H_2O$. They are stable in air; and since the velocity curve of the dehydration of the salts over sulphuric acid, or calcium chloride shows breaks, other hydrates probably exist. Thus with sulphuric acid of sp. gr. 1·58, at 25°, for the 1 : 1 : 11-salt:

Time . .	1·25	4·25	8·33	23·0	38·0	113·7	756·7	4000 min.
Loss . .	3·83	4·92	5·78	6·80	7·09	7·96	8·39	8·39 per cent.

with the 1 : 3 : 16-salt:

Time . .	1·25	4·25	8·33	23·0	66·0	139·7	782·7	3991 min.
Loss . .	3·13	5·22	5·95	7·30	7·86	9·71	9·99	9·99 per cent.

and with the 1 : 5 : 23-salt:

Time . .	1·25	4·92	8·33	23·0	66·0	139·8	783·0	3991 min.
Loss . .	3·49	5·06	5·93	7·07	7·77	8·46	9·95	9·95 per cent.

According to F. R. M. Hitchcock, a soln. of sodium tungstate added to one of lanthanum chloride, in the presence of alcohol, gives a precipitate, presumably **lanthanum tungstate,** which, on drying has a delicate blue colour. H. Traube obtained crystals as a sublimate by the method indicated in connection with cerium tungstate. A. Rogers and E. F. Smith prepared **ammonium lanthanum tungstate,** $2(NH_4)_2O.La_2O_3.16WO_3.16H_2O$, as in the case of the corresponding cerium salt. It is white, and insoluble. A. J. Högbom dissolved lanthanum oxide and tungsten trioxide in a fused mixture of sodium chloride and an excess of sodium tungstate, and obtained crystals of **sodium lanthanum tungstate,** $Na_8La_2(WO_4)_7$; if the sodium chloride be in excess, crystals of $Na_6La_4(WO_4)_9$ are formed. A. Rogers and

E. F. Smith observed that when a dil. soln. of ammonium lanthanum tungstate is treated with silver nitrate, white, insoluble **silver lanthanum tungstate,** $5Ag_2O.La_2O_3.16WO_3.4H_2O$, is formed; and with barium chloride, white and insoluble **barium lanthanum tungstate,** $5BaO.La_2O_3.16WO_3.16H_2O$, is produced. F. R. M. Hitchcock prepared **præseodymium tungstate** as a greenish-yellow gelatinous precipitate on treating a soln. of sodium tungstate with a soln. of præseodymium chloride; and **neodymium tungstate** was obtained in a similar way as a pale rose-coloured precipitate which becomes violet after ignition. A. Rogers and E. F. Smith prepared **ammonium præseodymium tungstate,** $2(NH_4)_2O.Pr_2O_3.16WO_3.16H_2O$, as in the case of the corresponding cerium salt. It appears as a green, transparent, gummy mass which is sparingly soluble in water. A pink-coloured salt, $3(NH_4)_2O.Nd_2O_3.16WO_3.20H_2O$, was obtained in a similar way. By treating the ammonium salt with silver nitrate, greenish-white **silver præseodymium tungstate,** $4Ag_2O.Pr_2O_3.16WO_3.8H_2O$, was prepared; and with barium chloride, white **barium præseodymium tungstate,** $4BaO.Pr_2O_3.16WO_3.7H_2O$, as well as $6BaO.Pr_2O_3.16WO_3.9H_2O$, were obtained. Pink and insoluble **barium neodymium tungstate,** $6BaO.Nd_2O_3.16WO_3.17H_2O$, was also prepared by adding barium chloride to a soln. of the ammonium salt. H. Traube obtained crystals of **didymium tungstate,** $Di_2(WO_4)_3$, as a sublimate as in the case of cerium tungstate. The salt was prepared by A. Cossa, who gave 6·69 for the sp. gr. at 14°. A. J. Högbom also reported **sodium didymium tungstate,** $Na_6Di_4(WO_4)_9$, by dissolving the oxide in a fused mixture of sodium tungstate and chloride with the tungstate in excess—if the chloride is in excess, $Na_2O.Di_2O_3.4WO_3$ is formed. When barium metatungstate is treated with the theoretical quantity of samarium sulphate, and the soln. evaporated over conc. sulphuric acid, topaz-yellow crystals of **samarium tungstate,** $Sa_2O_3.12WO_3.35H_2O$, were formed—*vide infra*, the metatungstates; they become opaque when exposed to light. The sp. gr. is 3·992 to 3·996 at 18·4°. The salt is not deliquescent, and is freely soluble in water. A. J. Högbom prepared **sodium samarium tungstate,** $Na_6Sa_4(WO_4)_9$, from a soln. of samarium oxide in a fused mixture of sodium tungstate and an excess of sodium chloride; similarly with **sodium gadolinium tungstate,** $Na_6Gd_4(WO_4)_9$, using an excess of sodium tungstate; with **sodium erbium tungstate,** $Na_6Er_4(WO_4)_9$, using an excess of sodium chloride; and with **sodium yttrium tungstate,** $Na_8Y_2(WO_4)_7$, using an excess of sodium tungstate. By treating barium metatungstate with ytterbium sulphate, and concentrating the soln., A. Cleve obtained **ytterbium tungstate,** $Yb_2O_3.12WO_4.35H_2O$, in prismatic crystals, not deliquescent, stable in air, and freely soluble in water; and by fusing a mixture of ytterbium oxide and sodium tungstate and chloride, extracting the mass with water, the residue contains a pale reddish-grey, microcrystalline powder of **ytterbium oxytungstate,** $Yb_2O_3.WO_3$, or $(YbO)_2WO_4$; and colourless, acicular crystals of **sodium ytterbium tungstate,** $4Na_2O.2Yb_2O_3.7WO_3$, which can be separated by evaporation. If fused with sodium chloride as flux, microscopic needles of insoluble $9Na_2O.Yb_2O_3.12WO_3$ appear to be formed.

The **silicotungstates** were discussed in connection with the silicates—**6**. 40, 50; and the *titanium tungstates* have not been investigated. O. Kulka[9] reported that if a soln. of zirconium nitrate be poured into a cold soln. of ammonium metatungstate, and the gelatinous precipitate be washed by suction with hot water, and dried, the product has the composition **zirconium tungstate,** $5ZrO_2.9WO_3.33H_2O$; if sodium paratungstate be employed, the dried precipitate has the composition $5ZrO_2.7WO_3.21H_2O$. Both products are insoluble in water; the first is insoluble and the second is soluble in hydrochloric acid. Both may be mixtures. L. A. Hallopeau reported **ammonium zirconium tungstate,** $3(NH_4)_2O.ZrO_2.10WO_3.14H_2O$, to be formed by crystallization in vacuo from a syrupy soln. of zirconium hydroxide in ammonium paratungstate. The small prismatic crystals act strongly on polarized light and show parallel extinction. They lose water even in contact with the mother-liquor. The salt is freely soluble in water, and is very deliquescent. O. Kulka said that soln. of normal sodium tungstate, and of sodium or ammonium metatungstate, do not dissolve zirconium hydroxide. O. Kulka reported **potassium zirconium tungstate,** $K_2O.ZrO_2.2WO_3.33H_2O$, to be formed by boiling a soln. of potassium paratungstate with zirconium hydroxide, after separating the excess of paratungstate. He represented the constitution $KO.WO_2.O.ZrO.O.WO_2.OK$. L. A. Hallopeau found that a boiling soln. of potassium paratungstate dissolves zirconium hydroxide, and the soln. deposits small crystals of the composition $4K_2O.ZrO_2.10WO_3.15H_2O$, and which act feebly on polarized light. When the mother-liquor is concentrated in vacuo, it furnishes small prismatic crystals of the composition $4K_2O.2ZrO_2.10WO_3.20H_2O$, which act strongly on polarized light, and show extinction at 30° from the axis of elongation. Both these compounds are almost insoluble in cold water, are converted into insoluble compounds when heated, and yield a mixture of tungstate and zirconate when fused with alkali carbonates. In general properties, they resemble the silicotungstates; the zirconodecatungstate is analogous in composition to the silicodecatungstate, except that it contains a somewhat smaller proportion of water. According to J. J. Berzelius, a soln. of a thorium salt gives a white, flocculent precipitate of **thorium tungstate** when treated with sodium tungstate; and, according to W. Nernst, if a mol of thoria is heated with 2 mols of tungsten trioxide a thorium tungstate is formed. A. J. Högbom prepared microscopic, tetragonal crystals of **sodium thorium tungstate,** $Na_4Th(WO_4)_4$, by dissolving thoria in a fused mixture of sodium chloride and an excess of sodium tungstate. G. N. Wyrouboff said that thoria readily dissolves in many acid tungstates forming salts of complex acids.

According to F. de Carli,[10] when a mixture of stannous oxide and tungsten trioxide is heated, combination begins at about 265°. E. F. Anthon observed that **stannous tungstate,** $SnWO_4.6H_2O$, is formed as a yellow powder by mixing soln. of sodium tungstate and stannous chloride. Hydrochloric acid extracts the stannous oxide, and the tungsten trioxide is at the same time reduced to the blue oxide. The salt is insoluble in water, slowly soluble in phosphoric acid, and soluble in oxalic acid, and potash-lye. W. Lotz found that on mixing soln. of ammonium paratungstate and ammonium chlorostannate, a white flocculent precipitate, presumably stannic tungstate, $9SnO_2.13WO_3.nH_2O$, is formed. It is soluble in an excess of the chlorostannate, but not in a soln. of ammonium tungstate. It is soluble in phosphoric, oxalic, and tartaric acids. S. Prakash and N. R. Dhar found that the viscosities of a soln. of **stannic tungstate,** $Sn(WO_4)_2.nH_2O$, having 8 c.c. of $1{\cdot}35M$-$SnCl_4$, 2 c.c. of water, and 14 c.c. of a 15 per cent. soln. of sodium tungstate, at 30°, are:

Age . .	0	90	125	168	210	245	283 min.
Viscosity .	0·01349	0·01570	0·01640	0·01691	0·01807	0·02015	0·02280

The soln. sets to a firm, white jelly in 10 hrs. G. von Knorre treated a molten mixture of a mol of lithium oxide and 2 mols of tungsten trioxide with tin, and obtained, presumably, **lithium stannic tungstate,** $2Li_2O.SnO_2.6WO_3$, as a steel-grey, amorphous powder.

A. Breithaupt,[11] described a mineral which he called *Scheelbleispath* occurring at Zinnwald, Bohemia, and at Bleiberg, Carinthia. F. S. Beudant called it *Scheelitine;* and W. Haidinger, **stolzite**—after Dr. Stolz of Teplitz who first drew attention to the mineral. The same mineral occurs in Coquimbo, Chili; at Southampton, and Loudville, Massachusetts; Marianna de Itacolumi, Brazil; Bena e Padru, Sardinia; and the Broken Hill Mines, New South Wales. Analyses of the mineral by W. A. Lampadius, K. H. T. Kerndt, W. Florence, C. Hlawatsch, and of artificial **lead tungstate,** $PbWO_4$, by E. F. Anthon, H. C. Germs, N. S. Manross, and C. Friedheim are in agreement. E. J. Chapman obtained a variety from Coquimbo containing 6·37 per cent. of calcium, $(Ca,Pb)WO_4$. Another mineral called **raspite**—after Mr. Rasp, the discoverer of the Broken Hill Mines—was described by C. Hlawatsch. It occurs at the Broken Hill Mines, N.S.W., and is also a normal lead tungstate, or possibly $Pb_2(WO_4)_3$—but stolzite occurs in tetragonal crystals, raspite in monoclinic crystals. A mixed molybdate and tungstate, $Pb(W,Mo)O_4$, between stolzite and wulfenite from Chillagoe, Queensland, was called **chillagite** by A. T. Ullmann, and C. D. Smith and L. A. Cotton. J. C. H. Mingaye reported some analyses. F. Krantz called it *lyonite* or *lionite* after D. Lyon.

F. de Carli said that mixtures of lead oxide and tungsten trioxide begin to react at 210°; G. Tammann observed a hump on the heating curve between 480° and 700°; and D. Balareff said that the maximum effect occurs at about 700°. W. Jander said that the reaction with lead oxide and tungsten trioxide begins at 480°. E. F. Anthon, J. Brown, and E. F. Smith and R. H. Bradbury obtained lead tungstate as a white, flocculent precipitate by treating a soln. of a lead salt with a soln. of potassium tungstate; C. Friedheim mixed lead acetate and metatungstic acid in dil. soln.; F. M. Jäger and H. C. Germs treated with lead acetate a soln. of sodium tungstate, or a boiling, ammoniacal soln. of tungstic acid mixed with acetic acid. W. Lotz mixed hot conc. soln. of lead acetate or nitrate and ammonium metatungstate, and on cooling, found that the liquid solidified to a crystal magma, which was soluble in much water, and from this soln., on spontaneous evaporation, crystals of lead metatungstate were formed. E. F. Smith filtered a soln. of the crystal magma at room temp., and evaporated it on an iron plate over a small flame. As the liquid became hot, it became turbid and finally deposited a dense, white, insoluble powder. This white powder had a composition of the *hemipentahydrate*, $PbWO_4.2\frac{1}{2}H_2O$. N. S. Manross, and W. Meyerhoffer melted a mixture of sodium tungstate and lead chloride; and L. Michel, a mixture of sodium tungstate, lead chloride, and sodium chloride in a crucible lined with magnesia. The cold product was lixiviated with water. L. Michel also used lead sulphate in place of the chloride. The crystals formed by the fusion processes correspond with those of stolzite. E. Zettnow found that amorphous lead tungstate becomes crystalline when fused with sodium tungstate; and H. Traube that lead tungstate may be obtained as a crystalline sublimate by heating it mixed with sodium and potassium chlorides, to a high temp.

The mineral stolzite occurs in green, yellowish-grey, brown, and red masses of crystals indistinctly aggregated. The artificial preparation is colourless. According to K. H. T. Kerndt, the crystals are tetragonal with pyramidal hemihedrism. The axial ratio $a:c=1:1{\cdot}5667$; C. Hlawatsch gave $1:1{\cdot}5606$. The habit is acute octahedral, and the crystals may form plates or pyramids. The (001)- and (111)-changes are imperfect. C. Hlawatsch, and W. Florence examined the corrosion figures. The optical character is negative. The crystals of stolzite were described by A. Lévy, F. von Kobell, B. K. Emerson, E. Artini, D. Lovisato, E. Hussak, F. C. Naumann, etc. C. Hlawatsch observed that raspite forms monoclinic prisms with the axial ratios $a:b:c=1{\cdot}3363:1:1{\cdot}1112$, and $\beta=107°\ 41'$; and with another specimen $1{\cdot}34497:1:1{\cdot}11468$, and $\beta=72°\ 23'$. The (100)-cleavage is complete. According to E. S. Larsen, the optic axial angle 2V is nearly zero; and the optical character is positive. L. Vegard and A. Refsum found that the X-radiograms corresponded with the lattice parameters $a=7{\cdot}696$ A., $c=12{\cdot}010$ A., $a:c=1{\cdot}1561$; a radius of the oxygen atom 1·18 A., of the metal in WO_4, 1·04 A., and of the positive ion, 1·17 A. The sp. gr. of raspite has not been reported; that of stolzite given by K. H. T. Kerndt is 8·1032 to 8·1275; and for artificial lead tungstate, N. S. Manross gave 8·232 to 8·238. P. Niggli gave 8·30 for the sp. gr. of stolzite; and 54·8 for the eq. vol.; J. J. Saslawsky gave 7·9 to 8·1 for the sp. gr., and calculated that a contraction of 0·66 to 0·67 occurs in the formation of lead tungstate from its elements. F. A. Henglein gave 54·81 for the mol. vol. The hardness of stolzite is 2·75 to 3·0; and that of raspite is 2·5 to 3·0. E. Cane found the sp. ht. to be 0·077. F. Zambonini gave 1125° for the m.p. of lead tungstate; and F. M. Jäger and H. C. Germs, 1123°. The latent heat of fusion is said to be smaller than that of lead molybdate. D. Vorländer and H. Hempel observed no sign of a transition temp., but F. M. Jäger and H. C. Germs found that on cooling, there is a transition corresponding with the passage of what they call β-lead tungstate to α-lead tungstate, the form stable at ordinary temp. There is only a small thermal change at the transition temp. The transformation is more marked in the presence of lead sulphate, and it vanishes in the presence of lead chromate and molybdate. In the system: $PbSO_4$–$PbWO_4$, Fig. 42, the solid soln. containing β-$PbWO_4$ separating at the eutectic temp. contains respectively 37 molar per cent. of sulphate, and 7 of the tungstate. The eutectic is at 995° corresponding with 51 molar per cent. of tungstate. The change α-$PbSO_4 \rightleftharpoons \beta$-$PbSO_4$ occurs at 875°, and α-$PbWO_4 \rightleftharpoons \beta$-$PbWO_4$ at 859°. The equilibrium diagram of the system: $PbCrO_4$–$PbWO_4$ is incomplete. There is a eutectic at 837°, and the limiting solid soln. on the tungstate side of the diagram contains 41 molar per cent. of chromate. Lead molybdate and tungstate, Fig. 43, form an isodimorphous series of solid soln. with a transition temp. at 1082°. A mixture containing 75 molar per cent. of lead molybdate is in equilibrium at this temp. with both kinds of solid soln. In the system: PbO–$PbWO_4$, Fig. 45, there is one combination, namely, **lead oxytungstate,** or $PbO.PbWO_4$, that is Pb_2WO_5, melting at 889°. This compound shows no transition temp. corresponding with a polymorphous transformation. The transition temp. is 877°. There are eutectics at 722° corresponding with 82·5° molar per cent. PbO, and one at 882° corresponding with 46 molar per cent. PbO. F. Zambonini studied the f.p. of the system $Ce_2(WO_4)_3$–$PbWO_4$, and found for the following percentage proportions of lead tungstate:

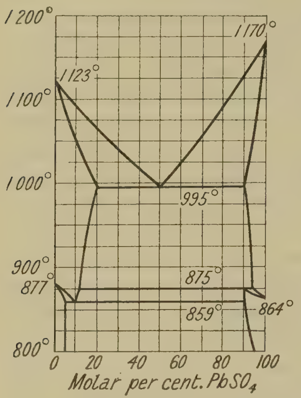

FIG. 42.—Freezing-point Curve $PbSO_4$–$PbWO_4$.

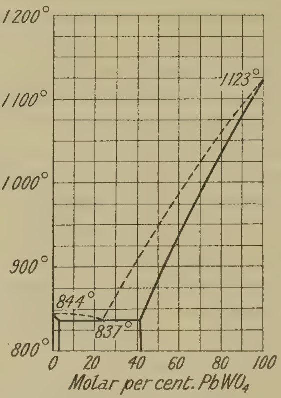

FIG. 43.—Freezing-point Curve $PbCrO_4$–$PbWO_4$.

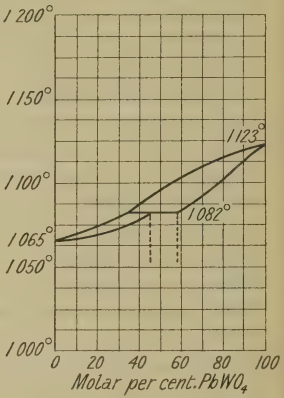

FIG. 44.—Freezing-point Curve $PbMoO_4$–$PbWO_4$.

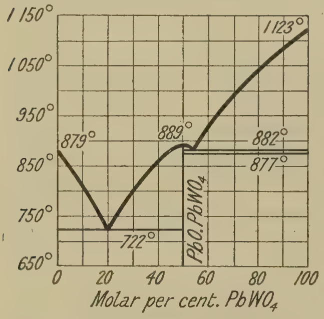

FIG. 45.—Freezing-point Curve of the Mixtures: PbO–$PbWO_4$.

$PbWO_4$ . .	0	20	40	60	80	100 per cent.
F.p. Beginning .	1089°	1103°	1115°	1122°	1123°	1125°
F.p. End . . .	—	1092°	—	1108°	1108°	—

G. Tammann gave for the heat of formation $(PbO,WO_3)=45·4$ Cals. W. Florence found the indices of refraction of stolzite to be $\omega=2·2685$, and $\epsilon=2·182$ for Na-light; and C. Hlawatsch, $\omega=2·2685$, and $\epsilon=2·182$. The index of refraction of raspite approximates 2·6; and E. S. Larsen gave $\alpha=2·27$, $\beta=2·27$, and $\gamma=2·30$. E. Wartmann found stolzite is a non-conductor of electricity. According to

E. F. Anthon, lead tungstate is insoluble in water and in cold nitric acid, but it is soluble in potash-lye. E. F. Smith and R. H. Bradbury said that lead tungstate is insoluble in a soln. of ammonium nitrate, and the presence of this salt facilitates the filtration of lead tungstate from its mother-liquor. L. Kahlenberg and W. J. Trautmann found that silicon reduces lead tungstate with difficulty forming no free metal or silicide.

The *arsenic tungstates* and the arsenato-tungstates have been previously discussed, **9**. 51, 22 ; and the *antimony tungstates*, and the *antimonatotungstates*, **9**. 52, 14. E. F. Smith and R. H. Bradbury[12] obtained insoluble **bismuth tungstate,** presumably $Bi_2(WO_4)_3$, by double decomposition by mixing soln. of sodium tungstate and bismuth nitrate. F. Zambonini found that normal bismuth tungstate is readily obtained by fusing an intimate mixture of bismuth and tungsten trioxides in the theoretical proportions, and allowing the mass to cool slowly. The product contained some monoclinic crystals with the axial ratios $a : b : c = 1{\cdot}006 : 1 : 1{\cdot}520$, and $\beta = 90° \ 34'$. If the monoclinic crystals are heated with an excess of sodium chloride for 3 hrs. at 900° to 1000°, and lixiviated with water, the residue contains tetragonal, bipyramidal crystals with the axial ratio $a : c = 1 : 1{\cdot}566$. The tetragonal crystals correspond perfectly with the tetragonal phase both of the normal molybdates and tungstates of the elements of the yttrium and cerium group, as well as of those of the isomorphogenic elements of the calcium-strontium-barium-lead group, the value of $a : c$ in these compounds varying from $1 : 1{\cdot}542$ to $1 : 1{\cdot}623$. The monoclinic form is distinctly pseudo-tetragonal, the axial ratios differing but little from $1 : 1 : 1{\cdot}566$ and the value of β but little from 90°. This monoclinic form exhibits undeniable crystallographic resemblances to raspite, the monoclinic form of lead tungstate, but the tetragonal bismuth tungstate shows far closer resemblances to stolzite, the tetragonal form of lead tungstate. The sp. gr. of the monoclinic crystals is 8·24 at 7·5°, and the m.p. is 832°. The f.p. curve of the binary system: $PbWO_4$–$Bi_2(WO_4)_3$ is shown in Fig. 46. The curve is characteristic of binary mixtures, either forming no solid soln. or exhibiting extremely limited mutual solubility in the solid state. The crystallization curve first falls rapidly from 1130° to a eutectic point at about 813°, corresponding with about 73 molar per cent. of $Bi_2(WO_4)_3$, and then rises directly to 832°. According to C. W. Balke and E. F. Smith, **ammonium bismuth tungstate,** $3(NH_4)_2O.2Bi_2O_3.11WO_3.10H_2O$, is produced by boiling bismuth hydroxide with a soln. of ammonium paratungstate for about two days, filtering the yellow liquid, and allowing it to cool. The oil of sp. gr. 3·6 which separates dries to a transparent, yellow, vitreous mass. No precipitate was produced on strongly diluting the soln. of this salt with water. Ammonium hydroxide caused no change in its cold dil. soln., but, when the latter was boiled in the presence of ammonia, a copious white precipitate separated. Nitric acid caused no change in the boiling dil. soln. of the salt, but in conc. soln. precipitation occurred on the addition of conc. nitric acid. The addition of a large vol. of hot water again effected soln. Hydrochloric acid occasioned no change in cold or hot dil. soln., while tungstic acid separated on boiling with conc. hydrochloric acid. The corresponding **potassium bismuth tungstate,** $3K_2O.2Bi_2O_3.11WO_3.15H_2O$, forms a yellow oil which dries to a transparent, pale yellow, vitreous mass; and **strontium bismuth tungstate,** $SrO.2Bi_2O_3.11WO_3.11H_2O$, appears as a yellow oil which solidifies to a wax-like mass, and when dried at 100°, forms a hard, yellow, insoluble, vitreous mass. When mercurous nitrate is added to a soln. of the ammonium salt, **mercurous bismuth tungstate** is formed as a yellowish-white precipitate. The complex *vanadatotungstates* have been previously discussed,

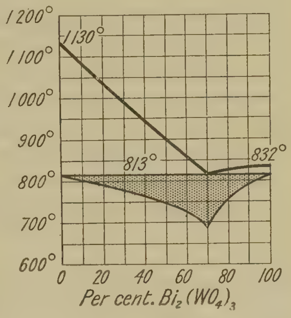

FIG. 46.—Freezing-point Curve of the System: $PbWO_4$–$Bi_2(WO_4)_3$.

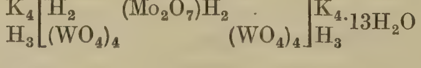
9. 54, 14. E. F. Smith[13] found that complex tungstates are formed with columbic and tantalic oxides with tungsten trioxide.

J. Lefort[14] obtained a dark green precipitate of **chromium tungstate,** $Cr_2(WO_4)_3.3H_2O$, by adding a soln. of sodium ditungstate to one of chrome alum; and W. Lotz obtained $Cr_2(WO_4)_3.30H_2O$ from soln. of normal sodium tungstate and chromic chloride. The pale green precipitate is soluble in an excess of the soln. of chromic chloride, and in phosphoric, oxalic, and tartaric acids. It loses 21·27 per cent. or 13 mols. of water when dried over calcium chloride at 100° and 7 more mols., or 12·19 per cent., when calcined at red-heat. The colour is then yellowish-grey. S. Prakash and N. R. Dhar prepared hydrogels of chromic tungstate. J. Lefort obtained **chromium oxytungstate,** $Cr_2O(WO_4)_2.5H_2O$, or $Cr_2O_3.2WO_3.5H_2O$, by pouring a soln. of chromic acetate into a small excess of a soln. of sodium tungstate (1 : 10). The green, pale blue, or violet precipitate dries to a green amorphous powder, which after ignition is brown. 100 parts of water dissolve 0·25 part of the salt at 15°. By mixing very conc. soln. of eq. proportions of chromic acetate and sodium ditungstate, and pouring in alcohol, a dirty green precipitate of **chromium tetratungstate,** $Cr_2O_3.4WO_3.6H_2O$, is formed which furnishes crystalline plates. 100 parts of water at 15° dissolve two parts of the salt. According to W. Kantscheff, a warm mixture of soln. of paratungstate and a chromic salt contain complex chromitungstates. He considers that the different acid tungstates which have been reported are either paratungstates or mixtures of the para- and meta-tungstates.

According to J. J. Berzelius,[15] when ammonium tungstate is mixed with a hydrochloric acid soln. of molybdenum dioxide, a deep purple-red colour appears, from which, if concentrated, ammonium chloride precipitates a red **molybdenum tungstate,** and the mother-liquor retains a pale yellow colour. The precipitate is washed with water containing ammonium chloride, and then with alcohol of sp. gr. 0·87. It is then dried at a gentle heat. The dark purple product is stable in air, and is freely soluble in water. The dil. aq. soln. gradually becomes colourless on exposure to air owing to the formation of a tungstate of molybdenum trioxide. An aq. soln. of the purple-coloured salt is decolorized by ammonia, and it then deposits, on standing, a white, powdered **ammonium molybdenum tungstate** which is insoluble in water, and from which soda-lye separates molybdenum dioxide. Several of the blue oxides of tungsten have been regarded as **tungsten tungstates,** thus, W_5O_{14} can be represented $(W^{V}O)_2.(W^{VI}O_4)_3$, etc.

L. Fernandes neutralized soln. containing stoichiometrical proportions of a molybdate and a tungstate by the addition of acetic acid, followed by crystallization; by the addition of molybdenum to a boiling soln. of a tungstate; and by mixing soln. of a polymolybdate and a polytungstate. There were thus obtained **potassium tetramolybdatoditungstate,** $2K_2O.4MoO_3.2WO_3.12H_2O$, and from the loss of water on heating, the co-ordination formula is taken to be $K_4H_6[H_2(WO_4)_2(MoO_4)_4].8H_2O$, **potassium trimolybdatoditungstate,** $2K_2O.3MoO_3.2WO_3.10H_2O$; **potassium trimolybdatotritungstate,** $3K_2O.3MoO_3.3WO_3.9H_2O$, *enneahydrate* as well as the *trihydrate*; **potassium molybdatopentatungstate,** $3K_2O.MoO_3.5WO_3.5H_2O$; **potassium molybdatotritungstate,** $2K_2O.MoO_3.3WO_3.4H_2O$; **potassium dimolybdatotetratungstate,** $3K_2O.2MoO_3.4WO_3.11H_2O$, or $K_6H_4[H_2(MoO_4)_2(WO_4)_4].8H_2O$; **potassium nickel dimolybdatotetratungstate,** $K_6H_4[Ni(MoO_4)_2(WO_4)_4].nH_2O$, was also prepared; **potassium molybdatodecatungstate,** $5K_2O.MoO_3.10WO_3.12H_2O$; and **potassium molybdatotetratungstate,** $2K_2O.MoO_3.4WO_3.9H_2O$, or



$$\begin{matrix}K_4\\H_3\end{matrix}\left[\begin{matrix}H_2 & (Mo_2O_7)H_2 & \\ (WO_4)_4 & & (WO_4)_4\end{matrix}\right]\begin{matrix}K_4\\H_3\end{matrix}.13H_2O$$

The addition of conc. hydrochloric acid to conc. aq. soln. of these salts results in the precipitation of the free molybdatotungstic acids as white, amorphous powders, and repeated treatment with hydrochloric acid fails to effect a separation of the two acids. Barium salts give white, sparingly soluble, microcrystalline precipitates when added to soln. of the molybdatotungstates ; and by the addition of a soluble guanidine salt to a boiling soln. of the alkali molybdatotungstate a series of guanidine derivatives was obtained.

J. J. Berzelius observed that a pale yellow precipitate of **uranyl tungstate,** UO_2WO_4, is formed when a soln. of a uranyl salt is treated with a soluble tungstate. J. Lefort obtained this salt from soln. of uranium acetate and sodium tungstate. The salt is insoluble in water, but soluble in strong acids, and in a soln. of ammonium carbonate. J. Lefort obtained **uranium tungstate,** $U(WO_4)_3.5H_2O$, as a yellow precipitate by treating uranyl acetate with sodium ditungstate ; if normal sodium tungstate is employed, the *dihydrate,* $UO_2(WO_4).2H_2O$, is formed as a yellow amorphous precipitate, sparingly soluble in water. O. W. Gibbs dissolved uranium trioxide in dil. sulphuric acid, treated the soln. with zinc, and then treated the insoluble, greyish-green powder with a soln. of sodium paratungstate, dark olive-green crystals of **sodium uranium tungstate,** $12Na_2O.6UO_2.8WO_3.25H_2O$, were formed. This is decomposed by nitric acid, and by boiling soda-lye. O. W. Gibbs prepared **potassium uranium tungstate,** $9K_2O.6UO_2.8WO_3.34H_2O$, in a similar way. It is insoluble in hot water and hydrochloric acid ; and it precipitates silver and mercury salts from soln. of their nitrates ; and it undergoes double decomposition with calcium and barium chlorides. **Ammonium uranium tungstate** was similarly prepared.

E. F. Anthon[16] treated a soln. of a manganous salt with normal sodium tungstate and obtained a greyish-white powder of **manganous tungstate,** $MnWO_4.2H_2O$. When the *dihydrate* is ignited it loses its water and becomes pale yellow, and finally melts. The dihydrate is not soluble in cold hydrochloric acid, but it is soluble in warm phosphoric or oxalic acid, and less soluble in boiling acetic acid. Potash-lye extracts the tungsten as trioxide from the dihydrate. A. Geuther and E. Forsberg melted a mixture of sodium tungstate, manganous chloride, and sodium chloride (1 : 2 : 2) in a covered crucible lined with magnesia ; extracted the cold mass with water ; and obtained pale brown crystals of the anhydrous salt $MnWO_4$. E. Zettnow said that if an excess of manganous chloride be employed, brownish-yellow needles are formed, and with an excess of sodium tungstate, a dirty canary-yellow crystalline powder ; and A. Geuther and E. Fosberg obtained dirty yellowish-green needles by using an excess of sodium chloride (5 : 1 : 16). The brown crystals form a canary-yellow powder of sp. gr. 6·7. E. K. Broch, and P. Groth and A. Arzruni found that the crystals are monoclinic with the axial ratio $a:b:c=0{\cdot}8315:1:0{\cdot}8651$, and $\beta=89°\ 38'$. E. K. Broch calculated from the X-radiograms, the lattice constants $a=4{\cdot}84$ A., $b=5{\cdot}76$ A., and $c=4{\cdot}97$ A. ; the axial ratios $a:b:c=0{\cdot}841:1:0{\cdot}863$, and $\beta=89°\ 7'$; with the calculated density 7·18. Twinning occurs about the (100)-plane. For natural crystals, *vide infra.* W. Jander found the electrical conductivity of the salt to be about 3000×10^{-6} at 970° ; and he calculated values for the diffusion coeff. W. Jander studied the action of magnesium oxide on manganese tungstate. A. Rogers and E. F. Smith prepared red crystals of **ammonium manganic tungstate,** $4(NH_4)_2O.Mn_2O_3.12WO_3.23H_2O$, by boiling an aq. soln. of ammonium paratungstate with manganic hydroxide and evaporating the clear liquid. A. Rosenheim and H. Schwer represented it $(NH_4)_4H_5[Mn(WO_4)_6].9H_2O$. According to A. Just, when a soln. of manganous sulphate is added to a boiling soln. of sodium tungstate, manganous tungstate is precipitated. Sodium persulphate is now added, and the soln. is boiled for 15 mins., the volume being kept constant. The dark red soln. is filtered from a small quantity of manganese dioxide, and, after a time, red crystals of **sodium permanganic tungstate,** $3Na_2O.5WO_3.MnO_2.18H_2O$, the colour of potassium dichromate, separate. The salt may be regarded as a double salt of sodium manganic tetratungstate and sodium tungstate, $Mn(NaWO_4)_4.Na_2WO_4$; or it may be represented according to A. Rosenheim and H. Schwer's formula $Na_6H_2[MnO(WO_4)_5].17H_2O$. Soln. of the salt decompose slowly in the cold, rapidly on heating, with deposition of manganese dioxide it can, however, be crystallized from soln. of sodium tungstate. Most metallic salt-soln. yield precipitates.

As indicated in connection with the history of tungsten, the mineral *wolfram* or **wolframite** was shown by J. J. and F. de Elhuyar[17] to be a tungstate of iron and manganese. E. Riotte, and H. Credner called the mineral **hübnerite** when the manganese largely predominates, $MnWO_4$, and A. Weisbach called it *manganowolframite.* A. Breithaupt described a manganese wolframite as *megabasite,* but C. F. Rammelsberg showed that it is a variety of hübnerite, and similar remarks apply to the blumite of K. L. T. Liebe. A nearly pure **ferrous tungstate,** $FeWO_4$, was described by K. L. T. Liebe under the name **ferberite**—after R. Ferber—A. Weisbach called it *ferrowolframite.* The mineral *reinite*—named after J. J. Rein—and described by K. von Fritsch, and O. Luedecke as a tetragonal ferrous tungstate, is now regarded as a pseudomorph after scheelite. F. L. Hess showed that there is a family group of minerals which can be grouped as wolframites with hübnerite, $MnWO_4$, and ferberite, $FeWO_4$, as end-members and with an indefinitely large number of intermediate manganous ferrous tungstates. For the purposes of classification, he suggested that hübnerite should be considered conventionally as manganous tungstate contaminated by not more than 20 per cent. of ferrous tungstate; ferberite, as ferrous tungstate contaminated by not more than 20 per cent. of manganous tungstate; and wolframite should come between these limits, being a mixture of ferrous and manganous tungstates containing not less than 20 per cent. and not more than 80 per cent. of either. E. T. Wherry proposed another arbitrary system based on the ratio Mn : Fe. If greater than 7 : 1, he called them *permanganowolframites;* if between 7 : 1 and 5 : 3, *domanganowolframites;* if between 5 : 3 and 3 : 5, *ferromanganowolframites;* if between 3 : 5 and 1 : 7, *ferrowolframites;* and if less than 1 : 7, *perferrowolframites.* Why not use the term 5 : 3-wolframite, and so on; or, using only one number if, say, Mn be conventionally made unity, the term 0·6-wolframite?

A. Geuther and E. Forsberg, and E. Zettnow obtained imitations of hübnerite, ferberite, and wolframite, with various proportions of iron and manganese by fusing sodium tungstate with different proportions of ferrous and manganous chlorides, and an excess of sodium chloride. Analyses of hübnerite were reported by W. Beck and N. Teich, I. Domeyko, J. B. Ekeley, H. F. Keller, F. A. Genth, F. N. Guild, W. P. Headden, F. L. Hess, W. F. Hillebrand, W. H. Hobbs, N. von Kulibin, A. H. Low, S. L. Penfield, C. F. Rammelsberg, etc. Analyses of ferberite were reported by W. Beck and N. Teich, F. A. Bernoulli, O. B. Bäggild, J. E. Carne, J. J. Ebelmen, J. B. Ekeley, L. L. Fermor, R. D. George, W. E. Greenawalt, F. L. Hess, K. L. T. Liebe, O. Luedecke, P. Nicolardot, C. F. Rammelsberg, R. Schneider, T. Wada, T. L. Walker, etc. Analyses of wolframite were reported by E. A. Atkinson, L. C. Ball, F. A. Bernoulli, J. J. Berzelius, A. W. G. Bleeck, G. Bodenbender, F. Bourion, C. A. Burghardt, A. Carnot, J. J. Ebelmen, A. M. Findlayson, P. Geiger, F. A. Genth, W. B. Giles, A. de Gramont, C. Granell, W. E. Greenawalt, F. N. Guild, F. L. Hess, F. Hoppe-Seyler, R. Helmhacker, W. Hempel, T. S. Hunt, J. D. Irving, A. Jahn, K. H. T. Kerndt, J. Lehmann, A. Liversidge, O. Luedecke, R. J. Meyer and H. Winter, P. Nicolardot, I. Pargo and A. Arango, P. Pondal and J. Vasquez-Garriga, A. Petzholdt, P. P. Pilipenko, G. J. Pöpplein, T. Richardson, B. Setlik, F. von Schaffgotsch, R. Schneider, O. J. Steinhart, L. Sipöcz, T. Thomson, L. N. Vauquelin, W. L. Walker, G. Weidinger, E. T. Wherry, etc.

The general formula for the whole family group is $(Fe,Mn)WO_4$. Magnesium and calcium oxides are commonly present to the extent of about a quarter per cent. A. Carnot reported 0·90 to 1·10 per cent. of tantalum pentoxide in a variety from Meymac; W. F. Hillebrand, 0·05 per cent. of columbium pentoxide in a sample from Ouray, California; L. Weiss, T. L. Phipson, A. Damour, and E. T. Wherry both tantalum and columbium pentoxides in samples from Cornwall, Arizona, etc.; G. Eberhard, H. S. Lukens, and H. Winter, scandium; G. Bodenbender, and F. A. Genth, stannic oxide, and copper oxide; E. A. Atkinson, and F. Hoppe-Seyler, indium oxide. Molybdenum may also be present. F. L. Hess, M. Kosaki, and W. T. Schaller reported Si, Al, Mg, Ca, Cr, Cb, Cu, Mo, Sc, Sr, Ti, and V to have been detected in ferberite by means of the spectroscope.

According to F. L. Hess, ferberite and wolframites are characteristically black;

hübnerite, reddish-brown, although some specimens are yellowish or nearly black. Except in the lighter coloured hübnerites, the presence of admixed ferberite cannot be detected by the eye. The dark-coloured varieties of the mineral are usually wolframites. Some specimens of hübnerite are almost garnet-red, but a specimen from Butte, Montana, is in part light yellowish-brown, and in part caramel-brown, while one from White Oaks, North Mexico, appears opaque black. Under the microscope, thin sections of hübnerite are light or dark yellowish-brown, or dark green by transmitted light. R. Tronquoy found that powdered hübnerite is sulphur yellow, and with plates of decreasing thickness the colour changes in different directions are: a, dark red to brown to pale brick-red to olive-green; b, bright red to orange-red to greenish-yellow; and c, orange-red to bright yellow with a faint green tinge. Usually the higher the proportion of ferric oxide, the blacker the colour; but the black mineral from White Oakes has only 0·55 per cent. of ferrous oxide, whereas lighter coloured hübnerite may contain more ferrous oxide. The cause of the dark colour is unknown. Hübnerite may be pleochroic with b yellowish-brown, and c, green. Ferberite is described by F. L. Hess as a black, opaque mineral which under the microscope may appear red by light transmitted through very thin edges—say 0·0001 to 0·0002 inch thick. Ferberite may occur coated with hydrated iron oxide, or be so intergrown with it that both the outside, and the parts exposed by fracture or cleavage may be brown. Some specimens are iridescent owing to thin films of oxide. The mineral may occur in bladed, irregularly lamellar, or columnar crystals; and also in granular, coherent masses. The crystals may be tabular or prismatic, and the faces in the prismatic zone may be vertically striated. The crystals of the wolframite family are all monoclinic, and V. Goldschmidt's value for the axial ratios $a:b:c$=0·8255 : 1 : 0·8664, and β=89° 32′ is typical of the whole series. Indeed, the crystallographic constants of the end-members do not show any characteristic differences. Ferberite has a greater tendency to form well-defined crystals than have the other members of the series. A. des Cloizeaux gave for the axial ratios of wolframite, $a:b:c$=0·8300 : 1 : 0·86781, and β=89° 21·6′; J. A. Krenner, 0·82447 : 1 : 0·86041, and β=89° 39′ 38″; and G. Seligmann, 0·82144 : 1 : 0·87111, and β=89° 34′; and for ferberite, P. Groth and A. Arzruni gave 0·8229 : 1 : 0·8462, and β=89° 22′.

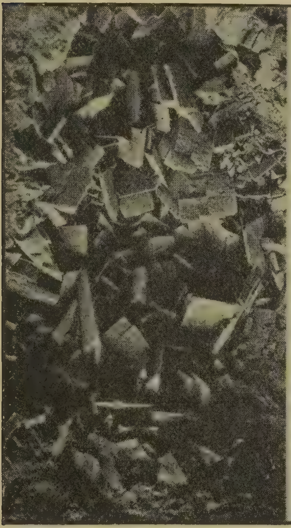


Fig. 47.—Wedge-shaped Crystals of Ferberite (×2).

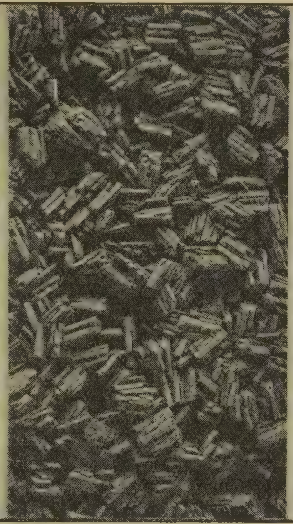

Fig. 48.—Rhomboidal Crystals of Ferberite (×1).

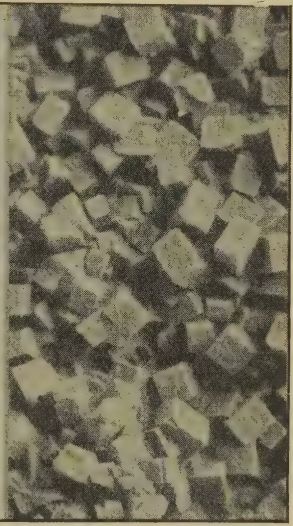

Fig. 49.—Cuboidal Crystals of Ferberite (×10).

R. Tronquoy gave $a : b : c = 0{\cdot}8315 : 1 : 0{\cdot}8651$, and $\beta = 90°\ 22'$ for hübnerite. F. Machatschky gave $0{\cdot}8362 : 1 : 0{\cdot}8668$, and $\beta = 89°\ 7\frac{1}{2}'$ for hübnerite, and $0{\cdot}8300 : 1 : 0{\cdot}8678$ and $\beta = 89°\ 22'$ for wolframite. E. K. Broch found that the crystals are like those of magnesium tungstate. The crystals of ferberite and wolframite are frequently wedge-shaped, Fig. 47 (Hoosier Mine, Colorado), and often in elongated rhomboids, Fig. 48 (Nugget Mine, Colorado), or in cubes, Fig. 49 (Georgia A. Mine, Colorado). These forms appear in ores where the crystals have grown in open cavities. The photographs, Figs. 47 to 49, are by F. L. Hess. Wolframite does not usually show good crystal boundaries, but occurs in tabular or irregular masses. Hübnerite has a marked tendency to form radiating groups of thin-bladed crystals, but dense, fine-grained aggregates of closely-packed crystals wherein irregular boundaries frequently occur. The shiny cleavage surfaces which are developed when these masses are broken may be mistaken for crystal faces. Wolframite rarely shows good external crystal forms; and it usually consists of irregular aggregates with no external crystal forms, and the individuals may have microscopic dimensions or be over 5 cms. in diameter. Crystals of all members of the series readily split along the (010)-plane. The plane cleavage is at right angles to the plane of elongation of the tabular forms. According to A. des Cloizeaux, parting is sometimes observed parallel to the (100)- and the (102)-planes. Twinning occurs about the c-axis, with (100) as the composition plane; G. Rose also gave (023) as a twinning plane. Observations on the crystals of wolframite were also made by C. Anderson, W. H. Miller, A. S. Eakle, P. Groth and A. Arzruni, P. von Jeremejeff, A. Jahn, K. Jimbo, F. Sandberger, L. J. Spencer, P. Geijer, F. L. Hess, and W. T. Schaller; the crystals of hübnerite were described by J. J. Bravo, E. Bertrand, S. L. Penfield, R. Tronquoy, F. L. Hess, D. J. Fisher, and W. T. Schaller; and those of ferberite by C. H. Warren, A. J. Moses, O. B. Böggild, F. L. Hess, and W. T. Schaller. P. Groth and A. Arzruni found the optic axial angles for red Li-light to be $2H_a = 93°$ and $2H_2 = 141°$; and $2V = 75°$. E. S. Larsen gave for hübnerite $2V = 73°$. The optical characters of wolframite and of hübnerite are positive. E. K. Broch calculated the following lattice-constants, in A-units, from the X-radiograms:

	a	b	c	β	$a : b : c$	Density
$MnWO_4$	4·84	5·76	4·97	89° 7′	0·841 : 1 : 0·863	7·18
Hübnerite	4·82	5·76	4·97	89° 7′	0·837 : 1 : 0·863	7·25
Wolframite	4·78	5·73	4·98	89° 34′	0·835 : 1 : 0·869	7·34
Ferberite	4·71	5·69	4·95	90° 0′	0·828 : 1 : 0·870	7·58
$FeWO_4$ (and reinite)	4·70	5·69	4·93	90° 0′	0·825 : 1 : 0·866	7·61

The sp. gr. of hübnerite is about 7·2 or 7·3. The artificial manganous tungstate prepared by A. Geuther and E. Forsberg had a sp. gr. of 7·1; A. Breithaupt gave for the mineral 7·14; R. Tronquoy, 7·09; P. Geijer, 7·283; and W. F. Hillebrand, 7·177 at 24°. The sp. gr. of ferberite is near 7·5, though A. Geuther and E. Forsberg gave for the artificial ferrous tungstate 7·1; and for the mineral, C. F. Rammelsberg gave 7·169, and A. Breithaupt, 6·801. L. Sipöcz gave 7·4581 for a variety with Fe : Mn = 2 : 1. O. Luedecke gave 6·640 for the sp. gr. of reinite. A. Geuther and E. Forsberg gave 7·0 for the sp. gr. of artificial $(0{\cdot}3Fe, 0{\cdot}7Mn)WO_4$; F. Mohs gave for wolframite 7·155, and A. F. Gehlen, 7·097. For the relation between sp. gr. of wolframite and the percentage amount of contained tungsten trioxide, the Wolf Tongue Milling Co. gave:

WO_3	1	5	10	15	20	25	30	35	40	44 per cent.
Sp. gr.	2·724	2·821	2·951	3·096	3·263	3·432	3·629	3·850	4·094	4·323

When the mineral is ground to an impalpable powder, or drawn over a surface of rough porcelain—the so-called streak of the mineral—the colour with ferberite is dark brown or nearly black, that of wolframite is dark brown to reddish-brown, and that of hübnerite is brownish-red or greenish-yellow. The hardness of ferberite is about 5, so that it is easily scratched by a pocket-knife, that of hübnerite is nearly the same—R. Tronquoy gave approximately 4 and added that the hardness on the (010)-face is smaller than that on the (001)-face—so also is the hardness of wolframite which is nearly 5. V. H. Regnault gave 0·09780 for the sp. ht. of crystals of wolframite between 6° and 98°; H. Kopp, 0·0930 between 21° and 53°; and G. Lindner, 0·09755 at 100°; 0·09840 at 200°; 0·09949 at 300°; and 0·10015 at 350°. E. S. Larsen gave $\beta=2{\cdot}40$ for the index of refraction of ferberite with Li-light, and added that the birefringence is large; for wolframite with Li-light, he found $\alpha=2{\cdot}26$–$2{\cdot}31$; $\beta=2{\cdot}32$; and $\gamma=2{\cdot}42$ to $2{\cdot}46$; and for hübnerite, with *D*-light, $\alpha=2{\cdot}17$–$2{\cdot}20$; $\beta=2{\cdot}22$; and $\gamma=2{\cdot}30$–$2{\cdot}32$. E. Wartmann, and F. Beijerinck found wolframite to be a non-conductor of electricity. C. Doelter gave for the electrical resistance, *R*, of wolframite:

	50°	150°	300°	400°	600°	780°	1000°	1100°
R . . .	11050	690	110	43·8	11·7	419	219	0·83

E. T. Wherry observed that ferberite is a good radio-detector. B. Bavink measured the magnetic properties of crystals of wolframite. A. Ambronn gave 241×10^{-6} mass units for the magnetic susceptibility, and G. Grenet, 35×10^{-6}. E. F. Smith found that wolframite dissolves when it is heated with sulphur monochloride. F. R. van Horn described replacements of wolframite by scheelite.

G. Tammann[18] observed that ferrous oxide reacts with tungsten trioxide between 480° and 700° forming **ferrous tungstate,** $FeWO_4$, and D. Balareff added that the reaction proceeds fastest at 700°. H. Debray obtained ferrous tungstate by strongly heating a mixture of tungsten trioxide and ferrous oxide in a current of hydrogen chloride; and A. Geuther and E. Forsberg prepared crystals of artificial ferberite by fusing together a mixture of sodium tungstate, ferrous chloride, and sodium chloride (1 : 2 : 2). E. Zettnow used a similar process. The lustrous, black crystals have a sp. gr. 7·1. For E. K. Broch's lattice-constants, *vide supra.* E. F. Anthon obtained the *trihydrate,* $FeWO_4.3H_2O$, as a light brown powder, by adding a soln. of a ferrous salt to one of sodium tungstate. The trihydrate is not dissolved by cold hydrochloric, sulphuric, or nitric acid, but it is completely dissolved by the boiling acids with the separation of tungsten trioxide; it is not soluble in water, but it is dissolved by boiling phosphoric acid, and by hot oxalic acid. J. Lefort found that the precipitate obtained by adding a soln. of normal or acid sodium tungstate to one of ferrous acetate produces a precipitate too unstable for analysis; but with a soln. of ferric acetate, definite ferric tungstates are formed, in the one case **ferric trioxytungstate,** $2Fe_2O_3.3WO_3.6H_2O$, or $Fe_2O_3.Fe_2(WO_4)_3.6H_2O$, and in the other case **ferric oxytungstate,** $Fe_2O_3.2WO_3.4H_2O$, or $Fe_2O(WO_4)_2.4H_2O$, or $Fe(OH)(WO_4).1\frac{1}{2}H_2O$. Both are yellow precipitates. 100 parts of water at 15° dissolve 33·3 parts of the former, and 2 parts of the latter. According to W. T. Schaller, the pale yellow, or brownish-yellow ochre from Deer Trail, Washington, consists of microscopic, hexagonal plates which are optically isotropic. The composition corresponds with ferric dioxytungstate, $Fe_2O_2(WO_4).6H_2O$, and he called the mineral **ferritungstite.** E. S. Larsen gave for the indices of refraction of ferritungstite, $\omega=1{\cdot}80$, and $\epsilon=1{\cdot}72$. S. Prakash and N. R. Dhar studied the properties of the hydrogel of ferric tungstate. A. Laurent reported a complex **potassium ferric tungstate,** $9K_2O.12H_2O.2Fe_2O_3.45WO_3+54H_2O$, to be formed by melting potassium carbonate and nitrate with an excess of wolframite, and digesting the mass with water. The salt separated from that soln. in large regular prisms. The soln. of the salt does not give the ordinary reactions for ferric iron. S. Prakash and N. R. Dhar prepared a hydrogel of ferric tungstate. A. Laurent obtained a basic salt $18K_2O.3H_2O.Fe_2O_3.45WO_3+54H_2O$; and **barium ferric tungstate,** $21BaO.2Fe_2O_3.45WO_3.27H_2O$. The formulæ are probably not correct, and A. Rosenheim and H. Schwer added that *ihre Darstellung ist nicht reproduzierbar*—*vide infra,* dodecatungstates.

F. de Carli[19] found that the heating curves of mixtures of cobaltous oxide and tungsten trioxide show that a reaction commences at about 255°. H. Schultze obtained crystals of **cobaltous tungstate,** $CoWO_4$, by melting a mixture of sodium tungstate, and cobaltous and sodium chlorides (1 : 2 : 2); E. Zettnow used the proportions 6 : 1 : 6. The monoclinic crystals are dark green, and non-magnetic. When powdered, the colour of the crystal is violet. E. F. Anthon obtained the anhydrous salt by calcining the hydrate. According to H. Schultze, and E. Zettnow, at a red-heat the product becomes greenish-blue, at a higher temp., bluish-black. E. K. Broch gave for the lattice constants, calculated from the X-radiograms, a=4·66 A., b=5·68 A., c=4·93 A., $a : b : c$=0·820 : 1 : 0·868, and β=90°; and the calculated density is 7·76. E. F. Anthon, and E. F. Smith and R. H. Bradbury treated a soln. of normal alkali tungstate with one of a cobaltous salt. The violet precipitate when washed and dried forms the *dihydrate*, $CoWO_4.2H_2O$, which loses its water at a red-heat; it is insoluble in water, and cold nitric acid; it is partially soluble in oxalic acid; and completely soluble in warm phosphoric or acetic acid. A. Carnot said that the grey precipitate produced by a cobaltous salt in soln. of ammonium tungstate becomes rose-red when dried. It easily oxidizes in air. Its composition is $8(NH_4)_2O.2CoO.15WO_3.3H_2O$. E. K. Broch found the crystals of the anhydrous salt to be monoclinic like those of the magnesium salt.

F. de Carli found that a mixture of nickelous oxide and tungsten trioxide shows evidence of combustion on the heating curve at 260°. H. Schultze obtained **nickel tungstate,** $NiWO_4$, by fusing a mixture of sodium tungstate, and nickel and sodium chlorides (1 : 2 : 2). The brown rhombic crystals have the appearance of zinc blende. E. K. Broch found that the crystals are monoclinic like those of the magnesium salt; and the lattice constants, calculated from the X-radiograms, are a=4·68 A., b=5·66 A., c=4·93 A., $a : b : c$=0·827 : 1 : 0·870, and β=89° 4′; and the calculated density is 7·78. F. W. Clarke and J. L. Davis gave 6·8846 for the sp. gr. at 20·5°, and 6·8522 for the sp. gr. at 22°. J. Lefort obtained the *trihydrate*, $NiWO_4.3H_2O$, and E. F. Anthon the *hexahydrate*, $NiWO_4.6H_2O$, as a pale green powder, by precipitation from mixtures of soln. of normal potassium tungstate and a nickel salt. It loses its water when heated to redness; it is insoluble in water, and soln. of oxalic acid; and it is soluble in boiling phosphoric and acetic acids, as well as in warm aq. ammonia. W. Jander gave about 600×10^{-6} for the electrical conductivity of nickel tungstate at 980°; and he also obtained values for the diffusion coeff. H. O. Schulze studied the action of tungstic acid on soln. of nickel chloride. G. L. Clark found the dissociation temp. of **nickel hexamminotungstate,** $NiWO_4.6NH_3$, to be 393° at 760 mm. According to A. Rogers and E. F. Smith, when hydrated nickel sesquioxide is boiled for 8 hrs. with an ammoniacal soln. of ammonium paratungstate, and the blue filtered soln. concentrated by evaporation, the soln. becomes green as the ammonia is expelled, and simultaneously deposits a green powder which redissolves if aq. ammonia is added forming a blue soln.; if the soln. be kept ammoniacal during the evaporation, a greenish-white, crystalline powder of **ammonium nickelic tungstate,** $3(NH_4)_2O.Ni_2O_3.16WO_4.22H_2O$, is formed. A second ammonium nickelic salt is formed, $(NH_4)_2O.Ni_2O_3.4WO_4.7H_2O$, if ammonia be passed through the soln. while it is being evaporated. The first salt is sparingly soluble in water once it has separated from soln., and, in consequence, salts are best obtained by double decomposition with the soln. before it is evaporated. In this way, barium chloride furnishes white, insoluble **barium nickelic tungstate,** $19BaO.Ni_2O_3.16WO_3$.

O. W. Gibbs[20] reported green or yellowish-green crystals of platinic decatungstate, $PtO_2.10WO_3.4H_2O$, to be formed by treating the barium salt with sulphuric acid, or the silver salt with hydrochloric acid; and pale yellow platinic cositungstate, $PtO_2.20WO_3.9H_2O$, by converting the corresponding sodium salt into the mercurous salt, adding hydrochloric acid, and spontaneously evaporating the filtrate. According to O. W. Gibbs, when platinic hydroxide is boiled with sodium paratungstate, two isomeric **sodium platinic decatungstates,** $4Na_2O.PtO_2.10WO_3.25H_2O$, are formed; one gives olive-green crystals, and the other honey-yellow prisms. They are readily soluble in water, and give flocculent or crystalline precipitates with the heavy metals, and the higher alkaloids. O. W. Gibbs reported that the deep orange soln. of platinic hydroxide in sodium paratungstate, furnishes, on standing, crystals of sodium platinic decatungstate, $6Na_2O.PtO_2.10WO_3.28H_2O$. According to A. Rosenheim, when a soln. of a paratungstate is boiled with platinic hydroxide, a large portion dissolves forming a deep red liquid; when the mixture is heated in a sealed tube at 250° to 300°, rather more platinic hydroxide dissolves, and a deep brownish-red liquid is formed, but in neither case could O. W. Gibbs' products be obtained. A. Rosenheim suggested that O. W. Gibbs' products consisted of paratungstates containing mechanically-occluded platinic hydroxide, coloured by partial reduction. Soln. of metatungstates dissolve platinic hydroxide in considerable quantities on boiling, and still more readily when heated in a sealed tube, although platinic hydroxide is quite insoluble in water, even when heated with it in a sealed tube at 300°; on evaporating these soln., even under diminished press., nothing but the unaltered reagents was obtained. When a conc. soln. of normal sodium tungstate is boiled with platinic hydroxide, the soln. becomes faintly yellowish, much less platinic hydroxide being dissolved than in the case of the acid salts; this is opposed to the view that platinic hydroxide acts as an acid. The strongly alkaline soln. is filtered as quickly as possible, and, on cooling, a neutral compound, exhibiting the reactions of a paratungstate, separates from the filtrate in small yellow needles of **sodium platinic heptatungstate,** $5Na_2O.7WO_3.2PtO_2.35H_2O$; this cannot be recrystallized, as it then undergoes decomposition; on this account a further yield is not obtained by concentrating the mother-liquor, and the compound cannot be prepared from dil. soln. of sodium metatungstate. It is a double salt of sodium paratungstate (1 mol.) and sodium platinate (2 mols.), as the following experiment proves. When the calculated quantities of sodium paratungstate and platinic hydroxide are boiled with sodium hydroxide soln., the same salt is formed, but this is not the case if sodium hydroxide is excluded. It appears, therefore, that platinic hydroxide has very weak acidic properties (comparable with those of alumina), which it exhibits only with such alkaline salts as normal tungstates; it dissolves in para- or meta-tungstates as a base.

O. W. Gibbs gradually added hydrochloroplatinic acid to a boiling soln. of sodium tungstate containing a considerable excess of sodium hydroxide, and treated the yellow soln. with an excess of acetic acid. Topaz-yellow crystals of **sodium platinic cositungstate,** $9Na_2O.PtO_2.20WO_3.58H_2O$, were formed. The salt loses water and oxygen when heated. It can be recrystallized without decomposition; the soln. is acidic to litmus. With ammonium chloride, the soln. gives a precipitate of sodium ammonium 1 : 4-paratungstate; thallous nitrate gives a granular precipitate—**thallous platinic cositungstate;** cobaltic hexamminotrichloride, pale brown plates—**cobaltic platinic hexamminocositungstate;** copper sulphate, a pale blue precipitate—**copper platinic cositungstate;** silver nitrate, a white precipitate—**silver platinic cositungstate;** and mercurous nitrate, a pale yellow, amorphous precipitate—**mercurous platinic cositungstate.** By boiling platinic hydroxide with sodium paratungstate honey-yellow crystals of **sodium platinic triacontatungstate,** $12Na_2O.PtO_2.30WO_3.72H_2O$, are formed. The salt is dehydrated on a water-bath. O. W. Gibbs also obtained sodium diplatinic triacontatungstate, $15Na_2O.2PtO_2.30WO_3.89H_2O$, in dull, yellow crystals, easily soluble in water, by the action of hydrochloroplatinic acid on sodium tungstate in the presence of an excess of sodium hydroxide, and then treating the soln. with an excess of acetic acid. The aq. soln. is acid to litmus, and with an ammonium salt furnishes **ammonium diplatinic triacontatungstate;** with a potassium salt, **potassium diplatinic triacontatungstate;** with barium chloride, **barium diplatinic triacontatungstate;** and with mercurous nitrate, **mercurous diplatinic triacontatungstate.**

O. W. Gibbs added that qualitative tests indicate that iridium, ruthenium, palladium, and osmium form similar salts.

§ 13. The Ditungstates and Tritungstates

The conditions of equilibrium of **lithium ditungstate,** $Li_2W_2O_7$, according to J. A. M. van Liempt,[1] and F. Hoermann are shown in Fig. 25. The crystals are probably rhombic, and the compound melts at 745°, and has a transition point at 687°. G. von Knorre melted a mixture of a mol of sodium carbonate and 2 mols of tungsten trioxide and obtained, on cooling, a mass of acicular—probably rhombic—crystals of **sodium ditungstate,** $Na_2O.2WO_3$. It dissolves completely when heated for some hours with water at 130°–150°, and the alkaline soln. does not crystallize ; it contains sodium tungstate and metatungstate. I. Traube found the drop weight of the molten salt to be 189 when that of water at 0° is 100. F. Hoermann, and J. A. M. van Liempt studied the conditions of equilibrium, Fig. 25 ; the compound has a m.p. of 738°, and a transition temp. of 747°. V. I. Spitzin and L. Kaschtanoff found the reaction with hydrogen chloride is to form the oxydichloride and normal tungstate which reacts as previously indicated. C. Scheibler studied the action of phosphoric acid on the tungstate ; and J. Lefort obtained quinine ditungstate by the action of a soln. of quinine. J. Lefort reported the *hexahydrate* to be formed in prismatic crystals when a cold, sat. soln. of sodium tungstate is mixed with acetic acid—if oxalic acid is used, the product is contaminated with sodium oxalate. The salt is stable in air ; it melts in its own water of crystallization ; and 100 parts of water at 15° dissolve 13 parts of the salt. G. von Knorre could not prepare this salt, but always obtained the paratungstate instead. C. Friedheim reported that prismatic crystals of the *dodecahydrate* separate from the mother-liquor obtained in preparing sodium vanadatotungstate. It is decomposed by water into normal tungstate and paratungstate. For the observations of V. I. Spitzin, and others, on the reduction of the ditungstates, *vide supra*, sodium bronzes. A. Riche fused an equimolar mixture of tungsten trioxide and potassium tungstate, poured the mass on a cold marble slab, and obtained a colourless crystalline mass. E. F. Anthon made a similar experiment. According to J. Lefort, if acetic or oxalic acid is gradually poured into a cold, conc. soln. of potassium tungstate, a white, curdy precipitate of **potassium ditungstate,** $K_2O.2WO_3.2H_2O$, is formed. 100 parts of water at 15° dissolve 8 parts of the *dihydrate*. If the soln. in boiling water be cooled, the *trihydrate* separates out. 100 parts of water dissolve 2 to 3 parts of the salt. M. Amadori's thermal analysis showed that a potassium ditungstate exists. As in the case of sodium ditungstate, G. von Knorre could not verify J. Lefort's observations, since the paratungstate was always formed. O. W. Gibbs, C. Gonzales, and E. F. Smith were unable to confirm J. Lefort's observation—*vide infra*, the decatungstates. J. A. M. van Liempt's study of the system $K_2WO_4.WO_3$ does not show the existence of any stable ditungstate, Fig. 33.

E. F. Anthon said that if a soln. of a copper salt is treated with an alkali ditungstate, a pale green precipitate of **copper ditungstate,** $CuO.2WO_3.4H_2O$, is formed.

It is decomposed by heat, with the loss of water. It is then brown. The salt is soluble in aq. ammonia, and is decomposed by nitric acid. Many of the ditungstates reported by the early workers appear to have been paratungstates. J. Lefort obtained anhydrous **calcium ditungstate**, $CaO.2WO_3$, as a white precipitate by treating a soln. of calcium acetate with sodium ditungstate at 15°. 100 parts of water dissolve 0·2 part of the salt. If the mother-liquor be evaporated, or if the precipitate be boiled with water, white plates of the *trihydrate* are formed. At 15°, 100 parts of water dissolve 3·3 parts of the salt. E. F. Anthon obtained what he regarded as **strontium ditungstate,** $SrO.2WO_3.4H_2O$, by double decomposition; and J. Lefort obtained a *trihydrate* as a white precipitate by the action of a soln. of sodium ditungstate on one of strontium acetate. E. F. Anthon's product was insoluble in cold water, but soluble in hot phosphoric and oxalic acids. J. Lefort prepared **barium ditungstate,** $BaO.2WO_3.H_2O$, as in the case of the calcium salt. It is more soluble in water than normal barium tungstate. J. Lefort prepared **magnesium ditungstate;** $MgO.2WO_3.8H_2O$, by warming a mixture of magnesium hydroxide with an excess of tungstic acid, and a little water on a sand-bath for several hours' replacing the water lost by evaporation from time to time. Prismatic crystals are formed; at 15°, 100 parts of water dissolve one part of salt. An aq. soln. of magnesium tritungstate deposits a basic salt, $3MgO.2WO_3.4H_2O$, after some hours. J. Lefort obtained **zinc ditungstate,** $ZnO.2WO_3.3H_2O$, in acicular crystals, by concentrating a mixed soln. of a zinc salt and sodium ditungstate; 100 parts of water at 15° dissolve 10 parts of the salt. E. F. Anthon treated an excess of a boiling soln. of mercuric chloride with sodium tungstate and obtained a white insoluble precipitate of **mercuric ditungstate,** $HgO.2WO_3$, which is decomposed by soda-lye to form red mercuric oxide.

J. Lefort mixed soln. of lead acetate and sodium ditungstate and obtained **lead ditungstate,** $PbO.2WO_3.2H_2O$, as a white precipitate which loses its water when heated; it melts at a red-heat; and at 15°, 100 parts of water dissolve 1·25 parts of salt. J. Lefort mixed soln. of bismuth acetate and sodium tritungstate in the presence of alcohol, and obtained **bismuth ditungstate,** $Bi_2(W_2O_7)_3.8H_2O$, as a white precipitate.

E. F. Anthon obtained **ferrous ditungstate,** $FeO.2WO_3.2H_2O$, as a brick-red or brown precipitate by treating a soln. of a ferrous salt with an alkali ditungstate —J. J. Ebelmen used ammonium ditungstate. The salt is not soluble in water, but it dissolves in hot oxalic or phosphoric acid; dil. hydrochloric acid extracts the iron, but with the conc. acid some ferrous iron is oxidized and some blue tungsten oxide is formed. Cold alkali-lye extracts tungsten trioxide. E. F. Anthon obtained a reddish-brown precipitate of **cobalt ditungstate,** $CoO.2WO_3.3H_2O$, by treating a cobalt salt soln. with sodium ditungstate. The precipitate is insoluble in water, sparingly soluble in oxalic acid, and soluble in warm phosphoric acid, acetic acid, and aq. ammonia. E. F. Anthon also reported **nickel ditungstate,** $NiO.2WO_3.4H_2O$. As indicated above, many of these ditungstates are now thought to be paratungstates.

J. C. G. de Marignac [2] obtained normal ammonium tungstate by evaporating over quicklime a soln. of hydrated tungstic acid in aq. ammonia; but, on one occasion he obtained **ammonium tritungstate,** $4(NH_4)_2O.3WO_3.3H_2O$, in indistinct crystals which dissolve in aq. ammonia, forming the normal salt; the aq. soln. soon deposits crystals of the normal salt. E. T. Allen and V. H. Gottschalk added hydroxylamine hydrochloride to a soln. of sodium tungstate, and obtained white crystals of **hydroxylamine tritungstate,** $4(NH_2OH).3WO_3.3H_2O$. When dry, the colour is pale yellow. The salt decomposes vigorously when heated; and it is freely soluble in water.

C. Scheibler obtained **sodium tritungstate,** $2Na_2O.3WO_3.7H_2O$, as a decomposition product of sodium paratungstate, for when that salt is heated to redness, and when cold, extracted with water, a tetratungstate remains undissolved. The aq. extract, on evaporation, furnishes first a crop of crystals of paratungstate, and then a crop of the tritungstate. This salt melts at a dull red-heat; it is freely soluble in water; and the aq. soln. reacts alkaline. J. Lefort studied the action of quinine on the alkali tritungstates. J. Lefort obtained the tritungstate, $Na_2O.3WO_3.4H_2O$, by adding a conc. soln. of sodium ditungstate, drop by drop, to boiling acetic acid. The white, gelatinous precipitate dissolves in its own weight of water, and the aq. soln. when evaporated over quicklime and sulphuric acid, furnishes prismatic crystals. According to J. Lefort, if a conc., aq. soln. of normal potassium tungstate is poured into boiling conc. acetic acid, **potassium tritungstate,** $K_2O.3WO_3.2H_2O$, is formed; but if the soln. is not filtered at once, the metatungstate is formed. The white precipitate is soluble in 5 or 6 times its weight of water at 15°. The salt is obtained in fine needles and prisms when the aq. soln. is evaporated over quicklime, and conc. sulphuric acid. If the aq. soln. is boiled a long time, the ditungstate is formed which separates in scaly crystals, while the normal tungstate remains in soln. If boiled with acetic acid, for a long time, the metatungstate is produced. M. Amadori's thermal analysis showed that a tritungstate of potassium can exist; and F. Hoermann's equilibrium diagram, Fig. 35, shows that potassium tritungstate has an incongruent m.p. at 660°.

J. Lefort was unable to prepare **copper tritungstate,** $CuO.3WO_3.nH_2O$, by adding alcohol to a soln. of aq. proportions of copper acetate and sodium tritungstate. By mixing soln. of calcium acetate and sodium tritungstate, J. Lefort obtained a white, curdy precipitate of **calcium tritungstate,** $CaO.3WO_3.6H_2O$, soluble in cold water; and similarly with **strontium tritungstate,** $SrO.3WO_3.5H_2O$; and with **barium tritungstate,** $BaO.3WO_3.4H_2O$. At 15°, 100 parts of water dissolve 0·33 part of the salt. The *tetrahydrate* is not decomposed by cold water, but with boiling water, the ditungstate and tetratungstate are formed. C. Scheibler obtained the *hexahydrate* as a white powder by the action of cold water on barium metatungstate. J. Lefort obtained white **magnesium tritungstate,** $MgO.3WO_3.4H_2O$, by pouring a mixed soln. of magnesium acetate and sodium tritungstate into alcohol. The salt is soluble in water, and after the soln. has stood for some hours, deposits a basic salt, $3MgO.2WO_3.4H_2O$. O. W. Gibbs obtained **zinc tritungstate,** $ZnO.3WO_3.5H_2O$, which he represented by $2ZnO.6WO_3.10H_2O$, by heating a soln. of sodium pentatungstate mixed with zinc sulphate. The soln. deposits aggregates of acicular crystals which are almost insoluble in boiling water, but soluble in soln. of zinc sulphate, and sodium tungstate. J. Lefort obtained **cadmium tritungstate,** $CdO.3WO_3.4H_2O$, as a white precipitate by adding alcohol to a mixed soln. of cadmium acetate and sodium tritungstate, and allowing the liquid to stand. J. Lefort obtained **mercurous tritungstate,** $2Hg_2O.3WO_3.8H_2O$, by dissolving mercurous nitrate, by the aid of glycerol, in water, and pouring the filtered soln. into a conc. soln. of sodium ditungstate. The pale yellow, stable precipitate loses water when warmed; 100 parts of water dissolve one part of the salt; but he was unable to obtain a tritungstate by pouring the soln. of mercurous nitrate in glycerol into a soln. of sodium tritungstate. The white precipitate first formed immediately blackened owing to the separation of mercury. E. F. Anthon treated a soln. of mercuric nitrate with normal sodium tungstate and obtained **mercuric tritungstate,** $2HgO.3WO_3$, as a white, insoluble powder. J. Lefort obtained the *heptahydrate,* $HgO.3WO_3.7H_2O$, by pouring a soln. of 2 eq. of sodium ditungstate into a sat. soln. of an eq. of mercuric chloride, and allowing the soln. to crystallize. The prismatic crystals, when heated, lose water while retaining their external crystalline form. At 15°, 100 parts of water dissolve 0·83 part of salt. J. Lefort mixed soln. of lead acetate and sodium tritungstate in excess, and obtained **lead tritungstate,** $PbO.3WO_3.2H_2O$, as a white powder, which is very sparingly soluble in water with partial decomposition.

C. F. Rammelsberg added ordinary ammonium tungstate to an aq. soln. of uranium tetrachloride, and obtained **uranium tritungstate** as a brownish-green precipitate, $(UO_2)3WO_3.6H_2O$. Boiling potash-lye extracts all the tungsten trioxide from the moist precipitate, but only part if the precipitate has been dried; and similarly with aq. ammonia. Nitric acid extracts the uranium, and leaves the tungsten trioxide. This compound is used in the manufacture of fluorescent screens for X-ray work. J. Lefort prepared **uranyl tritungstate,** $UO_2.W_3O_{10}.5H_2O$, from a soln. of uranium acetate and sodium tritungstate.

J. Lefort obtained **manganous tritungstate,** $MnO.3WO_3.5H_2O$ (dried at 100°), by adding alcohol to a mixed soln. of manganous acetate and sodium tritungstate. The precipitate is decomposed by cold or hot water forming di- and tetra-tungstates. J. Lefort prepared **cobalt tritungstate,** $CoO.3WO_3.4H_2O$, in the case of manganous tritungstate. The rose-red precipitate is decomposed by water. Greenish-white **nickel tritungstate,** $NiO.3WO_3.4H_2O$, was similarly obtained.

§ 14. The Paratungstates

> The alkali tungstates are numerous and unusually complex. Salts of essentially different formulæ approach so closely in percentage composition, that the differences lie very near the unavoidable errors of analysis. The analyses are hardly sufficiently close to decide the question upon purely analytical grounds.—O. W. Gibbs.

The so-called paratungstates are, in the literature, represented by the formula $3R_2O.7WO_3.nH_2O$, or by $5R_2O.12WO_3.nH_2O$—*vide supra*, paratungstic acid. A. Rosenheim[1] employed the co-ordinate formula $R_5H_5[H_2(WO_4)_6].nH_2O$. The usual product of the action of tungstic acid on aq. ammonia is **ammonium paratungstate,** $5(NH_4)_2O.12WO_3.11H_2O$, or $3(NH_4)_2O.7WO_3.6H_2O$, or $(NH_4)_5H_5[H_2(WO_4)_6]H_2O$. Thus, by concentrating an ammoniacal soln. of normal ammonium tungstate, or a soln. of tungstic acid in aq. ammonia, T. M. Taylor, W. Lotz, E. F. Anthon, and J. C. G. de Marignac obtained crystals of this salt. L. A. Hallopeau obtained it from a soln. of paratungstic acid neutralized by ammonia ; and E. Schaefer, by the electrolysis of a soln. of ammonium tungstate in a compartment cell—*vide infra*, sodium paratungstate. For C. Friedheim and R. Meyer's process for preparing the salt free from molybdenum, *vide infra*, sodium paratungstate. T. M. Taylor observed that a hot soln. furnishes needles of the *pentahydrate*, but, if the soln. is just warm, plates of the *henahydrate* are produced. According to J. C. G. de Marignac, the pentahydrate forms monoclinic prisms with the axial ratios $a:b:c=1\cdot0442:1:0\cdot7871$, and $\beta=109°\ 50'$. Twinning occurs about the (001)-plane. The salt loses 2·15 per cent. of water at 100° ; and ammonia begins to come off at 60°. The hot aq. soln. deposits crystals of the pentatungstate. According to O. W. Gibbs, a soln. of commercial ammonium tungstate in aq.

ammonia, when filtered, and treated with acetic acid, furnishes crystals of the *hexahydrate*, $5(NH_4)_2O.12WO_3.6H_2O$; A. Rosenheim and A. Wolff showed that the salt forms both the henahydrate and the *heptahydrate—vide infra.*

The henahydrate was analyzed by J. C. G. de Marignac, W. Lotz, C. Scheibler, A. Riche, E. Wegelin, J. J. Berzelius, E. F. Anthon, L. A. Hallopeau, A. Laurent, E. Schaefer, and A. Pinagel. According to A. Laurent, the salt is dimorphous, and, added E. F. Anthon, needles are obtained if slowly crystallized, and plates if rapidly crystallized; while A. Riche said that needles are deposited from a soln. at 50°–60°; and plates from a cold soln.; and E. Zettnow, that a warm soln. furnishes scaly crystals and a cold soln., prisms. According to J. C. G. de Marignac, the needles are pseudorhombic with the axial ratios $a:b:c=0·7995:1:0·4582$, and K. H. T. Kerndt added that the crystals are complex twinned forms of monoclinic plates. The crystals were also discussed by J. Schabus. J. C. G. de Marignac said that the plates are triclinic pinacoids with the axial ratios $a:b:c=0·9785:1:0·12154$, and $\alpha=65° 47'$, $\beta=117° 33'$, and $\gamma=119° 2'$. J. J. and F. de Elhuyar said that the crystals are stable in air, but they cannot be dehydrated without the loss of ammonia. According to A. Riche, W. Lotz, and J. C. G. de Marignac, the acicular form at 100° loses from 3·23 to 3·87 per cent. of water; and the tabular form 3·80 to 4·72 per cent. J. J. and F. de Elhuyar found that at a red-heat the salt is decomposed giving off water, ammonia, and nitrogen, and leaving behind the blue oxide or, if air be present, tungsten trioxide —as a pseudomorph of the tungstate (E. F. Anthon). T. M. Taylor found that at 100°, the acicular crystals lose 6 mols. of water; and inferred that the remaining 5 mols. are more closely associated in the molecule; and from the easy transformation of the para- into the meta-tungstate it is assumed that the 4 mols. of ammonia in the para-salt are differently combined in the molecule. If the henahydrate is deposited from a warm soln., continuously stirred, W. Lotz said that it is only sparingly soluble in water. E. F. Anthon found that 100 parts of cold water dissolve 3·6 to 4·0 parts of the salt; W. Lotz, 3·83 parts at 10·7°, and 1·69 parts at 100°; A. Riche, 3·003 parts in the cold, and 10·7 parts at 100°; and J. C. G. de Marignac, 2·63 to 4·54 parts at 15° to 18°. A. Rosenheim and A. Wolff found the solubility of the ammonium salt, S grms. of $5(NH_4)_2O.12WO_3$ in 100 grms. of soln., to be:

	17°	25°	35°	49°	52°	62°	70°
S . .	1·064	1·586	2·424	4·341	3·280	6·145	7·971
	11-hydrate				7-hydrate		

—*vide* the normal tungstate for its existence in aq. soln. W. Lotz added that the salt loses ammonia in boiling water, forming the more soluble metatungstate, and J. C. G. de Marignac also noted that the salt gradually changes in aq. soln. B. Kellner observed that the soln. of the salt in hydrogen dioxide is yellow, and when dried, it leaves an amorphous mass. E. F. Smith observed that aniline hydrochloride gives no precipitate with sodium and ammonium tungstates and meta-tungstates, but gives one with the paratungstate before, not after, the soln. is boiled. This shows that boiling water hydrolyzes the paratungstate into one of the other salts. According to T. M. Taylor, if dry ammonia, at about 14 mm. press., is passed over the acicular crystals, at 100° to 250°, about 9 mols. of water are given off; and at 100°–160° ammonia is absorbed to the extent of 3·2 mols. at 130°, but the actual amount varies with the temp. At 250°, the colloidal salt is formed containing tungsten trioxide. The composition of the product, assuming that a common nucleus, $NH_4OH.2WO_3$, is present, can be represented by the mol. ratios: $(NH_4OH.2WO_3):NH_4OH:NH_3$ at 100° is $6:1:4$; at 110°–120°, $6:1:5$; at 130°–140°, $6:1:6$; at 160°, $6:2:2$; at 200°, $6:2:1$; and at 250°, $4(NH_4OH.2WO_3).4WO_3.4NH_3$. E. F. Anthon found the salt to be insoluble in alcohol. D. Klein studied the action of boric acid on the salt. A. Laurent, and J. C. G. de Marignac evaporated a soln. of ammonium paratungstate mixed with a little nitric acid, or a soln. of ammonium paratungstate mixed with an excess of ammonium nitrate, and obtained hexagonal, prismatic crystals of **ammonium nitratometatungstate,** $NH_4NO_3.2(NH_4)_2W_4O_{13}.4H_2O$. The salt loses half its water at 100° ; and when heated, decrepitates, and decomposes without melting.

C. Scheibler prepared **lithium paratungstate,** $5Li_2O.12WO_3.33H_2O$, or $3Li_2O.7WO_3.19H_2O$, by adding tungstic acid to a soln. of lithium carbonate until the mixture is neutral to litmus ; and evaporating slowly over conc. sulphuric acid. The rhombic plates or prisms are stable in air, and the salt is more soluble in water than the corresponding sodium or potassium salt. The ordinary *sodium tungstate* of commerce is **sodium paratungstate,** $5Na_2O.12WO_3.mH_2O$, $3Na_2O.7WO_3.nH_2O$. F. Wöhler, and F. J. Malaguti prepared a salt with the composition $Na_2O : WO_3 = 3 : 7$ by fusing sodium tungstate with the required proportion of tungsten trioxide. The hydrated salt is manufactured by fusing wolframite with soda-ash, lixiviating the product with water, nearly neutralizing the boiling soln. with hydrochloric acid, and crystallizing—*vide supra*, the extraction of tungsten. Aq. soln. of the salt were obtained by E. F. Anthon by saturating a soln. of sodium hydroxide, carbonate, or tungstate with tungstic acid ; by C. Scheibler, O. W. Gibbs, G. von Knorre, and C. Gonzalez, by treating a boiling soln. of sodium tungstate with hydrochloric acid until it is faintly acid to litmus —C. Friedheim and R. Meyer recommended the process for preparing the salt free from molybdenum previously described in connection with the extraction of tungsten ; by V. Forcher, by saturating an aq. soln. of normal sodium tungstate with carbon dioxide ; by G. von Knorre, by mixing soln. of 5·8 grms. of $Na_2O.4WO_3.10H_2O$ and of 2 grms. of $Na_2O.WO_3.2H_2O$; and by E. Schaefer, by the electrolysis of a soln. of sodium tungstate in a compartment cell. The current acts by removing sodium hydroxide from the normal tungstate. A. Lottermoser thus described the process :

> A soln. of 51 grms. of dihydrated normal sodium tungstate in 200 c.c. of water is placed in a 250 c.c. porous pot which stands in a beaker containing 750 c.c. of 0·1*N*-NaOH. An anode consisting of a coil of platinum wire is placed in the porous cell, and the electrolysis carried out with a current of 2 amperes until the sodium hydroxide has increased in concentration by the calculated amount. When this state is reached, the anode solution is allowed to crystallize ; sodium paratungstate separates in large, vitreous crystals.

Several hydrates have been reported to have been obtained from the aq. soln. of sodium paratungstate. If the soln. be evaporated at ordinary or slightly elevated temp., the *octocosihydrate*, $5Na_2O.12WO_3.28H_2O$, or, according to C. Scheibler, $3Na_2O.7WO_3.16H_2O$, is formed. Analyses were reported by A. Laurent, J. C. G. de Marignac, E. Zettnow, O. W. Gibbs, G. von Knorre, C. Friedheim and R. Meyer, and L. A. Hallopeau. E. F. Anthon gave $Na_2O : WO_3 : H_2O = 1 : 2 : 4$; W. Lotz, 3 : 7 : 14 ; and V. Forcher, 2 : 5 : 12. The colourless or white crystals were found by J. C. G. de Marignac to be triclinic pinacoids with the axial ratios $a : b : c = 0·5341 : 1 : 1·1148$, and $\alpha = 93° 56'$; $\beta = 113° 36'$; and $\gamma = 85° 55'$. The habit is usually tabular. C. Scheibler thought that the crystals were monoclinic, and he gave 3·987 for the sp. gr. at 14°. According to E. F. Anthon, J. C. G. de Marignac, and C. Scheibler, the crystals are stable in air, but they effloresce in dried air ; thus, when kept over conc. sulphuric acid for 8 days two-thirds of the water was removed. At 100°, a loss of 10·42 to 12 per cent. was observed. A. Rosenheim found a loss of 24 mols. of water at 100°, and this led him to write the formula $Na_{10}H_4[H_4(WO_4)_6(W_2O_7)_3].24H_2O$, and later, $R_5H_5[H_2(WO_4)_6].nH_2O$; and A. Rosenheim and A. Wolff titrated the salt electrometrically with phenolphthalein as indicator and the results were in accord with this formula. H. Copaux observed a loss of 23 mols. of water at 110° ; 24 mols. at 150° ; 25·6 mols. at 200° ; and 26·6 mols. at 250°. E. F. Anthon, C. Scheibler, and J. C. G. de Marignac observed that almost the whole of the water is expelled at 300°, and the residue forms a clear soln. with water ; at a still higher temp., the salt melts forming a liquid which looks like a yellow oil. When the cold solid is extracted with water, there remains insoluble $Na_2O.4WO_3$, and Na_2WO_4 and $2Na_2O.3WO_3.7H_2O$ pass into soln. G. von Knorre said that the salt decomposes into Na_2WO_4 and $Na_2O.4WO_3$ when it is fused. F. Wöhler observed that when the dehydrated salt is heated in hydrogen, it forms a golden-yellow sodium-tungsten bronze; and L. A. Hallopeau observed that if heated with zinc powder, a golden-yellow sodium tungsten bronze is formed, as well as normal zinc tungstate, and, in some cases, tungsten itself. E. F. Anthon said that 100 parts of cold water dissolve 12·5 parts of salt. J. C. G. de Marignac said 8·33 parts, and V. Forcher, 7·94 parts at 22°. E. F. Anthon said that the aq. soln. tastes at first sweet, and then rough and bitter. J. C. G. de Marignac found that soln. of the salt saturated at 35° to 40°, and cooled to 18° to 20°, contain, per 100 parts of water, after standing for different periods of time:

	1	12	77	227	410 days
Salt .	10·81	8·88	9·16	8·40	8·52 parts

When heated, the solubility increases, and a deep-seated change occurs. Thus, a sat. soln. boiled for different periods of time, and cooled to 16° to 20°, contained in 100 parts of water:

	1	2	12	72	222	405 days
Salt .	147·0	109·8	38·6	14·5	10·26	11·36 parts

When these modified soln. are evaporated in air, the residue contains unchanged salt and $3Na_2O.7WO_3.21H_2O$. A. Rosenheim and A. Wolff gave for the solubility, *S* grms. per 100 grms. of soln.:

	0°	12°	21°	30°	40°	49°	59°	64°	73°
S . .	2·15	4·29	7·41	11·15	15·11	20·34	27·90	31·11	36·70

The vap. press. experiments over sulphuric acid of different sp. gr. indicated that there are 4 mols. of constitutional water. E. Wegelin measured the f.p. of soln. of sodium paratungstate, but was unable to decide between the 3 : 7-formula and the 5 : 12-formula. The calculated mol. wt. indicates that the salt in aq. soln. is probably resolved into sodium hydroxide and a metatungstate, and the results slightly favour the 3 : 7-formula. C. Scheibler said that the aq. soln. of sodium paratungstate has a neutral reaction; E. F. Anthon reported that it reddened blue litmus; G. von Knorre, that when freshly prepared, the aq. soln. is neutral, but when boiled and cooled, it is acid to phenolphthalien, and alkaline to tropæolin. It is assumed that when the soln. is kept for a long time, or boiled, it decomposes into normal sodium tungstate and $Na_2O.4WO_3.nH_2O$. H. Schmidt found that the salt can be titrated with a soln. of sodium hydroxide by using phenolphthalein or rosolic acid—*i.e.* aurin—as indicator; the results agreed with the 5 : 12-formula. G. Jander and co-workers' observations on the rate of diffusion, and the $H^{\cdot}$-ion concentration, agree with the assumption that the so-called sodium paratungstate is a hexatungstate. A. Rosenheim and A. Wolff found the eq. conductivity, λ mhos, for 0·1 mol $5Na_2O.12WO_3.nH_2O$ in v litres of water at 25°, to be:

v	32	64	128	256	512	1024
λ Made at 25° .	68·2	69·7	90·8	100·3	110	121·4
λ Boiled . .	89·4	96·6	106·3	116·3	126·6	136·3

J. Eltzbacher obtained much lower results; and A. Junius found that at 25° soln. with a mol of the salt in 25, 50, and 100 litres of water had the respective conductivities 61·2, 71·2, and 78·9 when prepared in the cold, and 82·4, 92·1 and 99·7 when prepared at 100°. R. G. Wells also noted that a change in the conductivity of soln. is produced by pre-heating, and this all agrees with the observations of J. C. G. de Marignac. For the observations of V. I. Spitzin and others on the reduction of sodium paratungstate, *vide supra*, tungsten bronzes. H. Uelsmann studied the action of hydrogen selenide on soln. of sodium paratungstate; and D. Klein, the action of polyhydric alcohols. J. C. G. de Marignac, F. Ullik, and

E. Zettnow observed that if a soln. of this salt be boiled for a long time with tungstic acid, an almost insoluble residue of variable composition is obtained.

With the *octocosihydrate*, $5Na_2O.12WO_3.28H_2O$, just described, C. Scheibler found that if a soln. be crystallized at 80° to 100°, or, according to J. C. G. de Marignac, at 60° to 80°, monoclinic prisms of the *pentacosihydrate*, $5Na_2O.12WO_3.25H_2O$, or $3Na_2O.7WO_3.14H_2O$ (C. Scheibler), with the axial ratios $a:b:c=0{\cdot}8069:1:0{\cdot}5328$, and $\beta=120°\ 10'$, are formed. J. C. G. de Marignac also reported that if the salt be crystallized from its aq. soln. at 100°, triclinic pinacoids of the *henicosihydrate*, $5Na_2O.12WO_3.21H_2O$, are formed. The crystals of octahedral habit have the axial ratios $a:b:c=0{\cdot}8695:1:1{\cdot}2787$, and $\alpha=91°\ 18'$, $\beta=86°\ 16'$, and $\gamma=97°\ 59'$. The salt loses nearly 15 mols. of water or 7·43 to 7·73 per cent. at 100°. While these two hydrates are referred by J. C. G. de Marignac to the 5 : 12-formula, there are two others which he referred to the 3 : 7-formula. If the aq. soln. of the 5 : 12 salt be mixed with some alkali carbonate, triclinic pinacoids of the *hexadecahydrate*, $3Na_2O.7WO_3.16H_2O$, are formed. The axial ratios are $a:b:c=0{\cdot}6836:1:1{\cdot}1802$, and $\alpha=95°\ 3'$, $\beta=123°\ 42'$, and $\gamma=91'\ 53'$. V. Forcher also reported a hydrate of the same composition from a soln. of tungstic acid and sodium carbonate. The salt loses 10·5 per cent. or 12 mols. of water at 100°. J. C. G. de Marignac obtained the *henicosihydrate*, $3Na_2O.7WO_3.21H_2O$, by boiling an aq. soln. of sodium paratungstate for a long time, and cooling—if necessary concentrating by evaporation. The triclinic pinacoids have the axial ratios $a:b:c=0{\cdot}9296:1:0{\cdot}5207$, and $\alpha=92°\ 47'$, $\beta=96°\ 28'$, and $\gamma=89°\ 40'$. This hydrate loses 14 per cent. or 17 mols. of water at 100°. When the hydrate is heated, it melts in its water of crystallization. It seems to dissolve in water more quickly than does the octocosihydrate of the 5 : 12-tungstate.

J. C. G. de Marignac allowed a soln. of ammonium paratungstate mixed with an excess of sodium paratungstate to crystallize, and obtained a crop of rhombic plates of **ammonium sodium 1 : 3-paratungstate,** $15(NH_4)_2O.5Na_2O.48WO_3.48H_2O$, followed by a mixture of this salt with the 3 : 2-paratungstate, and finally, the latter salt alone. The **ammonium sodium 3 : 2-paratungstate,** $3(NH_4)_2O.2Na_2O.12WO_3.15H_2O$, was also obtained by L. A. Hallopeau by adding ammonia, drop by drop, to a conc. soln. of sodium paratungstate, and concentrating the liquid for crystallization. J. C. G. de Marignac said that the crystals are rhombic bipyramids with the axial ratios $a:b:c=0{\cdot}9014:1:1{\cdot}4468$. L. A. Hallopeau added that 12 mols. of water are lost at 100°. W. Lotz found that if a soln. of a mol of normal sodium tungstate be poured into a boiling soln. of 4 mols of ammonium chloride, crystals of **ammonium sodium 4 : 1-paratungstate,** $4(NH_4)_2O.Na_2O.12WO_3.5H_2O$, are formed. The scaly crystals of the *pentahydrate* have a mother-of-pearl lustre ; A. Laurent represented it as a *heptahydrate ;* G. von Knorre represented it as a *tridecahydrate* ; and O. W. Gibbs reported a tetradecahydrate to be formed by adding a soln. of phosphoric acid neutralized by ammonia to an aq. soln. of normal sodium tungstate ; and L. A. Hallopeau, by adding an excess of ammonia to a conc. soln. of sodium paratungstate. The rhombic prisms lose 12 mols. of water at 100°. G. von Knorre reported the salt $2(NH_4)_2O.Na_2O.7WO_3.9H_2O$ to be formed in white scaly crystals from a soln. of a mol of sodium paratungstate and 2 mols of ammonium chloride, at 70°.

O. W. Gibbs reported **potassium paratungstate,** $5K_2O.12WO_3.10H_2O$, to be formed by boiling sodium decatungstate with potassium bromide or nitrate. The *decahydrate* forms a white, crystalline precipitate. He also said that a soln. of normal potassium tungstate is decomposed by boiling water with potassium hydroxide and paratungstate. E. Zettnow treated a soln. of sodium dodecatungstate with potassium nitrate and said that on crystallization the *tetradecahydrate,* $5K_2O.12WO_3.14H_2O$, or $3K_2O.7WO_3.8H_2O$, is formed. C. Scheibler, however, could obtain only the *henahydrate,* $5K_2O.12WO_3.11H_2O$, or $3K_2O.7WO_3.6H_2O$, by this process. A. Laurent's analysis agreed with that of

J. C. G. de Marignac. E. F. Anthon gave the formula $K_2O.2WO_3.2H_2O$, and A. Riche, $K_2O.2WO_3.3H_2O$. Analyses were also made by G. von Knorre, and E. Schaefer. E. F. Anthon prepared the henahydrate by boiling the dihydrate with a little water, filtering, and cooling; and also by adding tungstic acid to a boiling, aq. soln. of potassium hydroxide, carbonate, or normal tungstate so long as it dissolves, boiling the filtered soln., and cooling—C. Scheibler added that the mother-liquor contains metatungstate. A. Riche, and J. C. G. de Marignac prepared the salt by treating the normal tungstate with an acid, say by passing carbon dioxide through a filtered soln. obtained by melting wolframite with two-thirds its weight of potassium carbonate, and extracting the product with boiling water—C. Scheibler said that the extraction is best conducted by slowly adding the finely-powdered mass to boiling water. G. von Knorre said that this salt is obtained as a white precipitate by adding acetic acid to a conc. soln. of the normal tungstate—J. Lefort thought that the product is a ditungstate. E. Schaefer obtained it by electrolysis as indicated in connection with sodium paratungstate. J. C. G. de Marignac said that the thin six-sided plates are triclinic pinacoids with the axial ratios $a:b:c=0{\cdot}9137:1:1{\cdot}1362$, and $\alpha=65°\ 36'$, $\beta=117°\ 22'$, and $\gamma=115°\ 39'$; and they are isomorphous with the ammonium salt. The salt is stable in air; A. Riche said that the salt loses no water at 120°, and is dehydrated at 200°; and G. von Knorre said that only 1·44 per cent. of water is lost at 100°, and after heating for a long time at 200°, it retains one per cent. of water. H. Copaux observed that after heating to 110°, the salt retains 5·4 mols. of water; at 150°, 4·4 mols.; at 200°, 2·4 mols.; and at 250°, 1·4 mols. E. F. Anthon found that the dehydrated salt becomes yellow when heated, and melts below a red-heat to form a yellowish liquid which, when cooled, solidifies to a bluish or greenish, crystalline mass. G. von Knorre added that when the salt is fused, it forms the 5 : 14- and the normal tungstate. E. F. Anthon said that the salt is more easily soluble in hot than in cold water, and that the soln. reddens litmus, and has a rough and bitter taste. 100 parts of water at 16° dissolve one part of salt, and at 100°, 11·6 parts; on the other hand, J. C. G. de Marignac found that 100 parts of cold water dissolve 2·15 parts of salt, and with boiling water 6·6 parts of salt. If the crystalline powder be shaken for many days with water at 20°, 100 parts of water dissolve 1·4 parts of salt; if the salt be boiled many days with water, 100 parts of water at 18° contain 17·8 parts of salt, and on evaporating the liquid in dry air, it furnishes a white, amorphous mass. If the salt be kept in a closed vessel for many days, it seems to decompose forming a more soluble variety since after keeping for 1, 26, 153, and 334 days, the respective solubilities per 100 parts of water are 17·8, 8·4, 6·4 and 6·4. A. Rosenheim and A. Wolff found that when the sodium salt is boiled with arsenious oxide, and the soln. treated with potassium chloride, **potassium arsenitotungstate** is formed, $7K_2O.As_2O_3.18WO_3.24H_2O$; and similarly, with antimonious oxide, **potassium antimonitotungstate,** $8K_2O.Sb_2O_3.19WO_3.37H_2O$, was formed; and similarly with salts of other bases—ammonium, guanidine, barium, etc.

E. Schaefer fused an equimolar mixture of rubidium carbonate and tungsten trioxide, extracted the cold product with water, and boiled the liquid with enough hydrochloric acid to prevent blue litmus becoming red. On cooling, the liquid deposits white, **rubidium paratungstate,** $5Rb_2O.12WO_3.18H_2O$. When strongly heated, the salt melts and some rubidium is lost by volatilization. The salt is less soluble in water. The powdered salt is decomposed by evaporation with aqua regia a number of times.

C. Gonzalez prepared **copper paratungstate,** $5CuO.12WO_3.33H_2O$, or $3CuO.7WO_3.19H_2O$, from soln. of sodium paratungstate and copper sulphate; and G. von Knorre recommended using an excess of copper sulphate—say one mol of tungstate and 3 mols of the copper salt—at 70°. The bluish-green, microcrystalline precipitate does not melt at a red-heat, but after the ignition it is lemon-yellow. The salt is insoluble in water, but dissolves in water containing a few drops of nitric acid, and the clear soln. gelatinizes after standing for some time. If equimolar proportions of the tungstate and copper salt be mixed in soln., at 70°, G. von Knorre found that **sodium copper paratungstate,** $3Na_2O.3CuO.14WO_3.32H_2O$, is formed, as a green crystalline precipitate; and C. Gonzalez obtained pale blue needles of $4Na_2O.CuO.12WO_3.32H_2O$, by adding a soln. of copper sulphate to a boiling soln. of sodium paratungstate so long as the precipitate redissolves. The slightly turbid liquid is filtered rapidly, washed with cold water, and dried in air. It melts at a red-heat. According to S. Traverso, **cupro-scheelite** can be regarded as a **calcium copper tungstate,** and a variety from Villa Salto, Sardinia, corresponds with $2CaWO_4.CuWO_4$. I. Domeyko also found a variety at Llamuco, Chili; and J. D. Whitney, at La Paz, California. C. Gonzalez prepared **silver paratungstate,** $5Ag_2O.12WO_3.28H_2O$, by adding a soln. of silver nitrate to one of sodium paratungstate. The white, crystalline *octocosihydrate* becomes grey when dried at 60°, and is then an *octohydrate*. The salt melts at a red-heat, and solidifies on cooling to a mass of tabular crystals.

According to G. von Knorre, if a soln. of sodium paratungstate be treated with an excess of calcium chloride, a voluminous, white precipitate is formed, which, when digested with the mother-liquor, becomes granular and crystalline; when washed and dried, it is **calcium paratungstate,** $3CaO.7WO_3.18H_2O$. It does not melt at a red-heat; and at 100°, it loses 8·03 per cent. of water. It is more soluble than the strontium and barium salts. According to C. Gonzalez, if the aq. soln. of calcium chloride be added until the precipitate first formed no longer dissolves, and the slightly turbid soln. be rapidly filtered, white crystals of **sodium calcium paratungstate,** $3Na_2O.2CaO.12WO_3.34H_2O$, are formed. G. von Knorre prepared **strontium paratungstate,** $3SrO.7WO_3.16H_2O$, by the method used for the calcium salt. A. Rosenheim and A. Wolff gave for the strontium salt $5SrO.12WO_3.28H_2O$. W. Lotz also obtained it by mixing soln. of ammonium paratungstate and strontium chloride. It does not fuse at a red-heat; at 100°, it loses 8·53 per cent. of water, and 13·27 per cent. at a red-heat. C. Gonzalez prepared **sodium strontium paratungstate,** $Na_2O.4SrO.12WO_3.29H_2O$, as in the case of the calcium strontium salt. The white, scaly crystals do not melt at a red-heat. G. von Knorre prepared **barium paratungstate,** $3BaO.7WO_3.16H_2O$, by the method employed for the calcium salt. A. Rosenheim and A. Wolff gave for the barium salt $5BaO.12WO_3.28H_2O$. It loses 8·8 per cent. of water at 100°, and when dried over sulphuric acid, 8 mols. It is insoluble in cold water, and slightly soluble in hot water. W. Lotz obtained the *octohydrate* from soln. of barium chloride, and ammonium paratungstate. It loses 3·29 per cent. of water at 100°. This salt was also prepared by L. A. Hallopeau. C. Scheibler found that microscopic plates of **sodium barium paratungstate,** $3Na_2O.2BaO.12WO_3.24H_2O$, or $2Na_2O.BaO.7WO_3.14H_2O$, separate when an excess of baryta-water is added to a boiling soln. of sodium paratungstate, and the liquid cooled. This salt was also prepared by L. A. Hallopeau.

G. von Knorre prepared **magnesium paratungstate,** $3MgO.7WO_3.24H_2O$, by adding a soln. of a mol of sodium paratungstate to a soln. of an excess (3 mols) of magnesium sulphate. The white, crystalline powder is sparingly soluble in cold water, and more soluble in hot water; it is decomposed by acids. W. Lotz, and J. C. G. de Marignac prepared **ammonium magnesium paratungstate,** $2(NH_4)_2O.3MgO.12WO_3.24H_2O$, by mixing hot, conc. soln. of magnesium sulphate and ammonium paratungstate. No precipitation occurs with cold soln. The small, rhombic crystals are sparingly soluble in water. G. von Knorre obtained a white crystalline mass of **sodium magnesium paratungstate,** $3Na_2O.3MgO.14WO_3.33H_2O$, by mixing soln. of 20 grms. of hydrated sodium paratungstate in 15 c.c. of water at 70°, and 2·3 grms. of hydrated magnesium sulphate in 10 c.c. of water. L. A. Hallopeau also obtained **potassium magnesium paratungstate,** $5(\frac{2}{3}K_2O.\frac{1}{3}MgO).12WO_3.24H_2O$, by mixing equimolar proportions of soln. of potassium paratungstate, and magnesium sulphate, and concentrating the soln. The salt, recrystallized from hot water, forms microscopic prisms, almost insoluble in cold water. The crystals lose 17 mols. of water at 100°. C. Gonzalez obtained white needles of **zinc paratungstate,** $5ZnO.12WO_3.37H_2O$, by treating an excess of a soln. of a zinc salt with one of sodium paratungstate. A. Rosenheim and A. Wolff gave $5ZnO.12WO_3.35H_2O$. The salt dissolves in water acidified with a few drops of nitric acid, but the clear soln. soon gelatinizes. W. Lotz prepared **ammonium zinc paratungstate,** $(NH_4)_2O.2ZnO.7WO_3.13H_2O$, in snow-white needles, by adding ammonium paratungstate to a soln. of zinc sulphate. The salt is soluble in boiling water, and more soluble in water containing ammonium tungstate, or oxalic, tartaric, or phosphoric acid. The salt loses 8 mols. of water at 100°. G. von Knorre found that a boiling soln. of a mol of sodium paratungstate and 2 mols of zinc sulphate deposits white needles of **sodium zinc paratungstate,** $Na_2O.2ZnO.7WO_3.15H_2O$, on cooling. The salt is sparingly soluble in cold water; and is decomposed by mineral acids. L. A. Hallopeau obtained a **potassium zinc paratungstate** by precipitation from potassium paratungstate by means of zinc sulphate. C. Gonzalez prepared **cadmium paratungstate,** $5CdO.12WO_3.16H_2O$, as a white crystalline precipitate by the method employed for the zinc salt. W. Lotz treated cadmium sulphate with ammonium paratungstate and obtained white needles of **ammonium cadmium paratungstate,** $3(NH_4)_2O.12CdO.35WO_3.35H_2O$. The voluminous precipitate becomes grey when heated, then orange-yellow, and on cooling pale yellow. 12 mols. of water are expelled at 100°. G. von Knorre prepared the **sodium cadmium paratungstate,** $Na_2O.2CdO.7WO_3$, as in the case of the corresponding zinc salt. For **mercurous paratungstate,** *vide infra,* mercurous metatungstate.

W. Lotz reported **aluminium paratungstate,** $Al_2O_3.7WO_3.9H_2O$, to be formed as a white, caseous precipitate, by mixing soln. of ammonium paratungstate and an aluminium salt. The precipitate dissolves in an aq. soln. of alum. E. Schaefer added an excess of a soln. of thallous sulphate to one of sodium paratungstate and obtained a white precipitate of **thallous paratungstate,** $5Tl_2O.12WO_3.9H_2O$; it loses its water when dried in a desiccator, and melts at a red-heat with the volatilization of some thallium. It is insoluble in water but soluble in soln. of alkali carbonate or hydroxide, and it is decomposed by mineral acids. C. Gonzalez could not prepare thallous paratungstate. For **cerous, lanthanum, didymium, gadolinium, yttrium, and ytterbium paratungstates,** *vide supra,* the rare earth tungstates.

W. Lotz, and J. J. Berzelius obtained **lead paratungstate,** $3PbO.7WO_3.10H_2O$, by treating a soln. of a lead salt with one of ammonium paratungstate, washing the precipitate by decantation; and drying it in air. The white, powdered *decahydrate* forms the trihydrate when dried at 100°, and it becomes sulphur-yellow, and anhydrous after heating to redness. The hydrate is insoluble in water, and in soln. of ammonium paratungstate and of lead nitrate, but it is soluble in soda-lye, and boiling phosphoric acid. C. Gonzalez obtained white needles of **sodium lead paratungstate,** $4Na_2O.PbO.12WO_3.29H_2O$, by adding a soln. of a lead salt to a boiling soln. of sodium paratungstate until the precipitate no longer redissolves; the faintly turbid soln. is filtered and allowed to stand for a few hours. The salt melts at a red-heat.

W. Lotz reported **chromium paratungstate,** $Cr_2O_3.7WO_3.nH_2O$, by mixing soln. of sodium paratungstate and chromic chloride. The pale greyish-green powder after calcination appears straw-yellow with a tinge of green. When dried at 100° after calcination it loses 9 mols. or 8·06 per cent. of water. The compound is insoluble in water or a soln. of acid ammonium tungstate, but soluble in a soln. of chromic chloride. W. Lotz, and E. F. Anthon found that **manganese paratungstate,** $5MnO.12WO_3.18H_2O$, or $3MnO.7WO_3.11H_2O$, is precipitated by adding sodium paratungstate to a manganous salt. The white powder has a yellow tinge, and when heated to redness, it loses its water, and becomes yellow. When the octodecahydrate is dried over conc. sulphuric acid, it loses 2·79 per cent. or about 5 mols. of water. E. F. Anthon represented the salt by the formula $MnO.2WO_3.3H_2O$, and he said that it is soluble in phosphoric, nitric, or oxalic acid. When the soln. in nitric acid is boiled, yellow tungstic acid separates out. C. Gonzalez said that the precipitate is the *tetratriacontahydrate,* $3MnO.7WO_3.20H_2O$, or $5MnO.12WO_3.34H_2O$. G. von Knorre prepared white or pale yellow crystals of **sodium manganous paratungstate,** $3Na_2O.3MnO.14WO_3.36H_2O$, by mixing soln. of equimolar proportions of manganous sulphate and sodium paratungstate at 70°. Part of the salt separates out at once, and part separates gradually as the soln. cools. L. A. Hallopeau obtained **potassium manganous paratungstate,** $3K_2O.2MnO.12WO_3.16H_2O$, by mixing equimolar soln. of manganous sulphate, and potassium paratungstate. The white precipitate has a tinge of yellow, and it consists of microscopic, rhombic prisms, which lose about 10 mols. of water at 100°. The salt is insoluble in water. A. Rogers and E. F. Smith's **ammonium manganic paratungstate** is described in connection with the normal tungstates.

E. F. Anthon observed that a soln. of ammonium paratungstate precipitates yellow **ferrous paratungstate** from a soln. of ferrous chloride. C. Gonzalez prepared **cobaltous paratungstate,** $3CoO.7WO_3.25H_2O$, by adding a boiling soln. of sodium paratungstate to one of cobalt sulphate. If the admixing is reversed, some double salt may be formed. The oily, viscid mass forms, on cooling, a pale rose-coloured, microcrystalline powder ; it does not melt at a red-heat, and when the ignited salt is cooled, it is blue. As just indicated, if cobalt sulphate be added to sodium paratungstate, in boiling soln., **sodium cobaltous paratungstate,** $3Na_2O.2CoO.12WO_3.30H_2O$, separates out if the filtered soln. is allowed to stand for a few hours. The rose-red crystals become bluish-green after ignition, and they melt at a red-heat. E. F. Anthon, and W. Lotz prepared **nickelous paratungstate,** $3NiO.7WO_3.14H_2O$, by adding a soln. of alkali paratungstate to one of a nickel salt ; the pale green precipitate dries to a pale green powder. E. F. Anthon represented it by the formula $NiO.2WO_3.4H_2O$, but W. Lotz showed that it is a paratungstate. When heated to redness, the salt becomes brown, and sinters. The original salt is insoluble in water, sparingly soluble in oxalic acid, and soluble in warm phosphoric acid, and in acetic acid. A. Wolff, and A. Rosenheim and A. Wolff described an **ammonium ferric paratungstate,** $3(NH_4)_2O.Fe_2O_3.12WO_3.27H_2O$, as well as **guanidinium ferric paratungstate,** $2{\cdot}5(CN_3H_6)_2O.Fe_2O_3.12WO_3.17H_2O$.

§ 15. The Metatungstates, and Tetratungstates

F. Margueritte[1] boiled hydrated tungsten trioxide with an aq. soln. of ammonium tungstate or ammonia; some tungsten trioxide may separate from the soln. on cooling and evaporation, but afterwards the so-called **ammonium metatungstate,** $(NH_4)_2O.4WO_3.8H_2O$, is formed. A. Laurent as well as A. Riche, and V. Forcher boiled a soln. of ordinary or less acid ammonium tungstates for many hours, and obtained this salt by cooling the liquor. W. Lotz added that the conversion to metatungstate is incomplete after the soln. has been boiled for many days. T. M. Taylor boiled a soln. of the paratungstate for 2 or 3 days, and obtained the salt by evaporation—*vide infra*, the hexatungstate. A. Laurent treated an aq. soln. of ammonium tungstate with dil. nitric acid, and evaporated the filtered soln.; W. Lotz added that it is difficult to free the product from ammonium nitrate. C. Scheibler heated between 250° to 300° a thin layer of crystalline ammonium tungstate in a porcelain dish so long as ammonia is given off; and an aq. soln. of the residue after filtration furnishes crystals of this salt. T. M. Taylor heated ammonium paratungstate for 4 hrs. at 150° and obtained the metatungstate. E. F. Smith recommended saturating a hot soln. of purified ammonium paratungstate with a warm emulsion of tungstic acid; and concentrating the filtrate either at 70°, or spontaneously at ordinary temp. Methods of preparation were also described by J. Persoz, G. N. Wyrouboff, and J. C. G. de Marignac. Analyses were made by J. C. G. de Marignac, A. Laurent, W. Lotz, A. Riche, C. Scheibler, J. Persoz, F. Margueritte, and H. Copaux. F. Margueritte represented his results by $(NH_4)_2O.3WO_3.5H_2O$; A. Laurent, by $5(NH_4)_2O.H_2O.18WO_3.30H_2O$; W. Lotz, by $2(NH_4)_2O.8WO_3.5H_2O$; and C. Scheibler, by $(NH_4)_2O.4WO_3.8H_2O$. The best representative formula is based on the hypothesis that the parent acid is $H_{10}[H_2(W_2O_7)_6]$, and the octohydrated ammonium salt is symbolized $(NH_4)_6H_4[H_2(W_2O_7)_6].5H_2O$. If this hypothesis be correct, then the anhydrous salts $R_2O.4WO_3$ are not metatungstates at all, and can be provisionally regarded as tetratungstates. J. C. G. de Marignac found that when alcohol is added to a hot aq. soln. of ammonium metatungstate, monoclinic prisms of the *hexahydrate* are formed; the axial ratios are $a:b:c=0·8121:1:0·7963$, and $\beta=95° 9'$; the salt loses nearly 5 mols. of water at 100°; and the aq. soln. has a neutral reaction. A. Riche reported a *tetrahydrate*, but J. C. G. de Marignac showed that the product was probably a silicotungstate.

F. Margueritte, A. Laurent, C. Scheibler, and A. Riche described the colourless crystals of ammonium metatungstate as regular octahedra; W. Lotz, as tetragonal crystals, which, according to G. N. Wyrouboff, have the axial ratio $a:c=1:0·9747$. H. Copaux gave 1 : 1·012 for the axial ratio, and added that they are isomorphous with $5(NH_4)_2O.B_2O_3.24WO_3.52H_2O$. G. N. Wyrouboff found that the crystals are isomorphous with those of the metatungstates of sodium, cadmium, and manganese. The birefringence is strong and positive. C. Scheibler found that the crystals effloresce rapidly in air; F. Margueritte, and A. Riche, that they melt in their water of crystallization; and T. M. Taylor, that they begin to give off ammonia at 120°. The salt loses about 7 mols. of water at 100°, but the remaining mol. cannot be expelled below 200°. The residue remaining after the expulsion of water at 100°, namely, $(NH_4)_2O.4WO_3.H_2O$, or $2NH_4OH.4WO_3$, is the most stable form of the ammonium tungstates, and T. M. Taylor represented the ammonium tungstates as salts containing this as a nucleus. W. Lotz said that 12·17 per cent. of water is lost at 100°; G. N. Wyrouboff, 7 mols. at 105°; J. C. G. de Marignac, 10·84 per cent. or about 7 mols.; A. Laurent, 11 per cent. at 200°; and A. Riche, 10·95 per cent. at 100° or in vacuo. The salt is freely soluble in water—thus A. Riche found that 100 parts of water at ordinary temp. dissolve nearly 300 parts of the salt; and W. Lotz, 117·6 parts at 15°. The solubility increases rapidly with a rise of temp., and W. Lotz found that the soln. sat. at 40° is almost solid at ordinary temp. C. Scheibler said that the aq. soln. has a high index of refraction; and J. C. G. de Marignac, that it is almost neutral; conc. hydrochloric acid precipitates ammonium chloride and the 3 : 16-tungstate. V. I. Spitzin and L. Kaschtanoff found that with hydrogen chloride, tungsten dioxydichloride and sodium ditungstate are formed, and the latter then reacts as previously indicated. A. Riche found that hydrogen sulphide forms a soluble sulpho-salt; and W. Lotz, that ammonia transforms the salt in soln. into ordinary ammonium tungstate. T. M. Taylor found that when ammonia is passed over ammonium metatungstate at ordinary temp., needle-like crystals of ammonium tungstate are formed; and at 100°, plates of the paratungstate are formed. W. Lotz said that ordinary alcohol dissolves a little metatungstate, but absolute alcohol dissolves none; and J. C. G. de Marignac added that alcohol precipitates the metatungstate from its hot, aq. soln. A. Riche found that the salt is insoluble in ether. W. Lotz observed that with potassium ferrocyanide and hydrochloric acid, no precipitation occurs; and in opposition to a statement of F. Margueritte, alkali hydroxides or carbonates give no precipitate when added to the aq. soln. of the salt; silver nitrate gives a precipitate when ammonia is also added, and the precipitate is soluble in hot water. When ammonium or sodium metatungstate is gently heated with sodium chromate, E. F. Smith found that the filtered soln., on standing, deposits crystals of $4Na_2O.10WO_3.23H_2O$, and sodium molybdate also gives the corresponding salt. No tungsten trioxide is formed by heating the product to 250° in dry hydrogen chloride. No complex $m Na_2MoO_4.n Na_2W_4O_{13}$ was formed.

C. Scheibler obtained **lithium metatungstate,** $Li_2O.4WO_3.nH_2O$, by the action of a soln. of lithium carbonate on an excess of hydrated tungsten trioxide, and by the action of lithium sulphate on a soln. of the barium salt. The evaporation of the aq. soln. furnishes a non-crystallizable syrup. F. Hoermann, Fig. 25, found that the salt has an incongruent m.p. at 800°. G. von Knorre fused together a mixture of 5 mols of lithium carbonate and 12 mols of tungsten trioxide, and extracted the mass with boiling water. There remained needle-like prisms of **sodium tetratungstate,** $Li_2W_4O_{13}$—*vide supra*, O. Brunner on the tungsten bronzes. C. Scheibler obtained **sodium tetratungstate,** $Na_2O.4WO_3$, by heating the coarsely powdered paratungstate to redness, and extracting the mass with hot water; there remained thin scales of this salt. At a much higher temp., the paratungstate partly sinters, and forms bluish-green plates or cubes. F. Hoermann, Fig. 25, found that the salt has an incongruent m.p. at 784°. G. von Knorre said that if the metatungstate be melted, and afterwards extracted with water, there remains the octotungstate. C. Friedheim said that if the salt be dried at 110° to 120°, and then treated with water, normal sodium tungstate passes into soln. C. Scheibler, J. Eltzbacher, and H. Copaux prepared **sodium metatungstate,** $Na_2O.4WO_3.10H_2O$, by boiling an aq. soln. of the paratungstate with an excess of hydrated tungsten trioxide until the filtered soln. no longer gave a precipitate with hydrochloric acid. According to E. Wegelin, a reversible reaction is involved: $3Na_2W_4O_{13}.Aq.+5H_2O \rightleftharpoons 5H_2WO_4+3Na_2O.7WO.Aq.$ The aq. soln. was then concentrated over a water-bath, and allowed to crystallize over conc. sulphuric acid. C. Scheibler also prepared the metatungstate by treating a sat. aq. soln. of normal sodium tungstate with a large excess of conc. acetic acid. A heavy, oily layer of a conc. soln. of the metatungstate settles at the bottom of the vessel. F. Margueritte added a mineral acid to a conc. soln. of the paratungstate until the precipitate no longer redissolved. V. Forcher observed that this mode of preparation is not so good as that of C. Scheibler. E. F. Smith recommended the following process :

> First purify ordinary sodium paratungstate by about a dozen recrystallizations from aq. soln. Heat the aq. soln. at 70° to 75°, and add an emulsion of tungstic acid at 65° to 70°. When the soln. on agitation dissolves no more tungstic acid, it is allowed to stand overnight and filtered. The colourless, clear liquid is then evaporated at a temp. not exceeding 70°, and, when sufficiently concentrated, allowed to remain in the cold. Colourless crystals are formed, which, on placing between the finger and thumb, exhibit none of the stickiness which occurs when impure sodium paratungstate has been used. A soln. of the salt, recrystallized from water, should give no permanent precipitate when treated with a slightly acidulated soln. of barium chloride.

A. Lottermoser prepared the alkali metatungstates by the electrolysis of an aq. soln. of the normal tungstate in a partitioned cell until the anode liquor contained sufficient tungstic acid to form the metatungstate. The salt was analyzed by C. Scheibler, and V. Forcher ; R. C. Wells' analysis of a sample gave $3Na_2O.8WO_3.17H_2O$. E. F. Smith found that the composition of the dehydration product agrees with the formula $5(Na_2O.WO_3).7(H_2O.WO_3).21H_2O$. The colourless, octahedral crystals were considered by C. Scheibler to belong to the cubic system ; but C. F. Rammelsberg showed that they are tetragonal bipyramids with the axial ratio $a:c=1:0{\cdot}9930$, and G. N. Wyrouboff added that the salt is isomorphous with the tungstates of ammonium, cadmium, and manganese. The birefringence is fairly strong and positive. A slight reduction of the tungstate, said V. Forcher, may impart a bluish tinge. C. Scheibler gave 3·847 for the sp. gr. at 13° ; M. Soboleff gave 4·04. V. Forcher found the crystals are stable in air, but they effloresce in dry air ; they lose the greater part of their water over sulphuric acid ; when heated, the salt appears yellow, and on cooling, bluish-grey. If the ignited salt be extracted with water, normal sodium tungstate passes into soln. According to C. Friedheim, 7 mols. of water are expelled at 120°, and the remainder at a higher temp.—one mol. of water is still present at 240°. A. P. Sabanéeff made some observations on this subject. E. F. Smith found that the dehydrated salt melts at 706·6°. E. Wegelin found that the effect of the salt on the f.p. of water agrees with the assumption that the mol. wt. is 497 to 502—the theoretical value $Na_2W_4O_{13}$ is 990, so that on this hypothesis the salt furnishes two ions. A. P. Sabanéeff also made determinations of the f.p. of aq. soln. of the salt ; and G. Tammann found that the vap. press. of soln. of 24·01, 89·90, and 332·8 grms. of $Na_2W_4O_{13}$ in 100 grms. of water are respectively 6·4, 19·0, and 132·2 mm. lower than the value for water alone. M. Soboleff found the eq. electrical conductivity of soln. of an eq. of the salt in v litres of water, at 25°, to be :

v . .	32	64	128	256	512	1024
λ . .	89·3	98·7	107·6	116·6	126·0	134·1 mhos.

J. Eltzbacher's values are probably too low. A. Rosenheim and F. Kohn found $\lambda_{1024}-\lambda_{32}=38{\cdot}4$. E. Wegelin found that on electrolysis of aq. soln., the hydrogen and oxygen are given off in the proportions 2 : 1 in agreement with the assumption that no pertungstate is formed. The salt is extremely soluble in water. V. Forcher found that 100 parts of water at 19° dissolve 512 parts of salt ; and C. Scheibler, that 100 parts of water at 13° dissolve 1069 parts of salt, and the sp. gr. of the soln. is 3·02. The aq. soln. has a bitter taste, and it shows the ordinary reactions of the metatungstate. It gives precipitates with salts of the metals. F. Margueritte said that acidic soln. of the salt yield plates of the *trihydrate*, but this has not been confirmed. According to C. Schön, if cotton be worked in a 5 per cent. soln. of sodium metatungstate, it rapidly becomes blue when exposed to light, owing to the reduction of the compound. In a dark room the fabric again becomes white, the blue colour reappearing on renewed exposure to light. On treating the blue fabric with water a blue soln. is obtained, which, on the addition of lead acetate, gives a blue precipitate. Both the soln. and precipitate rapidly become colourless, even in full daylight. A simple soln. of the metatungstate does not change colour. The effect of adding a salt of copper to the metatungstate is to retard though not to prevent the action of light; fabrics prepared with metatungstate and a copper salt become at first yellower and then slowly bluer. The reducing action of light is partly overcome by the oxidizing properties of the copper salts. The observations of T. Graham, W. Biltz and A. von Vegesack, A. P. Sabanéeff, and N. Pappada on colloidal soln. of the salt have been discussed in connection with colloidal tungstic acid (*q.v.*). A. Rosenheim and F. Kohn treated 5 c.c. of $\frac{1}{10}N$-$H_2W_4O_{13}$ with increasing sp. conductivity at 25°. The results are summarized in Fig. 50. The results show that there is a definite break with the addition of 2 mols. of NaOH to a mol. of $H_2W_4O_{13}$ corresponding with the formation of $Na_2O.4WO_3$; and also a feeble change of curvature corresponding with the conversion of the metatungstate into normal tungstate. For the observations of V. I. Spitzin and others on the reduction of the tetratungstates, *vide supra*, tungsten bronzes. W. I. Baragiola obtained octahedral crystals of what is probably an isomorphous mixture, **ammonium sodium 1 : 3-metatungstate,** $(NH_4)_2O.3Na_2O.16WO_3.38H_2O$, from a soln. of ammonium and sodium metatungstates—the latter in excess. J. Lefort studied the action of quinine on the alkali metatungstates. The methods of preparing aq. soln. of **potassium metatungstate,** $K_2O.4WO_3.nH_2O$, are similar to those employed for the sodium salt. Several hydrates have been reported. C. Scheibler obtained the *octohydrate*, $K_2O.4WO_3.8H_2O$, by crystallization from an aq. soln. of the salt, according to H. Copaux, at a low temp.; or, according to C. Scheibler, from the mother-liquor obtained in preparing the paratungstate. G. N. Wyrouboff said that the octahedral crystals belong to the tetragonal system. They quickly effloresce in air, and lose 7 mols. of water at 100°. Along with the octahedral crystals, C. Scheibler, and J. C. G. de Marignac observed some acicular crystals which may be one of the lower hydrates. J. C. G. de Marignac prepared the *pentahydrate*, $K_2O.4WO_3.5H_2O$, by treating an aq. soln. of the salt with alcohol. The precipitate dissolves when the soln. is warmed, and on cooling, monoclinic prisms are deposited. They have the axial ratios $a : b : c = 0{\cdot}5945 : 1 : 0{\cdot}6609$, and $\beta = 123°\ 0'$. The birefringence is strong and positive. The hydrate does not effloresce in the cold, but at 100°, it loses 4 mols. of water. The hydrate is freely soluble in water. H. Copaux reported the hemitridecahydrate, $K_2O.4WO_3.6\frac{1}{2}H_2O$, or $6K_2O(3H_2O).24WO_3.36H_2O$, to be deposited from a soln. at 30°. The doubly refracting, hexagonal prisms have the axial ratio $a : c = 1 : 0{\cdot}659$, and they are isomorphous with potassium borotungstate or silicotungstate. The crystals are optically active in having a dextrorotary power for the *D*-line of 9°. H. Copaux also obtained the *octohydrate* from an aq. soln. of this salt at a low temp. Crystals of what were probably potassium metatungstate were also reported by F. Margueritte, A. Riche, and J. Lefort. F. Hoermann found that the tetratungstate has an incongruent m.p. at 930°—Fig. 35. G. N. Wyrouboff reported **rubidium metatungstate,** $Rb_2O.4WO_3.8H_2O$, to be formed by mixing soln. of barium metatungstate and rubidium sulphate, and slowly cooling the concentrated filtrate. The tetragonal, octahedral crystals have the axial ratios $a : c = 1 : 0{\cdot}9702$; and the birefringence is strong and positive. The crystals lose water when exposed to air; about 7 mols. of water are given off at 150°, and all at a much higher temp. 100 parts of cold water dissolve 10 parts of the salt, but warm water dissolves much more.

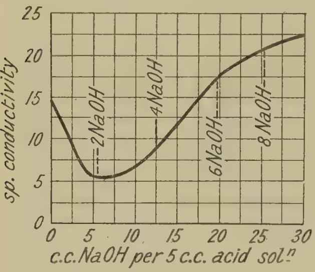

FIG. 50.—The Titration of Metatungstic Acid with Sodium Hydroxide.

C. Scheibler mixed soln. of barium metatungstate and copper sulphate, and obtained from the filtrate what were probably monoclinic plates of **copper metatungstate,** $CuO.4WO_3.11H_2O$. S. H. C. Briggs dissolved 20 grms. of tungsten trioxide in 20 c.c. of a cold, conc. aq. ammonia, and added a soln. of 5 grms. of hydrated copper sulphate in 7·5 c.c. of water and 7·5 c.c. of conc. aq. ammonia; and allowed the filtrate to stand in air. Pale blue needles of **copper hexamminometatungstate,** $CuO.4WO_3.6NH_3.8H_2O$, were formed. The salt is insoluble in water, and almost insoluble in dil. aq. ammonia. C. Scheibler mixed boiling soln. of sodium metatungstate and silver nitrate in equimolar proportions along with a couple of drops of nitric acid; filtered off the normal silver tungstate if necessary, and allowed the soln. to deposit white, octahedral crystals of **silver metatungstate,** $Ag_2O.4WO_3.3H_2O$. A. Rosenheim and F. Kohn, and C. Friedheim also prepared the salt, and found that the white, scaly crystals are almost insoluble in water; they lose 0·65 mol. of water at 110°; 0·87 mol. at 150°; 1·1 mols. at 160°; and 1·3 mols. at 200°. It is therefore assumed that at least 2, possibly 3, mols. of water are intimately associated with the molecule.

C. Scheibler obtained **calcium metatungstate,** $CaO.4WO_3.10H_2O$, from a soln. obtained by digesting hot metatungstic acid with calcium carbonate. G. N. Wyrouboff said that the crystals are triclinic pinacoids—pseudotetragonal—and have the axial ratios $a:b:c=1·0070:1:1·3694$, and $\alpha=91° 1'$; $\beta=93° 0'$; and $\gamma=90° 16'$. Twinning occurs about the (001)-plane. The birefringence is negative and feeble; and the optic axial angle $2E=115°$. C. Scheibler obtained **strontium metatungstate,** $SrO.4WO_3.8H_2O$, in a similar manner. C. Scheibler, and C. F. Rammelsberg described the crystals as tetragonal, but G. N. Wyrouboff showed that they are monoclinic prisms with the axial ratios $a:b:c=1·0556:1:0·7999$, and $\beta=90° 21'$. The birefringence is negative and feeble, and the optic axial angle $2E=93° 40'$. C. Scheibler obtained **barium metatungstate,** $BaO.4WO_3.9H_2O$, by mixing boiling conc. soln. of sodium metatungstate and barium chloride in the presence of a few drops of hydrochloric acid, and cooling. The tritungstate is also deposited as a white powder; this can be removed by levigation, or by recrystallization from water acidulated with hydrochloric acid. E. Zettnow dissolved 42 parts of sodium paratungstate, 15 parts of sodium hydrophosphate, and 15 c.c. of hydrochloric acid of sp. gr. 1·12 in 100 c.c. of water, and then added to the boiling liquid 9 parts of barium chloride. The filtrate was evaporated for crystallization, and the product recrystallized from water 2 or 3 times. L. A. Hallopeau boiled a soln. of paratungstic acid with an excess of barium carbonate, and concentrated the clear liquid in vacuo for crystallization. E. F. Smith found that the dehydration curve agreed with the formula $(BaO.WO_3)_3(H_2O.WO_3).6H_2O$. C. Scheibler, L. A. Hallopeau, and C. F. Rammelsberg described the white crystals as tetragonal octahedra, but G. N. Wyrouboff showed that they are rhombic bipyramids with the axial ratios $a:b:c=0·9962:1:1·5070$. Twinning occurs about the (110)-plane. The optic axial angle $2E=27°$; and the crystals are feebly birefringent. The sp. gr. is 4·298 at 14°. The optical character is positive; the birefringence feeble; and the optic axial angle $2E=27°$. C. Scheibler said that the crystals are stable in air; but L. A. Hallopeau, that they effloresce in air. G. N. Wyrouboff also said that the crystals lose water when exposed to air. They effloresce over conc. sulphuric acid. C. Scheibler found that the crystals lose 8·65 per cent. of water at 100°; L. A. Hallopeau, 9·27 per cent.—the theoretical loss for 6 mols. of water is 8·69 per cent. A. Rosenheim and F. Kohn found that 3 mols. of water are retained by the salt which has been heated over 100°, and that the loss of water at higher temp. is attended by diminished solubility. H. Copaux added that 1·5 mols. of water are retained at 110°, and the weight remains constant at 150°; more water is lost between 200 °and 250°, but about half a mol. is retained at 250°. After calcination the product is yellow and insoluble. The salt is freely soluble in hot water; cold water dissolves the salt with partial decomposition into barium tritungstate and free tungstic acid, but these products recombine if the liquid be heated. The addition of baryta-water to the aq. soln. precipitates normal barium tungstate.

According to C. Scheibler, on mixing soln. of barium metatungstate and silver nitrate, a liquid is obtained which furnishes aggregates of stumpy prisms of **silver barium metatungstate.**

C. Scheibler obtained a syrupy liquid by concentrating the filtrate containing **beryllium metatungstate,** obtained by double decomposition with say beryllium sulphate, and barium metatungstate. The syrup dries to a hard mass. A soln. of **magnesium metatungstate,** obtained in a similar way, furnishes monoclinic prisms of the *octohydrate*, $MgO.4WO_3.8H_2O$, which are stable in air. The axial ratios found by G. N. Wyrouboff are $a : b : c = 0{\cdot}6763 : 1 : 0{\cdot}7792$, and $\beta = 106° 43'$. The optical character is positive, and the optic axial angle $2V = 77° 50'$. Similarly with **zinc metatungstate,** $ZnO.4WO_3.10H_2O$, whose crystals are freely soluble in water. When the water is expelled by calcination at a red-heat, the residue is insoluble in water. If the soln. is crystallized between 6° and 20°, it deposits the *octohydrate*, $ZnO.4WO_3.8H_2O$, in monoclinic prismatic plates which were found by G. N. Wyrouboff to have the axial ratios $a : b : c = 0{\cdot}6626 : 1 : 0{\cdot}7557$, and $\beta = 105° 57'$. They are isomorphous with the corresponding octohydrates of magnesium and nickel metatungstates. The optical character is positive; and the optic axial angle $2H = 123°$. The corresponding **cadmium metatungstate,** $CdO.4WO_3.10H_2O$, was obtained by C. Scheibler in an analogous manner. The salt is stable in air. G. N. Wyrouboff found that the tetragonal, bipyramidal crystals have the axial ratio $a : c = 1 : 0{\cdot}9936$, and they are isomorphous with the corresponding salts of ammonium, sodium, and manganese. The birefringence is positive and strong. C. Friedheim found that the salt is stable in air; and it loses 7 mols. of water between 100° and 110°; and at a dull red-heat, 10 mols. C. Scheibler reported **mercurous metatungstate,** $Hg_2O.4WO_3.25H_2O$, to be formed by adding a soln. of mercurous nitrate to one of a soluble tungstate, or a soln. of tungstic acid; the voluminous, white precipitate becomes lemon-yellow and more compact after washing, and drying in air. C. Friedheim said that only the paratungstate is produced by this process. H. Copaux did not succeed in preparing mercurous metatungstate. Conc. soln. of metatungstic acid and mercurous nitrate give a crystalline powder whether the metatungstate or the mercurous salt be in excess, the composition of the salt is $Hg_2O : WO_3 = 1{\cdot}7 : 4$. He obtained **mercurous nitratometatungstate,** $9Hg_2O.24WO_3.N_2O_5.29H_2O$, which can be represented by the formula $H_2Hg_8[H_4(W_2O_7)_6].HgNO_3.12\frac{1}{2}H_2O$, in which the metatungstic acid has a higher basicity than is usual. G. N. Wyrouboff found that **mercuric metatungstate** prepared by double decomposition, is insoluble. A. Rosenheim and F. Kohn could not obtain a mercuric metatungstate of constant composition.

A. Rosenheim and F. Kohn prepared **thallous metatungstate,** $Tl_2O.4WO_3.3H_2O$, by mixing boiling soln. of eq. proportions of sodium metatungstate and thallous nitrate in the presence of a little nitric acid. The yellowish-white, insoluble, crystalline powder loses 2 mols. of water at 90°. C. Scheibler prepared yellow **cerous metatungstate,** $Ce_2(W_4O_{13})_3.30H_2O$, from a soln. of barium metatungstate and cerous sulphate. G. N. Wyrouboff found that the triacontahydrate is formed in triclinic prisms below 16°, and the heptacosihydrate above 16° in rhombic crystals. The triclinic crystals have the axial ratio $a : b : c = 0{\cdot}9338 : 1 : 0{\cdot}5825$, and $\alpha = 96° 43'$, $\beta = 92° 34'$, and $\gamma = 91° 30'$. The birefringence is strong. G. N. Wyrouboff similarly prepared **lanthanum metatungstate,** $La_2(W_4O_{13})_3.30H_2O$, whose triclinic crystals have the axial ratios $a : b : c = 0{\cdot}9859 : 1 : 0{\cdot}5786$, and $\alpha = 97° 6'$, $\beta = 93° 50'$, and $\gamma = 89° 2'$; and the rose-red rhombic crystals of the corresponding **didymium metatungstate,** $Di_2(W_4O_{13})_3.27H_2O$, have the axial ratios $a : b : c = 0{\cdot}9736 : 1 : 1{\cdot}2952$. The birefringence is positive and strong; and the optic axial angle $2H = 94°$. P. T. Cleve obtained **samarium metatungstate,** $Sa_2(W_4O_{13})_3.35H_2O$, by double decomposition. The crystals are soluble in water. Similarly, A. Cleve obtained **ytterbium metatungstate,** $Yb_2(W_4O_{13})_3.35H_2O$, in prismatic crystals, freely soluble in water.

J. Lefort reported **lead tetratungstate,** $3PbO.4WO_4$, to be formed by pouring a soln. of lead acetate into one of sodium tungstate, washing with water and alcohol, and drying over quicklime and sulphuric acid. The white, amorphous precipitate is stable in air. 100 parts of water dissolve 0·025 part of the salt. C. Scheibler obtained **lead metatungstate,** $PbO.4WO_3.5H_2O$, from soln. of lead acetate and metatungstic acid, or its salts, and drying the washed product in air. C. Friedheim obtained the *pentahydrate* in crystals which slowly effloresce in air, and over sulphuric acid, they lose 3·03 per cent. of water. The aq. soln. is decomposed by hydrogen sulphide; and the salt is dissolved by hot nitric acid. W. Lotz reported the hexahydrate in fine needles, to be formed by adding ammonium metatungstate to a soln. of lead nitrate, and spontaneously evaporating a soln. of the precipitate in much water. E. F. Smith said that if the mixed soln. employed by W. Lotz be not heated, but allowed to evaporate spontaneously, long silky needles of normal lead metatungstate, $PbO.4WO_3.7H_2O$, are formed. According to A. Rosenheim and F. Kohn, lead metatungstate cannot be prepared by saturating metatungstic acid with lead oxide, or by the double decomposition of an alkali metatungstate with a soln. of a lead salt. The products always have a variable composition. They found that W. Lotz's salt, as well as a similar substance obtained by V. Forcher, is **lead nitratometatungstate,** $Pb(NO_3)_2.PbW_4O_{13}.10H_2O$. The white needles lose 7 mols. of water at 100°.

C. Scheibler obtained **manganous metatungstate,** $MnO.4WO_3.10H_2O$, by double decomposition with soln. of barium metatungstate and manganous sulphate; and G. N. Wyrouboff found that the tetragonal octahedra have the axial ratio $a : c=1 : 0·9919$. The birefringence is strong and positive; and the colour by reflected light is dirty rose, and by transmitted light, amber-yellow. The crystals are isomorphous with those of the analogous sodium and cadmium salts. The salt remains unchanged in air, but loses 10·61 per cent. or 7 mols. of water at 105°. C. Scheibler found that **ferrous metatungstate** can be obtained by dissolving iron in metatungstic acid, but only impure crystals could be prepared from the soln.; while **ferric metatungstate** could not be obtained in a crystalline state. C. Scheibler obtained **cobaltous metatungstate,** $CoO.4WO_3.9H_2O$, by double decomposition with soln. of cobaltous sulphate and barium metatungstate; G. N. Wyrouboff found that the garnet-red, rhombic bipyramids have the axial ratios $a : b : c=0·9878 : 1 : 1·3764$. Twinning and trilling occur about the (110)-plane. It is isomorphous with the barium salt with which it forms solid soln. The double refraction is positive; and the optic axial angle $2E=47°$. C. Scheibler prepared **nickel metatungstate,** $NiO.4WO_3.8H_2O$, in an analogous manner; in dark green, monoclinic plates and prisms, which, according to G. N. Wyrouboff, have the axial ratios $a : b : c=0·6555 : 1 : 0·7464$, and $\beta=106° 22'$. The double refraction is positive, and the optic axial angle $2H_a=132°$.

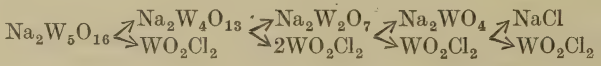
§ 16. The Penta- and Higher Tungstates

F. Jean[1] boiled a soln. of sodium tungstate with ammonium chloride, and obtained **ammonium pentatungstate,** $3NH_4OH.5WO_3$, as a white precipitate. The liquid, though acidic, slowly evolves ammonia. O. W. Gibbs, and J. C. G. de Marignac obtained a pentatungstate, $2(NH_4)_2O.5WO_3.5H_2O$, by dissolving ammonium paratungstate in boiling water, and cooling the soln. J. C. G. de Marignac described the crystals as triclinic pinacoids with the axial ratios $a:b:c=1{\cdot}1204:1:1{\cdot}71900$, and $\alpha=105° 46'$, $\beta=95° 17'$, and $\gamma=90° 1'$. The salt loses approximately 3·5 mols. of water at 100° ; and at ordinary temp., 100 parts of water dissolve 3·45 to 3·85 parts of salt. The aq. soln. is liable to decompose into the paratungstate and ammonia.

G. von Knorre prepared **sodium pentatungstate,** $Na_2O.5WO_3$, by fusing a mixture of a mol of sodium tungstate and two mols of tungsten trioxide, by heating sodium paratungstate to incipient fusion. On extracting the fused mass with cold water, it is left in very brilliant plates or scales. When heated for three hours with water at 150°, but little dissolves, the faintly acid liquid containing tungstate and metatungstate, the latter in by far the larger quantity. J. C. G. de Marignac occasionally obtained crystals of the henahydrate, $2Na_2O.5WO_3.11H_2O$, in the preparation of the paratungstate. The axial ratios of the monoclinic prisms are $a:b:c=0{\cdot}6056:1:0{\cdot}4477$, and $\beta=118° 36'$. J. Lefort, V. Forcher, and O. W. Gibbs seem to have obtained the same salt, which they represented $4Na_2O.10WO_3.22H_2O$, by pouring a cold, sat. soln. of normal sodium tungstate into glacial acetic acid, and washing the sparingly soluble, white, amorphous precipitate with alcohol. J. Lefort found that 100 parts of water at 15° dissolve 16 parts of the salt. O. W. Gibbs' $4Na_2O.10WO_3.23H_2O$ is probably the same salt incompletely dried ; and his $9Na_2O.22WO_3.51H_2O$, a mixture of this salt and the paratungstate. V. I. Spitzin and L. Kaschtanoff found that the action of hydrogen chloride can be represented :



$$Na_2W_5O_{16}\begin{array}{l}\nearrow Na_2W_4O_{13}\\ \searrow WO_2Cl_2\end{array}\begin{array}{l}\nearrow Na_2W_2O_7\\ \searrow 2WO_2Cl_2\end{array}\begin{array}{l}\nearrow Na_2WO_4\\ \searrow WO_2Cl_2\end{array}\begin{array}{l}\nearrow NaCl\\ \searrow WO_2Cl_2\end{array}$$

For the observations of V. I. Spitzin and others on the reduction of sodium pentatungstate, *vide supra*, tungsten bronzes. J. Lefort reported **potassium pentatungstate,** $2K_2O.5WO_3.4H_2O$, to be formed by pouring a conc. soln. of normal potassium tungstate into an excess of glacial acetic acid, and washing the white, amorphous precipitate with alcohol. Prismatic plates are formed when the cold aq. soln. is allowed to stand in a desiccator ; 100 parts of cold water dissolve 5 parts of the salt. When the salt is heated to redness, it becomes yellow and tungsten trioxide is set free. When the aq. soln. is boiled, the ditungstate and tritungstate are formed. O. W. Gibbs prepared this salt in an analogous manner, and also by mixing a cold soln. of the decatungstate with potassium bromide or nitrate; and by evaporating a soln. of normal potassium tungstate and boric acid to dryness, extracting the product with water, and allowing the soln. to crystallize. O. W. Gibbs represented the salt by the formula $4K_2O.10WO_3.9H_2O$. E. Schaefer melted a mol of rubidium carbonate with 3 to 3½ mols of tungsten trioxide and obtained a greenish mass, which was lixiviated with water acidulated with hydrochloric acid. White micaceous plates of **rubidium pentatungstate,** $Rb_2O.5WO_3$, remained. They are almost insoluble in hot water, and are decomposed by aqua regia.

O. W. Gibbs obtained **zinc pentatungstate,** $2ZnO.5WO_3.9H_2O$, which he represented by $4ZnO.10WO_3.18H_2O$, from cold soln. of sodium pentatungstate and zinc sulphate. J. Lefort mixed eq. proportions of mercuric acetate and sodium ditungstate in conc., aq. soln., and obtained a very pale yellow precipitate of **mercuric pentatungstate,** $3HgO.5WO_3.5H_2O$. It resists the action of light. 100 parts of water at 15° dissolve 0·4 part of salt. If a mixed soln. of sodium tritungstate and mercuric acetate be poured into alcohol, and the mixture allowed to stand for some hours, a white precipitate of $HgO.5WO_3.5H_2O$, is formed. It is decomposed by hot and by cold water.

According to J. Lefort, if a mixed soln. of sodium tritungstate and aluminium acetate is poured into alcohol, a white precipitate of **aluminium pentatungstate,** $Al_2O_3.5WO_3.6H_2O$, is formed. When freshly precipitated, it dissolves in water, but it soon decomposes into the tetratungstate and paratungstate. E. F. Smith and H. L. Dieck obtained **chromium pentatungstate,** $Cr_2O_3.5WO_3$, in the form of brown, rhombic needles, when eq. quantities of potassium dichromate and tungsten trioxide are heated together until the mixture fuses and no more gas is evolved. The crystals are not attacked by aqua regia; they were decomposed for analysis by fusion with sodium carbonate and potassium nitrate. J. Lefort obtained the *pentahydrate*, $Cr_2O.5WO_3.5H_2O$, by pouring into alcohol a mixed soln. of sodium tritungstate and chromic acetate. The greenish-white precipitate is considerably altered by cold and particularly by boiling water.

According to T. M. Taylor,[2] C. Scheibler's method of preparing ammonium metatungstate, *viz.*, by heating the paratungstate to 250°, furnishes a colloidal, gummy mass of **ammonium hexatungstate,** $(NH_4)_2O.6WO_3.4$ or $6H_2O$. T. M. Taylor said that to prepare this salt, the needles of the paratungstate are spread out on a watch-glass, and heated in an air-bath at 220° for one hour. The air-bath must allow the escape of water and ammonia. The product is covered with water and boiled vigorously for fifteen or twenty minutes, when a clear, but dark, heavy liquid results. This is filtered away from any residue and on evaporation dries into the gum with an almost quantitative yield. On standing several days in water, the residue will pass into the gum without previous boiling. At higher temp. considerable tungstic acid is separated and the yield is not so good. The metatungstate free from paratungstate must be heated to 250°, before yielding the gum, and the yields are nothing like so large as when the paratungstate salts are taken for the starting-out material. The yellow glass has a high index of refraction; it is miscible with water in all proportions; the aq. soln. has an acidic reaction and readily absorbs ammonia, and when neutralized with $\frac{1}{10}N$-NH_4OH, it forms the metatungstate. F. Margueritte, and A. Laurent mention the hexatungstate. A. W. Leontowitsch could not prepare F. Ullik's octotungstate but obtained instead **sodium hexatungstate,** $Na_2O.6WO_3.15H_2O$; and he obtained the same salt by dissolving 100 grms. of sodium metatungstate in 25 c.c. of water and 11·3 c.c. of hydrochloric acid of sp. gr. 1·124, and allowing the turbid soln. to stand for 4 or 5 hrs. The filtered soln. is allowed to crystallize in an ice-chamber. The sodium chloride is separated by recrystallization many times from water. The doubly refracting crystals are combinations of octahedra and hexahedra. G. Jander and co-workers also prepared $Na_6W_6O_{21}$. J. C. G. de Marignac obtained **potassium hexatungstate,** $K_2O.6WO_3.nH_2O$, as a by-product in preparing potassium metatungstate by the action of the normal tungstate on tungstic acid.

J. C. G. de Marignac obtained **sodium heptatungstate,** $Na_6W_7O_{24}.21H_2O$, by slowly cooling a soln. of sodium paratungstate which had been boiled for a long time. The triclinic pinacoids have the axial ratios $a:b:c=0·9296:1:0·5207$, and $\alpha=92° 47'$, $\beta=96° 28'$, and $\gamma=89° 40'$. The hexadecahydrate was obtained in a similar way with a soln. containing a little sodium carbonate. The triclinic pinacoids have the axial ratios $a:b:c=0·6836:1:1·1802$, and $\alpha=95° 3'$, $\beta=123° 43'$, and $\gamma=91° 53'$.

J. C. G. de Marignac[3] found that on cooling a soln. of ammonium paratungstate in boiling water, part of the unchanged salt crystallizes out, and part appears in tabular crystals of **ammonium octotungstate,** $3(NH_4)_2O.8WO_3.8H_2O$. A. Laurent obtained a similar salt. G. von Knorre obtained **sodium octotungstate,** $Na_2O.8WO_3$, by fusing sodium metatungstate or the tetratungstate, and extracting the fused mass with water. There remain scales or plates of the octotungstate, which are attacked with difficulty by acids or alkalies. F. Ullik prepared the *dodecahydrate* by mixing an aq. soln. of the metatungstate with nitric or hydrochloric acid, and spontaneously evaporating the soln. The crystals are stable in air; they are freely soluble in cold water, and the aq. soln. deposits the salt unchanged. Acids added to the aq. soln. do not give a precipitate. A. W. Leontowitsch could not prepare F. Ullik's salt but obtained instead the hexatungstate. R. C. Wells' analysis of a metatungstate gave the formula $3Na_2O.8WO_3.17H_2O$. L. A. Hallopeau treated sodium paratungstate with ammonia, dissolved the product in water, and allowed the soln. to crystallize—prismatic crystals of **ammonium sodium octotungstate,** $3\{(NH_4)Na\}_2O.8WO_3.11H_2O$, were formed. The crystals lose about 6 per cent. of water at 100°. G. von Knorre obtained steel-grey or bluish-black crystals of **potassium octotungstate,** $K_2O.8WO_3$, as a kind of tungsten bronze (*q.v.*) by electrolyzing a mixture of a mol of potassium carbonate and 3 mols of tungsten trioxide. The sp. gr. of the crystals is 6·53. E. Schaefer reported **rubidium octotungstate,** $Rb_2O.8WO_3$, by fusing a mixture of a mol of rubidium carbonate and 3 to $3\frac{1}{2}$ mols of tungstic acid, powdering the cold product, and then heating it for about three-quarters of an hour in an atm. of coal-gas. The dark-blue product can be purified by boiling it with hydrochloric acid, aqua regia, a soln. of potassium hydroxide or carbonate, and finally with water—*vide supra*, tungsten bronzes.

E. Zettnow obtained **barium octotungstate,** $BaO.8WO_3.8H_2O$, by treating a soln. of sodium paratungstate with phosphoric acid until no precipitation occurs when hydrochloric acid is added; the liquid is then acidified with hydrochloric acid, and treated with barium chloride. Most of the barium remains in soln. as metatungstate, but the remainder is precipitated as a snow-white powder of the octotungstate.

A. Riche studied the action of carbon dioxide on an aq. soln. of normal sodium tungstate, and V. Forcher found that after several days' action, small crystals of **sodium decatungstate,** $4Na_2O.10WO_3.24H_2O$, were formed. These were washed repeatedly with ice-cold water until the filtrate gave no effervescence with hydrochloric acid. J. C. G. de Marignac apparently obtained the same salt but regarded it as a pentatungstate (*q.v.*). O. W. Gibbs added that the action of acetic acid on neutral sodium tungstate is to form the 5 : 12-tungstate, the 9 : 22-tungstate, or the 4 : 10-tungstate, according to the circumstances of the case. The composition of the product depends mainly on the concentration of the acid, and the duration of its action. E. F. Smith thus described his observations:

> 100 grms. of $Na_2WO_4.2H_2O$ were dissolved in 140 c.c. of water and 50 c.c. of glacial acetic acid were gradually introduced into the soln.; the flask was cooled under running water as it became heated. Beautiful white needles separated, but on recrystallization from water the 4 : 10- and 5 : 12-salts were the products. Were the white needles not recrystallized, but simply washed with cold water, and then analyzed, the result approximated closely to the requirements of the formula $9Na_2O.22WO_3.51H_2O$. Many similar trials gave like results, which would mean that the preceding conditions gave in reality

two salts 4 : 10 and 5 : 12. Usually there was a preponderance of the first salt, the 4 : 10-salt, which J. Lefort made as a white, insoluble precipitate, by pouring a sat. soln. of the normal salt into an excess of glacial acetic acid in the cold. This was collected, washed with alcohol, and then dissolved in boiling water. On cooling, it separated in very beautiful, transparent, oblique prisms, unalterable in the air.

E. F. Smith added that the decatungstate is best made by gradually adding formic acid to a soln. of normal sodium tungstate in 100 c.c. of water until the soln. is distinctly acid, and allowing the mixture to stand for crystallization for 24 hrs. The 4 : 10-tungstate was the only product, the presence of the 5 : 12- and of the 9 : 22-tungstates was not observed. The product can be purified by recrystallization from water. The crystals are thought to be monoclinic. The sp. gr. of the salt, by E. F. Smith, is 4·3. The crystals effloresce in dry air, and when the dehydrated salt is redissolved in water much heat is evolved. V. Forcher gave $2Na_2O.5WO_3.12H_2O$ for the formula ; J. C. G. de Marignac, $2Na_2O.5WO_3.11H_2O$; and E. F. Smith, $4Na_2O.12WO_3.23H_2O$. The dehydration curve agrees with the assumption that the salt has 6 mols. of constitutional water, $4(Na_2O.WO_3).6(H_2O.WO_3).17H_2O$. V. Forcher found that the solubility of the salt is 7·94 parts per 100 parts of water at 22° ; J. Lefort, 16 per 100 at 15° ; and E. F. Smith, 19 parts per 100 at room temp. The dehydrated salt melts at 680·8°. E. F. Smith found that the addition of a cold aq. soln. of *zinc sulphate* produced a white precipitate soluble in a slight excess of zinc sulphate. From this solution, on standing, white needles separated in stellar aggregations. These were the 4 : 10-zinc salt described by O. W. Gibbs—*vide* the pentatungstates. *Cadmium sulphate* occasioned a white voluminous precipitate insoluble in an excess of cadmium sulphate as well as in cold and hot water, thus differing from the zinc salt. With *cobalt sulphate* and *nickel nitrate* precipitates soluble in an excess of the precipitants appeared. The precipitate with cobalt sulphate was quite granular. A soln. of *zirconium oxychloride* ($ZrOCl_2.8H_2O$) gave (in a soln. of the 4 : 10-salt) a heavy, white and extremely gelatinous precipitate, insoluble in water and in an excess of the precipitant. *Lanthanum sulphate* gave a white, insoluble gelatinous precipitate. This also occurred with praseodymium and neodymium nitrates. There was nothing remarkable about these products. They proved to be insoluble and were easily decomposed by nitric acid, even in the cold. *Uranyl nitrate* gave a flocculent yellow-coloured precipitate (with the 4 : 10-salt). It redissolved in a slight excess of the uranyl salt. The soln. was filtered, when a white, granular powder separated. *Ferric ammonium sulphate* gave a curdy, slightly yellow precipitate, insoluble in an excess of the precipitant. *Alum* produced a copious, finely-divided precipitate, which curdled on agitation. It proved perfectly insoluble. *Chromium potassium sulphate* occasioned a precipitate. It was greenish-grey in colour, gelatinous and insoluble in excess of the reagent and also in large volumes of water. *Lead nitrate* produced a white, gelatinous precipitate, insoluble in an excess of the precipitant and also in hot water. *Hydroxylamine hydrochloride* (in a soln. of 4 : 10-salt) caused no precipitation. With *hydrazine sulphate* a rather voluminous, somewhat flocculent, white precipitate appeared, insoluble in cold water, but dissolving rather freely in hot water, and was not soluble in an excess of hydrazine sulphate. *Benzidine hydrochloride* produced a white, heavy precipitate not soluble in an excess of the precipitant or in boiling water. *Phenylhydrazine hydrochloride* was without visible reaction. *Naphthylamine hydrochloride* gave a flesh-coloured precipitate, insoluble even in boiling water. Hydrochloric acid slowly decomposed it. *Aniline hydrochloride* gave no precipitation.

O. W. Gibbs[4] found that a mixed soln. of sodium pentatungstate and ammonium chloride, furnished white, talc-like scales of **ammonium sodium decatungstate,** $16(NH_4)_2O.4Na_2O.50WO_3.50H_2O$, or $4\{4(NH_4)_2O.10WO_3\}.4Na_2O.10WO_3.50H_2O$. W. I. Baragiola obtained **ammonium sodium 3 : 1-decatungstate,** $3(NH_4)_2O.Na_2O.10WO_3.12H_2O$, from a hot, sat. soln. of a mol of sodium tungstate and 2 mols of ammonium chloride. It is either an isomorphous mixture, or a salt

$NaO.WO_2.O.WO(O.WO_2.ONH_4)_3$. E. F. Smith prepared **calcium decatungstate,** $4CaO.10WO_3.25H_2O$, as a white, granular powder which did not melt at a low red-heat; similarly also with **strontium decatungstate,** $4SrO.10WO_3.26H_2O$, and barium decatungstate, $4BaO.10WO_3.22H_2O$; **zinc decatungstate,** $4ZnO.10WO_3.29H_2O$—*vide supra*, the pentatungstates; **manganese decatungstate,** $4MnO.10WO_3.30H_2O$, appears as a white precipitate; **cobalt decatungstate,** $4CoO.10WO_3.35H_2O$, is pink, and insoluble; and **nickel decatungstate,** $4NiO.10WO_3.34H_2O$, is a greenish-white powder. A. Wolff prepared **potassium ferric decatungstate,** $3K_2O.Fe_2O_3.10WO_3.23H_2O$.

A. Rosenheim and H. Schwer[5] prepared **ammonium ferric dodecatungstate,** $4(NH_4)_2O.Fe_2O_3.12WO_3.23H_2O$, which they represented by the formula $(NH_4)_4H_5[Fe(WO_4)_6].9H_2O$. Ferric chloride soln. was added in small portions at a time to a boiling soln. of sodium paratungstate. The brown precipitate first produced redissolves in the liquid. Ammonium chloride was added to saturation. On cooling the soln., a pale yellow, microcrystalline precipitate separated out. By using potassium chloride in place of ammonium chloride, **potassium ferric dodecatungstate,** $K_4H_5[Fe(WO_4)_6].9H_2O$, was similarly obtained. When the salt is heated nine mols. of water are expelled more readily than the remainder. Thus, at 120°, 8·8 mols. were given off; similarly at 130°; at 140°, 8·9 mols. were given off; at 160°, 9·3 mols.; and at a red-heat, 11·5 mols. The eq. conductivity of a soln. of an eq. of $K_4H_5[Fe(WO_4)_6].9H_2O$ in v litres of water at 25° was:

v . .	32	64	128	256	512	1024
λ . .	78·13	88·36	97·27	105·65	116·7	125·9

from which it follows that $\lambda_{1024}-\lambda_{32}=47{\cdot}8$. The sp. conductivities of $\frac{1}{64}N$-$\{K_4H_5[Fe(WO_4)_6].9H_2O\}$ with additions of 0, 1, and 2 eq. of $\frac{1}{10}N$-NaOH, are respectively 1·349, 1·562, and 1·704 mhos, and with more of the soda-lye, ferric hydroxide separates out. All this is taken to mean that an enneabasic ferritungstic acid is involved, resembling the corresponding ferrimolybdic acid. The anion is unstable towards hydroxyl ions so that acids of higher basicity are scarcely possible. The tetrabasic potassium salt is ionized approximately the same as an ordinary "neutral salt." A guanidinium salt, $(CH_6N_3)_3H_6[Fe(WO_4)_6].9H_2O$, has been prepared—*vide supra*, paratungstates.

G. von Knorre[6] fused potassium paratungstate, or a mixture of a mol of the normal tungstate with one or two mols of tungsten trioxide, and extracted the mass with water. Crystals of **potassium tetradecatungstate,** $5K_2O.14WO_3$, remained. They are very sparingly soluble in cold water, and rather more soluble in hot water.

W. I. Baragiola[7] obtained **ammonium sodium 3 : 2-pentadecatungstate,** $3(NH_4)_2O.2Na_2O.15WO_3.25H_2O$, in white plates from a soln. of 2 mols of ammonium chloride and a mol of sodium tungstate after the decatungstate has separated out. A hot, sat. soln. of 2 mols of ammonium chloride and one mol of sodium tungstate furnishes crystals of **ammonium sodium 4 : 2-pentadecatungstate,** $4(NH_4)_2O.2Na_2O.15WO_3.21H_2O$.

J. C. G. de Marignac[8] obtained **ammonium hexadecatungstate,** $3(NH_4)_2O.16WO_3.17H_2O$, by the spontaneous evaporation of a soln. of the metatungstate mixed with some hydrochloric acid. The crystals are probably triclinic, and they lose about 13 mols. of water at 100°. The aq. soln. has an acid reaction; and on crystallizing the aq. soln., the metatungstate separates out first. O. W. Gibbs, and G. von Knorre prepared **ammonium sodium hexadecatungstate,** $4(NH_4)_2O.3Na_2O.16WO_3.18H_2O$. G. Jander and co-workers prepared **arsenic octodecatungstic acid,** $H_8[As(W_2O_7)_9]$.

As indicated in connection with the decatungstates, O. W. Gibbs[9] prepared a complex **sodium docositungstate,** $5Na_2O.12WO_3.5Na_2O.10WO_3.51H_2O$, or $9Na_2O.22WO_3.51H_2O$, in following the directions of C. Scheibler for preparing the paratungstate, and he added that this salt is produced in crystals if the proportion of hydrochloric acid is just sufficient to give a wine-red reaction with litmus. E. F. Smith found the dehydrated salt melts at 683·3°. He obtained this salt, but doubted its individuality. By treatment with zinc sulphate, **zinc docositungstate,** $9ZnO.22WO_3.66H_2O$, is formed.

§ 17. The Pertungstic Acids and the Pertungstates

According to T. Fairley,[1] hydrogen dioxide dissolves tungsten trioxide forming a soln. containing an unstable higher oxide from which green, scaly crystals are deposited on evaporation over sulphuric acid in vacuo; this product is soluble in water, and forms unstable, crystalline compounds with the alkali dioxides. J. B. Cammerer treated tungsten trioxide with a boiling, two per cent. soln. of hydrogen dioxide, and on evaporating the soln. he obtained a deep orange, amorphous mass of **monopertungstic acid,** $H_2WO_5.H_2O$, or $WO_3.H_2O_2.H_2O$, which dissolves in water, and the soln. has an acidic reaction. B. Kellner could not isolate a product of definite composition from a soln. of hydrated tungstic acid in hydrogen dioxide. When the soln. is concentrated, it decomposes when heated, although the dil. soln. does not decompose when boiled at 100°. No precipitation occurs when alcohol or ether is added. If evaporated in a desiccator, an amorphous substance approximating **perditungstic acid,** $H_2W_2O_8.2H_2O$, or $W_2O_7.3H_2O$, is formed. It decomposes at about 35°. It decomposes in water with the evolution of oxygen; L. Pissarjewsky was unable to prepare this compound; but he inferred from his observations on the thermal value, *Q* Cals., of the reaction between tungsten trioxide and hydrogen dioxide that such a compound probably exists but is less stable than that between hydrogen dioxide and molybdenum trioxide (*q.v.*):

Mols H_2O_2 per mol WO_3	1	2	3	4	5	6	10
Heat developed, *Q* .	0·89	1·536	2·001	2·728	3·233	3·335	3·466 Cals.

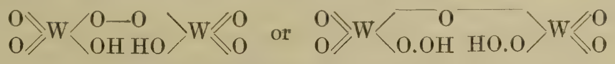
J. Brode's observations on the distribution of hydrogen dioxide between ether and aq. soln. of tungstic acid, at 20°, confirm the view that if monopertungstic acid exists in aq. soln., it is even more dissociated in aq. soln. than is the case with the corresponding monopermolybdic acid. Thus, with soln. containing $\frac{1}{2}M$-Na_2WO_4 and $\frac{1}{8}M$-H_2SO_4:

Free H_2O_2 . . .	0·265	0·200	0·097 mol
Bound H_2O_2 per mol WO_3 .	1·34	1·13	0·77 mol

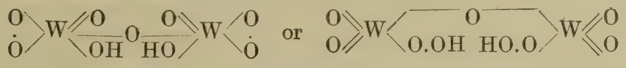
L. Pissarjewsky assumed that the soln. contained monopertungstic acid, $WO_2(OH)(OOH)$, and dipertungstic acid, $WO_2(OOH)_2$, in equilibrium: $nWO_2(OOH)_2+(n+m)H_2O \rightleftharpoons (n-m)WO_2(OOH)(OH)+mWO_2(OH)_2+(n+m)H_2O_2$. He calculated the heat of formation of H_2WO_5 in soln. from tungstic acid and oxygen to be −18·154 Cals. A. Mazzucchelli and C. Barbero found the potential of a gram-equivalent of sodium pertungstate in 10 litres of N-H_2SO_4, against a $Hg : Hg_2SO_4 : N$-H_2SO_4-electrode, after 1, 4, and 15 hrs., to be respectively −0·891, −0·881, −0·865 volt with a large platinum electrode; −0·894, −0·886, −0·865 volt with a small platinum electrode; and −0·970, −0·952, and −0·947 volt with a gold electrode. A. Mazzucchelli and M. Borghi studied the formation of complexes with optically active organic substances. E. P. Alvarez studied the action of the pertungstates on soln. of lead acetate (white precipitate), silver nitrate (white precipitate), mercurous nitrate (white precipitate, with rapid decomposition), mercuric chloride (red precipitate), copper sulphate (blue precipitate), zinc and cadmium sulphates (white precipitates), bismuth nitrate (white precipitate), gold chloride (slight effervescence and escape of oxygen), manganous chloride (pink precipitate), nickelous chloride or sulphate (greenish-white precipitate), cobaltous nitrate and chloride (pink precipitate), ferrous sulphate (green or bluish-green precipitate), ferric chloride (red ferric hydroxide), and alkaline earth chlorides (white precipitates). The precipitates are all per-salts of the bases in question.

According to E. Péchard, when a soln. of sodium paratungstate is boiled for a few minutes with hydrogen dioxide, it assumes a yellow tint, and no longer gives a precipitate with nitric acid; when it is evaporated in vacuo, the syrupy liquid deposits small, white, radiating crystals of $Na_2O.W_2O_7.2H_2O$, that is, **sodium monoperditungstate,** $Na_2W_2O_8.2H_2O$. He also prepared **ammonium monoperditungstate,** in a similar manner, but B. Kellner could not isolate an ammonium pertungstate. E. Péchard added that sodium perditungstate is more soluble in water than sodium paratungstate; it gives off water when heated in vacuo, and finally decomposes with the evolution of oxygen. Alkali-lye destroys these salts with the liberation of oxygen; and aq. soln. liberate iodine from potassium iodide, and chlorine from hydrochloric acid. G. E. Thomas found that by electrolyzing a 30 per cent. soln. of sodium tungstate slightly acidified with acetic acid, sodium pertungstate is formed, but he did not isolate the salt; but J. Eltzbacher could not prepare sodium pertungstate by the electrolysis of a soln. of the normal tungstate using a high anodic current density. B. Kellner could not prepare E. Péchard's hydrate, but he obtained crystals of the *tetrahydrate*, $Na_2W_2O_8.4H_2O$, belonging to the rhombic system, by the action of hydrogen dioxide on an acid soln. of sodium paratungstate mixed with a little sodium tungstate so that the soln. would not react acid. A. Mazzucchelli and C. Barbero found the electrode potentials towards the normal calomel electrode with soln. of sodium perditungstate, $Na_2W_2O_8.6H_2O$, after 1, 3, and 7 hrs. to be respectively —0·746, —0·733, and —0·733 volt with large platinum electrodes; —0·729, —0·736, and —7·730 volt with small platinum electrodes; and —0·699, —0·687, and —0·699 volt with gold electrodes. Hydrogen dioxide does not dissolve silver paratungstate, and it is decomposed by normal silver tungstate; but **silver perditungstate,** $Ag_2W_2O_8.4H_2O$, was obtained by adding silver nitrate to a soln. of potassium pertungstate. The white precipitate is sparingly soluble in water. B. Kellner also prepared **strontium perditungstate,** $SrW_2O_8.6H_2O$, by adding an excess of strontium nitrate to a soln. of potassium hypertungstate containing a little hydrogen dioxide; and similarly with **barium perditungstate,** $BaW_2O_8.6H_2O$.

L. Pissarjewsky prepared a salt with the composition, **sodium perditungstate,** $Na_2W_2O_9.6H_2O$, by warming sodium paratungstate for 10 minutes with an excess of hydrogen dioxide, precipitating the salt by the addition of alcohol, and recrystallizing from water. The white powder has a yellow tinge, and it consists of microscopic, rhombic prisms. It deliquesces a little in air, and with dil. sulphuric acid it forms hydrogen dioxide, and with conc. sulphuric acid, ozone. B. Kellner obtained white rhombic crystals of **lithium perditungstate,** $Li_2W_2O_9.6H_2O$, by adding a soln. of lithium sulphate to a soln. of ammonium paratungstate in hydrogen dioxide. The salt is sparingly soluble in water. According to L. Pissarjewsky, the ratio of WO_3 to active oxygen in $Na_2W_2O_8.2H_2O$ is 2 : 1, and in $Na_2W_2O_9.6H_2O$, 1 : 1, when determined by titration with potassium permanganate in sulphuric acid soln. Hence, by analogy with the persulphates, the constitutions of the acids corresponding with these two salts may be represented:

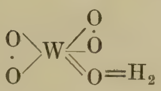


Monoperditungstic Acid, $H_2W_2O_8$

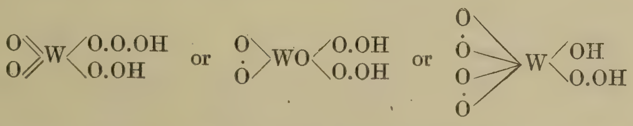


Diperditungstic Acid, $H_2W_2O_9$

so that L. Pissarjewsky's acid can be regarded as a condensation product of two molecules of H_2WO_5, *i.e.*

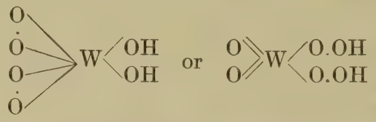


with the expulsion of a mol. of water. P. G. Melikoff and L. Pissarjewsky also prepared a peroxidized salt of this acid, namely, **sodium dipertungstate,** $Na_2O_2.WO_4.H_2O_2$, or $Na_2O_2.WO_5.H_2O$, which can be regarded as a derivative of *dipertungstic acid,* H_2WO_7, or

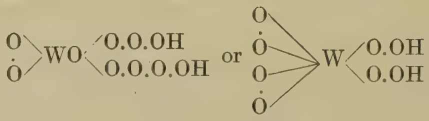


The salt was prepared by the action of a well-cooled soln. of sodium hydroxide (1½ mol NaOH to one mol of $NaWO_4$) and hydrogen dioxide (six times the calculated quantity) on a soln. of perditungstate. The yellow powder slowly decomposes with the evolution of oxygen; when warmed it decomposes with a feeble detonation; and when treated with water, the evolution of oxygen is attended by effervescence.

Iodine is liberated from potassium iodide ; and with conc. sulphuric acid ozone is given off, and with dil. sulphuric acid, hydrogen dioxide is formed. By cooling to —2° a soln. of 3 mols of sodium hydroxide, half a mol of $Na_2W_2O_8$, and an excess of hydrogen dioxide, P. G. Melikoff and L. Pissarjewsky obtained a yellow complex $(Na_2O_2)_2WO_4(Na_2O_2.WO_4.H_2O_2).7H_2O$, which behaves chemically like the preceding salt. E. Wegelin reported sodium dipertungstate, $Na_2WO_6.4H_2O$, or $Na_2WO_4.2H_2O_2.2H_2O$, a derivative of dipertungstic acid, H_2WO_6 :



to be formed by cooling a soln. of normal sodium tungstate with an excess of 25 per cent. hydrogen dioxide. The white, crystalline powder has a yellow tinge ; it gives off oxygen when dissolved in water. The salt also exhibits the general properties of the pertungstates. P. G. Melikoff and L. Pissarjewsky prepared **potassium hypertungstate,** $K_2O_4.WO_4.H_2O$, derived from the acid



or, if the water of crystallization be included in the formula, and pertungstic acid be represented $WO(OOH)_4$, the potassium salt becomes $WO(OOK)_2(OOH)_2$. It was obtained by adding an excess of hydrogen dioxide to a well-cooled soln. of potassium hydroxide and tungstate, and precipitating the salt by the addition of alcohol. The pale yellow precipitate decomposes in air ; it explodes by friction, or by rapidly heating it to 80° ; if slowly heated, oxygen is given off. When treated with water, oxygen is given off ; and the salt gives other reactions characteristic of the pertungstates. B. Kellner prepared hexagonal prisms of **potassium hyperditungstate,** $K_2W_2O_{11}.4H_2O$, from a soln. of potassium paratungstate and cold 20 per cent. hydrogen dioxide. The salt is stable ; and it is precipitated from its aq. soln. by a mixture of alcohol and ether. Most salts of the heavy metals give precipitates with the aq. soln.—*e.g.* barium, lead, mercuric, and silver nitrates, and thallosic sulphate.

B. Kellner obtained **lithium pertetratungstate,** $Li_6W_4O_{16}.9H_2O$, in hexagonal crystals, from the mother-liquor in the preparation of the diperditungstate. He also prepared **rubidium pertetratungstate,** $Rb_4W_4O_{15}.3H_2O$, in stable, rhombic plates by evaporating the filtrate from a soln. of rubidium paratungstate in an excess of 20 per cent. hydrogen dioxide ; and white crystals of **magnesium pertetratungstate,** $Mg_2W_4O_{20}.9H_2O$, from a soln. of magnesium paratungstate in an excess of 20 per cent. hydrogen dioxide. B. Kellner reported **calcium perhexatungstate,** $Ca_3W_6O_{27}.8H_2O$, to be formed, as a white precipitate, by adding calcium nitrate to a soln. of sodium paratungstate and normal tungstate in an excess of hydrogen dioxide. If potassium hypertungstate is dissolved in 10 to 15 times its weight of cold water, and the soln. allowed to stand overnight, rhombic crystals of **potassium perdecatungstate,** $K_{14}W_{30}O_{52}.22H_2O$, are formed. If cæsium sulphate be added to a hot soln. of 5 mols of sodium paratungstate and 2 mols of the normal sulphate in an equal weight of 20 per cent. hydrogen dioxide, on cooling, a microcrystalline precipitate of **cæsium perdodecatungstate,** $Cs_6W_{12}O_{41}.12H_2O$, is formed. An excess of a soln. of cæsium sulphate added to a hot soln. of sodium paratungstate in 1·2 to 1·4 times its weight of 15 per cent. hydrogen dioxide, yields yellow crystals of **cæsium perparatungstate,** $Cs_{10}W_{12}O_{65}.11H_2O$; and rubidium sulphate similarly furnishes **rubidium perparatungstate,** $Rb_{10}W_{12}O_{44}.12H_2O$, as a microcrystalline powder. These salts want overhauling.

§ 18. Tungsten Fluorides and Oxyfluorides

According to H. Moissan,[1] fluorine at ordinary temp. attacks tungsten with incandescence forming a volatile fluoride. J. J. Berzelius observed that while tungsten trioxide which has been ignited dissolves sparingly in hydrofluoric acid, hydrated tungsten trioxide forms with hydrofluoric acid a yellow, milky liquid, which is soluble in a large proportion of water. On evaporation, the soln. yields a yellow syrup, which, at a higher temp., loses some acid and solidifies to a greenish mass. The product is not decomposed by ignition in a closed vessel, and redissolves imperfectly in water to form a milky liquid as before; while the insoluble part retains hydrofluoric acid so very tenaciously that it can be expelled only by ignition with lumps of ammonium carbonate. The salts obtained by J. J. Berzelius were probably fluodioxytungstates—*vide infra*. A. Riche said that hydrated tungsten trioxide dissolves in conc. hydrofluoric acid at 50° to 60°, but on evaporating the soln. in air, crystals of hydrated tungsten trioxide separate out.

A. Rosenheim and T. H. Li[2] obtained complex salts of **tungsten trifluoride,** WF_3, namely, **ammonium tungsten tetrafluoride,** $(NH_4)WF_4.H_2O$; and **potassium tungsten tetrafluoride,** $KWF_4.H_2O$—*vide infra*, tungsten trichloride.

O. Ruff and co-workers[3] obtained **tungsten hexafluoride,** WF_6, by the action of anhydrous hydrogen fluoride on tungsten hexachloride in a copper-lined bomb at ordinary temp. The gas is passed over titanium tetrafluoride to absorb the excess of hydrogen fluoride, and then into a platinum vessel, or a paraffin-lined vessel, cooled to —70°, at which temp. the product is solid. Tungsten hexafluoride is also formed by the interaction of the hexachloride and arsenic trifluoride, but even repeated fractionation does not quite free the product from arsenic trifluoride. The most convenient mode of preparation is gradually to add antimony pentafluoride to tungsten hexachloride, cooled by a freezing mixture, and subsequently to distil the product. Glass vessels can be used. The yield is 60 to 80 per cent. Tungsten hexafluoride is a colourless gas at ordinary temp. It is ten times as heavy as air, and is the heaviest of all known gases. At atm. press., it condenses at the b.p., 19·5° to a pale yellow liquid, and below the m.p. 2·5° it forms a white solid. The vap. press. at 2·5° is 375 mm.; at 15°, 649 mm.; at 19°, 751 mm.; and at 19·5°, 760 mm. It vaporizes without melting at —20° under 380 mm. press., and at 0° under 760 mm. press. The vapour density at 18·5° is 303—theory 298. The compound fumes strongly in air forming a bluish-white cloud. It is decomposed by water with the separation of yellow, hydrated tungsten trioxide. The gas is freely soluble in aq. alkalies, and aq. ammonia; and it is absorbed by alkali fluorides forming complex salts. Ammonia gas reacts vigorously forming a brown solid; while liquid ammonia in a closed vessel forms ammonium fluoride and a clear soln. which on evaporation leaves a white solid. Tungsten hexafluoride, particularly if it contains traces of hydrogen fluoride, rapidly attacks copper, zinc, mercury, tin, lead, antimony, iron, cobalt, and nickel, the metal so acquires a blue or grey film. Gold and platinum are not attacked by tungsten hexafluoride.

O. Ruff and co-workers prepared **tungsten oxytetrafluoride,** WOF_4, by the interaction of equal amounts of the oxytetrachloride and anhydrous hydrogen fluoride in a platinum vessel at 20°, and then allowing the temperature to rise gradually. After 24 hrs., the vessel is heated to 280°, while the upper part is kept cool. The oxytetrafluoride condenses in the neck as a snow-white mass. It has also been obtained by the action of lead or bismuth fluoride on tungsten trioxide, while moisture is carefully excluded. At ordinary temp., the oxytetrafluoride forms colourless, hygroscopic plates; its m.p. is 110°, and its b.p. 185° to 190°. It is coloured yellow in moist air owing to the separation of hydrated tungsten trioxide; it forms a clear soln. with water while generating much heat, hydrogen fluoride is given off, and the soln. soon deposits hydrated tungsten trioxide. Hydrogen sulphide attacks it superficially, with partial reduction to a blue substance. It absorbs ammonia in the cold forming **tungsten hemiamminoxytetrafluoride,** $2WOF_4.NH_3$. This substance is orange coloured; it acquires a white crust on exposure to air; it melts when heated giving off hydrogen fluoride and ammonium fluoride, and leaving a residue of blue tungsten trioxide; when heated in ammonia, it detonates slightly; it is insoluble in liquid ammonia; it dissolves in water and acquires a blue colour; and the aq. soln. remains clear for some time, but slowly deposits hydrated tungsten trioxide. Tungsten oxytetrafluoride is insoluble in carbon tetrachloride, but soluble in carbon disulphide, chloroform, and absolute alcohol; it is sparingly soluble in dry benzene, and with moist benzene the tungsten is partly reduced; it is slightly soluble in ether with the development of heat; and in acetic anhydride with partial decomposition. It does not attack in the cold copper, silver, zinc, tin, lead, aluminium, arsenic, bismuth, and iron, but when heated, or when moist, the metal acquires a blue film.

Attempts by O. Ruff and co-workers to prepare **tungsten dioxydifluoride,** WO_2F_2, were not successful, although this compound mixed with the oxytetrafluoride results when tungsten trioxide and lead fluoride are heated in the presence of a trace of moisture; and a little is formed by the action of water on the oxytetrafluoride. According to J. C. G. de Marignac,[4] when the normal or meta-tungstates are dissolved in hydrofluoric acid, compounds of the metal fluorides with tungsten dioxydifluoride—**fluodioxytungstates**—are formed. The salts are usually soluble in water, and they crystallize readily. The dry salts attack glass. Acids do not produce a precipitate in aq. soln., but the soln. slowly deposits hydrated tungsten trioxide. Some reactions of soln. of these salts were described by R. D. Hall and E. F. Smith—*vide* Table III, **9.** 55, 4.

J. C. G. de Marignac prepared **ammonium trifluodioxytungstate,** $NH_4F.WO_2F_2.H_2O$, or, according to A. Werner, $NH_4[WO_2F_3(H_2O)]$, by the action of hydrofluoric acid on ammonium paratungstate; the exact conditions are not known because often the tetrafluodioxytungstate and tungsten trioxide are produced. The rhombic bipyramids have the axial ratios $a:b:c=0{\cdot}5224:1:0{\cdot}7268$. Some combinations are pseudohexagonal; and twinning like aragonite may occur. F. Mauro discussed the isomorphism of the salt. The salt is decomposed by water, but can be crystallized unchanged from water containing hydrofluoric acid. J. C. G. de Marignac also prepared rectangular plates of **ammonium tetrafluodioxytungstate,** $2NH_4F.WO_2F_2.H_2O$, which A. Werner formulated $(NH_4)_2[WO_2F_4]$; and J. W. Mallet

$$\begin{matrix}\mathrm{O}\\ \mathrm{O}\end{matrix}\!\gg\mathrm{W}\!<\!\begin{matrix}\mathrm{F:F.NH_4}\\ \mathrm{F:F.NH_4}\end{matrix}$$

The salt was obtained from a soln. of ammonium tungstate in hydrofluoric acid. The rhombic bipyramids have the axial ratio $a:b:c=0{\cdot}4128:1:1{\cdot}0027$. F. Mauro, and E. Scacchi found the salt to be isomorphous with $2NH_4F.MoO_2F_2$, and $2NH_4F.MoOF_3$. J. J. Berzelius seems to have prepared this salt as well as the corresponding potassium compound—*vide supra*. J. C. G. de Marignac found that ammonium tetrafluodioxytungstate does not change at 100°, and at a higher temp. it decomposes without melting. When rapidly heated, vapours of tungsten hexafluoride are given off leaving a blue oxide of tungsten behind. The salt is very soluble in water, and the addition of ammonia to a conc. soln. gives a precipitate which is soluble in excess. If the aq. soln. is evaporated in air, crystals of ammonium paratungstate are formed, and a crust adheres to the walls of the vessel. When this is recrystallized from a hot ammoniacal soln., regular octahedra of **ammonium trifluotrioxytungstate** are formed—*viz.* $(NH_4)_2WO_4.4NH_4F.WO_2F_2$, or, according to A. Werner, $(NH_4)_3[WO_3F_3]$. F. Mauro said that the crystals are isomorphous with the corresponding salt of molybdenum; and H. Baker discussed its relationship with other complex salts. The salt does not change at 100°, but at a higher temp., it loses ammonia, ammonium fluoride, and hydrogen fluoride. Water dissolves all but a small residuum; aq. ammonia dissolves the salt freely and when the soln. is evaporated ammonium paratungstate is formed.

J. C. G. de Marignac obtained crystals of **sodium tetrafluodioxytungstate,** $2NaF.WO_2F_2$, or $Na_2[WO_2F_4]$, from soln. of the normal or acid tungstates in hydrofluoric acid. J. J. Berzelius also prepared a similar salt. J. C. G. de Marignac said that the crystals are probably monoclinic; they melt at a dull red-heat. There is very little loss if the salt is heated in a closed vessel, but in air, the molten mass becomes yellow probably by the separation of tungsten trioxide, and there is a loss of 13·5 to 13·7 per cent. A soln. of potassium paratungstate in an excess of hydrofluoric acid furnishes rhombic bipyramids of **potassium trifluodioxytungstate,** $KF.WO_2F_2.H_2O$, or $K[WO_2F_3(H_2O)]$, with the axial ratios $a:b:c=0·5243:1:0·7349$, and isomorphous with the ammonium salt. The salt loses all its water at 100°; and when heated to a higher temp. it behaves like the tetrafluodioxytungstate. The salt acquires a yellow colour when heated; it is soluble in water with decomposition. The salt can be recrystallized in the presence of an excess of hydrofluoric acid, otherwise **potassium tetrafluodioxytungstate,** $2KF.WO_2F_2.H_2O$, or $K_2[WO_2F_4].H_2O$, is formed—*vide supra* for the alternative formula. This salt was prepared by J. J. Berzelius, J. C. G. de Marignac, G. Marchetti, and A. Piccini from a soln. of tungsten trioxide in hydrofluoric acid, and adding potassium hydroxide, or from a hydrofluoric acid soln. of potassium tungstate. The soln. is evaporated to dryness on a water-bath, extracted with hot water, and the filtrate cooled. The colourless plates resemble those of boric acid, or of mica; J. C. G. de Marignac observed that they are monoclinic prisms with the axial ratio $a:b:c=1·0019:1:1·0481$, and $\beta=98°\ 47'$. E. Scacchi said that the (010)-cleavage is incomplete. G. Marchetti said that the salt becomes anhydrous at 100° forming tabular crystals. J. J. Berzelius said that the salt melts at a red-heat without decomposition, and when cooled it is greenish-yellow. J. C. G. de Marignac added that if heated to redness in air, it gives off hydrogen fluoride, and forms tungsten trioxide; and ultimately normal potassium tungstate with a loss of about 16 per cent. J. J. Berzelius found that the salt is sparingly soluble in cold water, and freely soluble in hot water; and J. C. G. de Marignac observed that 100 parts of water at 15° dissolve 5·88 parts of the salt. J. J. Berzelius said that the salt can be crystallized unchanged from its soln. in water, or dil. hydrochloric acid.

J. C. G. de Marignac prepared monoclinic prismatic crystals of **copper tetrafluodioxytungstate,** $CuF_2.WO_2F_2.4H_2O$, isomorphous with $CuF_2.TiF_4.4H_2O$, and with the axial ratios $a:b:c=0·7648:1:0·5629$, and $\beta=103°\ 14'$. The salt is not altered at 100°; at a higher temp. it loses water and hydrogen fluoride, ultimately forming normal copper tungstate. The salt is freely soluble in water. If an aq. soln. of this salt be mixed with ammonium fluoride, it furnishes tetragonal crystals of **ammonium copper pentafluodioxytungstate,** $NH_4F.CuF_2.WO_2F_2.4H_2O$, with the axial ratio $a:c=1:1·0945$, and isomorphous with $NH_4F.CuF_2.TiCl_4.4H_2O$. J. C. G. de Marignac obtained **silver tetrafluodioxytungstate** as a deliquescent mass which easily decomposes; and **zinc tetrafluodioxytungstate,** $ZnF_2.WO_2F_2.10H_2O$, or $Zn[WO_2F_4].10H_2O$, in triclinic crystals which effloresce in dry air, and melt in their water of crystallization below 100°. The salt is easily soluble in water. The corresponding **cadmium tetrafluodioxytungstate** is easily decomposed, and is very deliquescent. F. Ephraim and L. Heymann prepared **thallous trifluodioxytungstate,** $TlF.WO_2F_2$, and **thallous tetrafluodioxytungstate,** $2TlF.WO_2F_2$, in rhombic plates, from a conc. hydrofluoric acid soln. of tungsten trioxide mixed with thallous fluoride in the cold; hot soln. furnish **thallous heptafluotetroxyditungstate,** $3TlF.2WO_2F_2$, in long prisms. J. C. G. de Marignac prepared **manganese tetrafluodioxytungstate** which is easily decomposed and very deliquescent; and **nickel tetrafluodioxytungstate,** $NiF_2.WO_2F_2.10H_2O$, in deliquescent crystals. A. Miolati and G. Rossi prepared **cobaltic hexamminoheptafluotetroxyditungstate,** $[Co(NH_3)_6]F_3.2WO_2F_2$, as a yellow crystalline powder, by adding the hexamminotrifluoride to a soln. of tungsten trioxide in hydrofluoric acid, and crystallizing from the soln. in dil. acid. The crystals are stable at 110°.

A. Piccini [5] prepared **potassium tetrafluotrioxypertungstate,** $2KF.WO_3F_2.H_2O$, by cooling a hot soln. of potassium tetrafluodioxytungstate in hydrogen dioxide, washing the product with water, and recrystallizing from hydrofluoric acid mixed with hydrogen dioxide. The tabular crystals are not changed in air; they give off water vapour at 100°; at 150°, oxygen comes off; and after a prolonged heating in air, normal potassium tungstate remains. The salt is sparingly soluble in cold water, and freely soluble in hot water. The aq. soln. is fairly stable. According to A. Mazzucchelli and C. Barbero, the oxidation potential of a soln. of a mol of the salt in 15 litres of water is 0·787 to 0·751 volt.

§ 19. The Tungsten Chlorides

H. E. Roscoe [1] reported **tungstous chloride,** or **tungsten dichloride,** WCl_2, to be formed by heating in a bath of molten zinc tungsten tetrachloride in a current of carbon dioxide; or by tungsten hexachloride in hydrogen. H. E. Roscoe described the product as a grey, amorphous mass, which is not stable in air. When heated in hydrogen previously passed over warm nitric acid, it forms ammonium nitrite. Water dissolves a little of the dichloride forming a brown soln., but hydrogen is slowly evolved and a brown oxide and hydrochloric acid are produced. W. Hampe said that the dichloride is infusible.

J. B. Hill found that it is difficult to control the reduction of the hexachloride by sodium amalgam, or potassium-sodium alloy, and the yield of dichloride is poor. According to K. Lindner and co-workers, tungsten dichloride cannot be prepared from the metal and carbonyl chloride, because, over a wide range of temp., carbon and red oxytetrachloride, as well as tungsten hexachloride and pentachloride are formed. The hexachloride is readily reduced to the dichloride when it is heated with powdered quartz and aluminium, magnesium, zinc, or lead in a current of nitrogen. The product is extracted with hydrochloric acid, and the reddish-yellow extract is concentrated and saturated with hydrogen chloride, thus causing the separation of **chloroaquotungstous acid,** $H[W_3Cl_7(H_2O)].3H_2O$, in slender, yellow needles which are much less stable than the corresponding compound of molybdenum. The mol. wt. of $C_5H_5N.H[W_3Cl_7]$, calculated from the f.p. of soln. in nitrobenzene is 889, when the theoretical value is 901. K. Lindner made some observations on the constitution of the salt. Chloroaquotungstous acid readily loses hydrogen chloride when exposed to air. In alcoholic soln., or on gently heating, a mol. of hydrogen chloride is evolved, and there remains a yellow insoluble residue of *monohydrate,* $W_3Cl_6.H_2O$. The compound is soluble in alkali-lye with the evolution of hydrogen and the formation of alkali tungstate. J. B. Hill said that the aq. soln. of chloroaquotungstous acid when treated with potassium hydroxide forms a clear yellow soln., which rapidly darkens, and from which weak acids precipitate a black, gelatinous precipitate of hydrated W_2O_3. The brown alkaline soln., on keeping for twenty-four hours in the air, slowly loses its colour, and when treated with weak acids yields a yellow, gelatinous precipitate of hydrated WO_2. According to K. Lindner and A. Köhler, hydrolysis with a little water furnishes the *dihydrate,* $[W_3Cl_4(H_2O)_2]Cl_2$, whereas with an excess of water, tungstic acid is formed. Sulphuric acid converts it into $W_3Cl_4(SO_4)$; and hydrobromic acid into $H[W_3Br_4Cl_3(H_2O)].9H_2O$. J. B. Hill said that chloroaquotungstous acid is soluble in alcohol, acetone, acetic acid, and mixtures of alcohol and ether, but almost insoluble in ether. K. Lindner and A. Köhler prepared a number of complex salts with pyridine: $C_6H_5N.H[W_3Cl_7(H_2O)]$, in yellow leaflets $C_5H_5N.H[W_3O_7].3H_2O$; $(C_5H_5N)_3H_3[W_3Cl_9]$, in yellow octahedra; $C_5H_5N.H[W_3Cl_7(C_5H_5N)].2(C_2H_5)_2O$; and $C_2H_4(NH_2)_2.H_2[W_3Cl_7]_2.2H_2O$. W. Biltz and C. Fendius gave 5·436 for the sp. gr. of the anhydrous chloride at 25°/4°, and 46·9 for the mol. vol. F. W. Bergstrom found that a slightly soluble ammoniobasic halide is formed with liquid ammonia.

R. F. Bernhardi-Grisson[2] found that in the electrolytic reduction of hydrofluoric acid, or aq. alcoholic soln. of tungstic acid, the reddish-brown liquid behaves towards potassium permanganate, or an ammoniacal soln. of silver nitrate as if it contained a tervalent tungsten salt. O. Olsson also was able to reduce soln. of tungstic acid to tervalent tungsten, by means of tin, and from the soln., he prepared complex salts of **tungsten trichloride,** WCl_3. O. Collenberg and co-workers discussed the electrolytic reduction of hydrochloric acid soln. of tungstic acid to the tervalent stage—*vide supra,* tungsten trioxide; and K. Someya, the titration of soln. of tungsten trichloride with copper sulphate soln. A soln. of tungstic acid in conc. hydrochloric acid was prepared by gradually adding a soln. of potassium metatungstate to boiling hydrochloric acid. The soln. at 40° to 60° is then reduced with tin until the colour is a deep green; it is then rapidly filtered through glass wool, and the filtrate sat. with hydrogen chloride, cooling meanwhile with a freezing mixture. A yellowish-green to yellowish-brown powder gradually separates; the current of hydrogen chloride is stopped after six to seven hours, and the crystals allowed to deposit for twenty-four hours, after which time they are collected, washed with alcohol and ether, dried in a current of carbon dioxide, and preserved in a carbon dioxide desiccator. The yield of **potassium tungsten enneachloride,** $K_3W_2Cl_9$, is about 50–55 per cent. A. Rosenheim and E. Dehn also prepared this salt. If ammonium metatungstate is employed in place of the potassium salt, **ammonium tungsten enneachloride,** $(NH_4)_3W_2Cl_9$, is formed. O. Collenberg and K. Sandved found that 100 c.c. of a soln. at 20° has 15·4 grms. of the potassium salt. O. Collenberg and K. Sandved found the f.p. of soln. with 9·362, 3·521, and 0·8681 grm. $K_3W_2Cl_9$ per 100 grms. of water are lowered respectively 0·639°, 0·267°, and 0·078°, corresponding with the respective osmotic factors $i=2·95$, 3·28, and 3·89. The eq. conductivity, λ, and the degree of ionization, a, for soln. with an eq. of the salt in v litres of water at 1°, are :

v .	8	16	32	64	128	256	∞
λ .	55·8	61·0	65·5	69·8	75·1	78·4	86·3
a .	—	0·71	0·76	0·81	0·87	0·91	—

P. Ray and H. Bhar gave $-0{\cdot}265\times10^{-6}$ mass unit for the magnetic susceptibility. O. Olsson added that by treating the potassium salt with a hydrochloric acid soln. of rubidium chloride, **rubidium tungsten enneachloride,** $Rb_3W_2Cl_9$, is formed; and similarly with **cæsium tungsten enneachloride,** $Cs_3W_2Cl_9$, and **thallous tungsten enneachloride,** $Tl_3W_2Cl_9$. All these salts are anhydrous, have the general formula $M_3W_2Cl_9$, and crystallize in thin, hexagonal plates, which have a greenish-yellow colour in transmitted light. The conc. aq. soln. are green, becoming greenish-yellow on dilution. The solubility decreases as the atomic weight of the alkali metal increases. They can be preserved for several days when dry, but are rapidly oxidized when moist. The solutions show no characteristic absorption bands, but a general absorption at either end of the spectrum, the visible spectrum extending from $\lambda=700$ to $\lambda=520$ for a soln. of 1 grm. of the potassium salt in 100 c.c. of 3 per cent. hydrochloric acid, the thickness of the absorbing layer being 1 cm. For a soln. containing 0·1 grm. of the salt per 100 c.c., the spectrum extends from $\lambda=100$ to $\lambda=490$. O. Collenberg and K. Sandved obtained a soln. of the free acid, **enneachloroditungstic acid,** $H_3W_2Cl_9$, by treating the thallous salt with hydriodic acid, but the acid itself could not be isolated. The term " ous " and " ic " lose their significance in the case of the multivalent elements like vanadium, molybdenum, etc.—*vide* **9**. 54, 6. Some such system as that suggested by A. Werner is required—*e.g.* bivalent tungsten compounds are tungst**i**-compounds ; tervalent tungsten, **tungsto ;** quadrivalent tungsten, tungst**e-** ; quinquevalent tungsten, tungst**an-** ; and sexivalent tungsten, tungst**on-**.

According to O. Collenberg and K. Sandved, the complex character of the potassium salt can be demonstrated by ionic migration ; and the lowering of the f.p. of aq. soln. indicate that not more than four ions are formed by ionization : $K_3W_2Cl_9 \rightleftharpoons 3K^{\cdot}+W_2Cl_9'''$. The salts are strong reducing agents since soln. of copper, silver, gold, and mercury are readily reduced ; and strong oxidizing agents oxidize tervalent tungsten to tungstic acid. The reaction is quantitative with ferric salts. The stability of the complex anion, W_2Cl_9''', is shown by the interaction of the potassium salt with copper, silver, and cadmium salts in the presence of conc. aq. ammonia to form ammines without the precipitation of tungsten hydroxide. These compounds are usually sparingly soluble in water ; the conc. aq. soln. are green, and they become yellow on dilution. The following salts are prepared by double decomposition as just indicated ; and the soln. are fairly stable—more so in the presence of hydrochloric acid. The solubilities are expressed in grams of salt per 100 c.c. of soln. at 20°. **Potassium copper tungsten tetramminoenneachloride,** $KCu(NH_3)_4W_2Cl_9.H_2O$, is a crystalline powder with a solubility of 1·85 grms. ; **ammonium copper tungsten tetramminoenneachloride,** $NH_4Cu(NH_3)_4W_2Cl_9.H_2O$, is a green crystalline powder with a solubility of 2·17 grms. ; silver tungsten hexamminoenneachloride, $[Ag(NH_3)_2]_3W_2Cl_9$, is unstable towards air and water, losing ammonia, and depositing silver ; **potassium cadmium tungsten tetramminoenneachloride,** $KCd(NH_3)_4W_2Cl_9$, has a solubility of 1·9 grms. ; **ammonium cadmium tungsten tetramminoenneachloride,** $NH_4Cd(NH_3)_4W_2Cl_9$, has a solubility of 2·17 grms. ; **chromium tungsten hexamminoenneachloride,** $Cr(NH_3)_6W_2Cl_9.2H_2O$, forms dark green, microscopic, rectangular prisms ; and **cobalt tungsten hexamminoenneachloride,** $Co(NH_3)_6W_2Cl_9.6H_2O$, is a bright green, microcrystalline powder of solubility 0·96 grms. In addition, salts of pyridine, hexamethylenetetramine, tetramethylammonium, tetraethylammonium, triethylamine, dimethylamine, aniline, phenyltrimethylammonium, p-tolyltrimethylammonium, and trimethylsulphine have been described.

A. Riche[3] prepared impure **tungsten tetrachloride,** WCl_4, in voluminous, greyish-brown crystals, by the partial reduction of the hexachloride, a reaction studied by F. Wöhler, and J. B. von Borck. A. Michael and A. Murphy obtained the tetrachloride by heating tungsten dioxide for many hours at 250° in a sealed tube with carbon tetrachloride. According to H. E. Roscoe, the tetrachloride is formed by distilling in a current of hydrogen or carbon dioxide a mixture of the pentachloride and hexachloride heated by a sulphuric acid bath; the non-volatile portion is mixed with the volatile portion, and the distillation repeated to convert any dichloride to tetrachloride. The non-volatile portion obtained in the preparation of the pentachloride is mainly the tetrachloride. The flocculent, hygroscopic, greyish-brown, crystalline mass neither fuses nor volatilizes when strongly heated, but at a high temp. it decomposes into the volatile pentachloride, and the non-volatile dichloride. W. Hampe also found it to be infusible. W. Biltz and C. Fendius gave 4·624 for the sp. gr. of the anhydrous chloride, and 70·5 for the mol. vol. H. E. Roscoe added that hydrogen at the temp. of a zinc-bath reduces the tetrachloride to metal. The salt is hydrolyzed by water forming a brown oxide and a greenish-brown hydrochloric acid soln. which deposits the brown oxide on standing some time. O. C. M. Davis found that it unites with nitrogen tetrasulphide to form **tungsten nitrogen tetrachlorotetrasulphide,** $WCl_4.N_4S_4$, in brown crystals which readily decompose. A. W. Cronander reported the complex $WCl_4.PCl_5$ to be formed when tungsten hexachloride is heated with phosphorus pentachloride. There appears to be something wrong with this statement. According to O. Olsson, when the soln. obtained by gradually adding potassium tungstate to boiling hydrochloric acid is reduced with tin at the ordinary temp., it first becomes light blue in colour, the colour then gradually deepens, and finally suddenly changes to an intense reddish-violet colour, similar to that of permanganate. This colour persists for a long time, and a small quantity of a dark green powder deposits, consisting of quadratic, tabular crystals of **potassium tungsten hydroxypentachloride,** $K_2W(OH)Cl_5$. They are red in transmitted light. The salt is stable when dry, but oxidizes rapidly when moist. The absorption spectrum of the hydrochloric acid soln. is similar to that of the tervalent compounds, the visible spectrum for a soln. of 1 grm. in 150 c.c. of 4 per cent. hydrochloric acid and a thickness of 1 cm. extending from $\lambda=730$ to $\lambda=610$.

C. W. Blomstrand[4] showed that **tungsten pentachloride,** WCl_5, reported by F. J. Malaguti, was probably the oxytetrachloride; and the pentachloride of J. B. von Borck, and V. Forcher, a mixture of the hexachloride and oxytetrachloride. C. W. Blomstrand prepared the pentachloride by heating the hexachloride for a long time in hydrogen, so as to avoid volatilization; the substance gradually becomes less fusible, and shows no inclination to crystallize on cooling. If the temperature is too high, some tungsten, or, according to H. E. Roscoe, tungsten dichloride may be formed. C. W. Blomstrand said that an alcohol-lamp suffices for the heating. The product is finally distilled in a current of carbon dioxide; the residue is the tetrachloride. C. W. Blomstrand added that only traces of pentachloride are formed in the distillation of the hexachloride in hydrogen, but, according to H. E. Roscoe, a reduction always occurs. If the temp. be kept but little above the b.p. of the hexachloride, the dark red colour of the vapour is seen to vanish, and a light yellow-coloured vapour makes its appearance, which soon condenses into black drops or long, shining, black needles. After two or three distillations in hydrogen a pure product is obtained. C. W. Blomstrand found only traces are formed by V. Forcher's process in which a mixture of tungsten trioxide and carbon is heated first in carbon dioxide and afterwards at a red-heat in chlorine. C. H. Ehrenfeld obtained the pentachloride along with the hexachloride and tungsten oxytetrachloride by heating a mixture of tungsten trioxide and phosphorus pentachloride. F. de Carli heated ferrotungsten at 400° to 500° in chlorine gas. The compound was prepared and analyzed by C. W. Blomstrand, H. E. Roscoe, and C. G. de Laval. R. F. Bernhardi-Grisson observed that quinquevalent tungsten can be obtained by the electrolytic reduction of a soln. of tungsten trioxide in hydrochloric acid and mixed with alcohol. O. Collenberg and co-workers studied the electrolytic reduction of hydrochloric acid soln. of tungsten trioxide to the quinquevalent state—*vide supra*, tungstic acid. Tungsten pentachloride crystallizes in long, black, shining needles, but if condensed in fine powder its colour is dark green, and the powdered crystals are also dark green like potassium manganate. W. Biltz and C. Fendius found 3·875 for the sp. gr. at 25°/4°, and 93·3 for the mol. vol. C. W. Blomstrand gave 244° for the m.p., and H. E. Roscoe said that it melts at 248° and freezes to a crystalline mass at 242°; and it boils at 275·6°. It is less readily volatilized than the hexachloride, and, according to C. W. Blomstrand, it yields a greenish-yellow vapour. H. E. Roscoe found the vapour density at 440° is 12·83 to 12·89; and at 350°, 12·14 to 12·43, in agreement with the formula WCl_5. W. Hampe said that the molten pentachloride is a non-conductor of electricity; A. Voigt and W. Biltz gave for the sp. conductivity $0{\cdot}67\times10^{-6}$ mho at 250°; $1{\cdot}35\times10^{-6}$ mho at 275°; and $1{\cdot}84\times10^{-6}$ mho at 300°. H. E. Roscoe, and C. W. Blomstrand found that the salt does not decrepitate like the hexachloride when heated; it is reduced when heated in hydrogen. In oxygen, the pentachloride rapidly forms brown vapours of the oxytetrachloride; it deliquesces in moist air, and is so hygroscopic that in air, the crystals immediately acquire a dark yellowish-green film, and small particles are converted into drops. When treated with water, there is a hissing noise, and the development of much heat, and the formation of a bluish-black oxide, and an olive-green soln. which slowly deposits a greenish oxide in the cold, rapidly when heated. B. Kalischer observed that the pentachloride unites with sulphur monochloride, brown needles are produced. According to H. E. Roscoe, and C. W. Blomstrand, boiling nitric acid forms tungsten trioxide; aq. ammonia added to the boiling aq. soln. gives a precipitate. A. W. Cronander found that tungsten and phosphorus pentachlorides react to form **tungsten phosphoenneachloride,** $WCl_4.PCl_5$—*vide* **8.** 50, 32. Alkali-lye acts more vigorously than water; likewise hydrochloric acid. B. Kalischer said that carbon disulphide dissolves very little pentachloride, but it acquires a deep blue colour; carbon tetrachloride forms a brown soln. Most organic compounds act vigorously on the pentachloride—*e.g.* methyl, ethyl, propyl, and amyl alcohols form yellow soln. with a hissing noise; the heat of the reaction may be so great that vapour is developed—*e.g.* with cinnamic aldehyde; and in some cases crystals may be formed—*e.g.* with alcohol, ether, benzaldehyde, and cinnamic aldehyde. Pyridine and quinoline do not form crystalline compounds. F. W. Bergstrom observed the pentachloride forms a red soln. of an ammoniobasic halide when it is treated with liquid ammonia. R. F. Bernardi-Grisson said that all salts of quinquevalent tungsten react according to $W^{V}+Ag^{\cdot}\rightarrow W^{IV}+Ag$ when treated with an ammoniacal soln. of a silver salt. A. Fischer and co-workers obtained a complex, $WCl_2(OC_2H_5)_3$, with quinquevalent tungsten by the electrolytic reduction of an alcoholic soln. of tungsten hexachloride.

A. Riche,[5] F. Wöhler, H. Rose, C. W. Blomstrand, C. G. de Laval, and H. E. Roscoe prepared **tungsten hexachloride,** WCl_6, by the action of chlorine on heated tungsten. The first action of ordinary dry chlorine is to form a yellow and then a red oxychloride, and afterwards the hexachloride. The red oxychloride cannot be separated by distillation from the hexachloride owing to the slight differences in their b.p. Metallic tungsten takes fire when moderately heated in chlorine. To prepare the hexachloride, the metal is first heated in a current of dry hydrogen in a tube, so as to remove completely every trace of air and moisture. The hydrogen is then replaced by dry chlorine free from air. The metal is then heated to dull redness—E. F. Smith and F. F. Exner recommended a temp. of 350°. A granular sublimate of dark violet crystals of the hexachloride is formed. When the hexachloride is prepared in quantity, the hexachloride collects as a reddish-black liquid. For purification, this liquid is distilled several times in an excess of chlorine, and finally rectified in a stream of hydrogen. F. de Carli passed chlorine over ferrotungsten at 400° to 500°, and extracted the chloride with carbon disulphide. After filtration and evaporation of the solvent, the residual chloride is purified by sublimation. E. F. Smith and F. Fleck obtained the hexachloride by heating the metal in the vapour of sulphur monochloride and an excess of chlorine—without the chlorine, the hexachloride is not formed; E. Defacqz heated tungsten disulphide in dry chlorine at a dull red-heat, and purified the product by sublimation; and A. Michael and A. Murphy heated a soln. of chlorine in carbon tetrachloride and tungsten trioxide in a sealed tube—the oxytetrachloride is produced at 240°, and the hexachloride at 280°—carbon tetrachloride alone converts the trioxide into the hexachloride at 280°. According to N. Teclu, when a mixture of a mol of tungsten trioxide and 3 mols of phosphorus pentachloride is heated in a sealed tube up to 170° to 200°, and the phosphoryl chloride removed by distillation, and finally by heating to 120° in a current of carbon dioxide, tungsten hexachloride of a high degree of purity is formed. C. H. Ehrenfeld observed that when tungsten trioxide is heated with an eq. weight of phosphorus pentachloride in an atm. of carbon dioxide, phosphoryl chloride is evolved, and a mixture of tungsten pentachloride and hexachloride is formed. The product is red-brown, melts to a dark red liquid, and gives off reddish-brown vapours resembling bromine; these condense to steel-blue isomeric forms of the hexachloride mixed with reddish-brown needles of the pentachloride. The intensity of the heat applied, and the duration of the action determine the quantity of the brown material produced. The hexachloride of course is converted into pentachloride by ignition in carbon dioxide or hydrogen. The bright red product is the oxytetrachloride. Nitrogen can be used instead of carbon dioxide but the results are not so good. According to H. Schiff, if a soln. of phosphorus pentachloride in carbon disulphide be heated with an equimolar proportion of tungsten trioxide for many days at 80° to 90° in a sealed tube, and the solvent removed by heating the product in a current of carbon dioxide, a mixture of tungsten oxychlorides, hexachloride, and lower chlorides is formed. H. Schiff also observed that when equimolar proportions of tungsten oxytetrachloride and phosphorus pentachloride are heated to 170° in a sealed tube, tungsten hexachloride is formed.

The salt was analyzed by A. Riche, C. W. Blomstrand, N. Teclu, V. Forcher, H. E. Roscoe, C. G. de Laval, A. Michael and A. Murphy, etc. The results agree with the formula WCl_6. N. V. Sidgwick discussed the co-valency of tungsten in the hexachloride. H. E. Roscoe said that the dark violet crystals of the sublimate decrepitate on cooling and the mass falls to a crystalline powder. H. E. Roscoe found that on several occasions sealed tubes exploded when opening them with a file owing to sudden decrepitation. V. Forcher described the crystals as dark violet needles or scales; and C. W. Blomstrand said that the colour in the molten state is brownish-black, with no tinge of red. The molten salt solidifies to a mass of scaly crystals. The soln. in carbon disulphide furnishes hexagonal plates. C. H. Ehrenfeld said that the crystals are steel-blue and cubic. F. Wöhler said that the vapour is the colour of nitrogen trioxide; C. W. Blomstrand said reddish-yellow; V. Forcher, dark red; and H. E. Roscoe, reddish-brown. E. F. Smith and F. F. Exner gave 3·518 for the sp. gr.; W. Biltz and C. Fendius gave 3·520 at 25°/4°, and for the mol. vol., 112·7. H. E. Roscoe found the vapour density at 440° to be 18·67, and at 350°, 13·16 in agreement with the formula WCl_6. and with the assumption that with higher temp. the molecules dissociate, rather than to assume with J. Persoz that the salt has the formula WCl_5. H. Debray, and R. Rieth also observed the anomalous vapour density at the higher temp. A. Riche, C. W. Blomstrand, and V. Forcher found that the salt softens when heated to 170° to 183°—N. Teclu said 189°—presumably owing to impurities—say oxychloride—because H. E. Roscoe found that the salt melts to a black liquid at 275°, and freezes at 270° owing to surfusion. H. Debray gave 300° for the b.p., and H. E. Roscoe, 346·7° at 759·5 mm. H. G. Grimm, and G. von Hevesy discussed the m.p. and electrical conductivity. W. Hampe found that the molten hexachloride is a non-conductor of electricity; A. Voigt and W. Biltz gave for the sp. conductivity $1{\cdot}98\times10^{-6}$ mho at 280°; $2{\cdot}85\times10^{-6}$ mho at 305°; and $6{\cdot}94\times10^{-6}$ at 330°; and W. Biltz gave 0·0000020 for the temp. coeff. of the conductivity. O. Collenberg and A. Guthe found that the reduction potential of sexivalent to quinquevalent tungsten for soln. with 0·143 gram-atom of tungsten per litre in $2N$-H_2SO_4 at 18° is 0·395 volt. S. Berkman and H. Zocher gave $-0{\cdot}14\times10^{-6}$ mass unit for the magnetic susceptibility.

The reducing action of hydrogen—*vide supra*, tungsten tetrachloride and pentachloride—was observed by A. Riche, H. E. Roscoe, W. Spring, and F. Wöhler. V. Forcher, and H. Debray said that the salt changes slowly in moist air, but H. E. Roscoe added that the purified hexachloride does not undergo any change even in moist air, but if the smallest trace of oxychloride is present, it at once absorbs moisture evolving fumes of hydrogen chloride, and changing its colour from violet to brown. V. Forcher found that, when the hexachloride is heated in air, it forms tungsten oxytetrachloride. N. Teclu, and C. W. Blomstrand said that the hexachloride is very slowly attacked by cold water, but H. E. Roscoe added that if the salt is impure, it is at once decomposed by cold water forming a greenish hydrated oxide. Water begins to attack the purified hexachloride at about 60°; boiling water decomposes it rapidly. The tungstic acid which is formed retains chlorine very tenaciously. According to C. W. Blomstrand, alkali-lye acts on the hexachloride slowly in the cold, and when heated the action is very vigorous, the salt swells up and the liquid becomes blue, and after a short time, colourless. Brown flecks separate out. If lower chlorides are present, added H. Debray, some hydrogen may be developed by the action of the alkali-lye. W. Biltz and E. Meinecke said that the hexachloride is very sparingly soluble in liquid chlorine. C. W. Blomstrand observed that hydrochloric acid produces no change at first, and when heated, the liquid remains colourless, but after a short time tungstic acid is formed; E. Defacqz found that hydrogen bromide at about 300° forms tungsten pentabromide; when heated with liquid hydrogen bromide in a sealed tube, a chlorobromide is formed whose composition depends on the temp.; hydrogen iodide forms tungsten diiodide; liquid hydrogen iodide heated in a sealed tube, forms tungsten tetraiodide; hydrogen sulphide forms tungsten disulphide; and liquid hydrogen sulphide, in a sealed tube, forms a chlorosulphide. S. Rideal found that ammonia acts rapidly on the hexachloride forming tungsten hemitrinitride; and O. C. M. Davis found that a soln. of the hexachloride soln. forms $WCl_4.N_4S_4$, as indicated above. N. Teclu said that the salt is soluble in phosphoryl chloride. A. W. Cronander studied the action of phosphorus pentachloride—*vide supra*, tungsten tetrachloride. E. Defacqz found that phosphine forms tungsten diphosphide; and arsine, tungsten diarsenide—liquid arsine in a sealed tube forms a chloroarsenide. A. Fischer and A. Roderburg found that at 18°, a red soln. of 0·2364 grm. of the hexachloride in 20 c.c. of arsenic trichloride with a sp. conductivity of $6{\cdot}2\times10^{-6}$ mho has a conductivity of $1{\cdot}3\times10^{-6}$ mho. J. N. Pring and W. Fielding observed that tungsten hexachloride is reduced by carbon at 1000°–1500°. H. E. Roscoe found that the hexachloride dissolves in carbon disulphide forming a reddish-brown soln.; O. C. M. Davis found that it is soluble in chloroform. A. Riche said that alcohol acts vigorously without forming a tungstic ether; and B. Kalischer found that the hexachloride dissolves in alcohol. The soln. is yellow, but no addition product is formed. A. Fischer and A. Roderburg found that the yellow soln. of 0·1937 grm. of the hexachloride in 20 c.c. of methyl alcohol of sp. conductivity $1{\cdot}8\times10^{-6}$ mho at 18° has a conductivity of $5{\cdot}23\times10^{-3}$ mho; and the yellow soln. of 0·4428 grm. of hexachloride in 20 c.c. of 99·8 per cent. ethyl alcohol of sp. conductivity 2×10^{-6} mho at 18°, has a conductivity of $3{\cdot}46\times10^{-3}$ mho at 18°. The eq. conductivity, λ, of an eq. of the salt in v litres of alcohol of sp. conductivity $1{\cdot}56\times10^{-6}$ mho at 2°, is:

v .	1·30	2·82	5·82	9·84	123	417	925
λ .	7·0	8·7	10·4	11·6	16·7	20·9	24·6 mho.

The e.m.f. of the cell W | WCl_6(alcohol) | LiCl(sat. soln. in alcohol) | Hg_2Cl_2 | Hg for one-sixth of a mol of the hexachloride in *v* litres is :

v	1·30	2·82	5·82	9·84	123	417	925
E.m.f.	0·504	0·492	0·474	0·465	0·399	0·362	0·349 volt.

The electrolysis of an alcoholic soln. of the hexachloride colours the liquid green as the tungsten is reduced to the quinquevalent form, and the complex $WCl_2(OC_2H_5)_3$ separates out. In opposition to the patent of the Wolframlampen A.G., no evidence of the separation of tungsten was observed with soln. in methyl alcohol, ethyl alcohol, acetone or pyridine, although with glycerol soln. a little tungsten was deposited. F. W. Bergstrom observed that the hexachloride forms a red soln. with liquid ammonia. A. Rosenheim observed that a compound with oxalic acid is formed in chloroform soln. B. Kalischer observed the formation of no addition products with aldehydes, ketones, or esters, although salicylic ether forms $WCl_4(OC_6H_4.COOC_2H_5)_2$; salicylic acid formed a similar compound. No complex salts were formed with organic chlorides in alcoholic soln. The soln. of the hexachloride in ether is yellow ; in benzene, brown ; and in chloroform, carbon disulphide, carbon tetrachloride, and ligroïn, brown or reddish-brown. The soln. gradually change owing to the reduction of the hexachloride. The change is rapid if water be present.

A. Fischer and A. Roderburg found that with a soln. of the bracketed number of grams of the hexachloride in 20 c.c. of solvent, at 18°, the colour is red with chloroform (0·203) and the sp. conductivity is $8·6\times10^{-6}$ mho when that of the pure solvent is zero ; is violet with carbon disulphide (0·2316) and the sp. conductivity of solvent and soln. is zero ; red with carbon tetrachloride (0·1899), conductivity of solvent and soln. zero ; dark blue with benzene (0·1622), sp. conductivity of solvent and soln. zero ; red with acetylene tetrachloride (0·1262), sp. conductivity of solvent zero, of soln., 9×10^{-6} mho ; dark blue with chlorobenzene (0·2201), sp. conductivity of solvent and soln. zero ; red with ethyl ether (0·2309), sp. conductivity of solvent zero, of soln., $1·5\times10^{-7}$ mho ; red with ligroïn (0·1434), sp. conductivity of solvent and soln. zero ; red with pyridine (0·1587), sp. conductivity of soln. $1·4\times10^{-7}$ mho, and of soln. $5·8\times10^{-4}$ mho ; brownish-yellow with glycerol (1·2557), sp. conductivity of solvent zero, and of soln. at 100°, $1·47\times10^{-2}$ mho ; and yellow with dried acetone (1·3443), sp. conductivity of solvent $2·4\times10^{-6}$ mho, and of soln. 2×10^{-3} mho. W. Brydowna found that tungsten hexachloride reacts with a soln. of phenyl-magnesium iodide in ether producing diphenyl.

A. Riche observed that sodium reduces the vapour of the hexachloride to tungsten ; and K. Seubert and A. Schmidt that magnesium at a red-heat reduces the hexachloride to metal. C. W. Blomstrand found that the hexachloride is reduced to a lower chloride by copper, silver, and molybdenum, but not by tungsten. H. Debray observed that when the hexachloride is heated with tungsten trioxide, the oxytetrachloride is formed.

§ 20. The Tungsten Oxychlorides

O. Olsson [1] prepared **potassium tungsten hydroxylpentachloride,** $K_2W(OH)Cl_5$, as indicated in connection with tungsten tetrachloride. B. Kalischer's attempts to prepare **tungsten oxytrichloride,** $WOCl_3$, with quinquevalent tungsten were not successful, but O. O. Collenberg obtained complex salts of this oxychloride. A soln. of an alkali tungstate in a conc. soln. of oxalic acid containing a slight excess of alkali oxalate was reduced with tin. The course of the reduction can be followed by the colour change, through dark blue, green, and yellow to deep red. After removal of tin and excess of oxalic acid, the complex oxalate is precipitated by means of alcohol, and can be purified by dissolving in hot water and salting out the sodium salt with sodium bromide, and the potassium salt with potassium iodide. The compounds must be dried in a current of carbon dioxide, but are fairly stable in air when dry. The sodium salt has the composition $3Na_2O.2W_2O_5.4C_2O_3.12H_2O$, and the potassium salt $3K_2O.2W_2O_5.4C_2O_3.9H_2O$. They are red, crystalline powders which slowly oxidize in air, and at 100° lose their water, but do not decompose. They are very soluble in water, insoluble in organic solvents. These complex oxalates are supposed to be derived from a hypothetical tungstous acid, $WO_2.OH$. The oxalotungstites dissolve in concentrated hydrochloric acid, forming a deep blue soln., which contains an *oxychloride* of quinquevalent tungsten, probably $WOCl_3$. From this soln., complex chlorides can be isolated containing $WOCl_3$ in combination with chlorides of the alkali metals or ammonium or hydrochlorides of organic bases. The ammonium and potassium salts are precipitated by saturating a hydrochloric acid soln. of the corresponding oxalotungstite with hydrogen chloride. The rubidium, cæsium, aniline, tetraethyl- and tetrapropyl-ammonium compounds are precipitated when the corresponding chloride is added to a hydrochloric acid soln. of an oxalotungstite, and the pyridine and quinoline compounds are prepared by double decomposition of their hydrochlorides with ammonium chlorotungstite. There are two main types of salt, those derived from $2RCl.WOCl_3$, or R_2WOCl_5, and those derived from $RCl.WOCl_3$, or $RWOCl_4$. The co-ordination formulæ are respectively $R_2[WOCl_5]$, and $R[WOCl_4(H_2O)]$. The $RCl.WOCl_3$ compounds can be regarded as derivatives of metatungstous acid, $WO_2.OH$, and the $2RCl.WOCl_3$ compounds as derivatives of orthotungstous acid, $W(OH)_5$, in which one oxygen is replaced by two chlorine atoms, and three hydroxyl groups by three chlorine atoms, thus :

$\left.\begin{matrix}Cl_2\\Cl_2\end{matrix}\right\rangle W{-}OH$

$RCl.WOCl_3$

$Cl_3{\equiv}W\left\langle\begin{matrix}Cl_2H\\OH\end{matrix}\right.$

$2RCl.WOCl_3$

A green crystalline powder of **ammonium oxypentachlorotungstite,** $(NH_4)_2WOCl_5$, is hydrolyzed by water ; 20 c.c. of hydrochloric acid dissolve a gram of the salt ; and it is soluble in absolute methyl or ethyl alcohol. Similarly with **potassium oxypentachlorotungstite,** $K_2WOCl_5.2H_2O$, as a reddish-brown or yellowish-brown powder ; **rubidium oxypentachlorotungstite,** Rb_2WOCl_5 ; and with **cæsium oxypentachlorotungstite,** Cs_2WOCl_5. The salt with aniline was also prepared. Salts of the type $RCl.WOCl_3$, were prepared with pyridine, quinoline, tetraethylammonium, and tetrapropylammonium. These salts are stable in dry air at the ordinary temp., but decompose with oxidation to tungstates at 60° to 70°. They are immediately hydrolyzed by water with the formation of a brown hydroxide. The less soluble cæsium compound is, however, far more stable than the readily soluble ammonium and potassium compounds. The salts dissolve readily in absolute methyl and ethyl alcohols, with the exception of the rubidium and cæsium compounds, but not in other organic solvents. Conc. hydrochloric acid and 35 per cent. sulphuric acid also dissolve them, but alkalies and aq. ammonia decompose them. Oxidizing agents convert them into tungstates, and permanganate and iodine have been employed for quantitative determinations of the quinquevalent tungsten. The chlorotungstites react vigorously with a conc. soln. of potassium cyanide with evolution of hydrogen cyanide. A reddish-brown soln. is formed containing cyanides of the type $M_4W(CN)_8$. A thiocyanic acid compound has also been isolated in the form of a pyridine salt. P. Ray and co-workers found the magnetic susceptibility of $K_2W(OH)Cl_5$ to be $4{\cdot}0\times10^{-6}$ mass unit at 31°.

F. Wöhler [2] discovered **tungsten oxytetrachloride,** $WOCl_4$, which he obtained by heating the sulphide in chlorine. J. B. von Borck, F. J. Malaguti, and C. G. de Laval used a similar process. C. W. Blomstrand, and V. Forcher said that the " sulphide " was probably the oxysulphide, or air and moisture were not excluded from the system. A similar remark applies to the formation of the oxytetrachloride observed by J. B. von Borck, C. W. Blomstrand, and H. E. Roscoe when chlorine containing air and moisture is passed over heated tungsten, or, according to A. Vosmaer, ferrotungsten. This subject was also studied by J. Persoz, R. Weber, N. Teclu, H. Schiff, C. Gerhardt and L. Chiozza, and A. Kremer. H. Debray, C. W. Blomstrand, C. G. de Laval, and H. E. Roscoe considered that the oxytetrachloride is best obtained by passing the vapour of tungsten hexachloride over heated tungsten trioxide or dioxydichloride. O. Ruff and co-workers recommended the following process :

> A hard glass tube 50 cms. long was packed with tungsten hexachloride in the first third of its length, and with tungsten dioxydichloride in the middle third, while the last third was left for the reception of the oxytetrachloride. The middle part of the tube, wrapped in asbestos, was heated to about 230°, while a current of well-dried carbon dioxide is passed through the tube. When all the air has been displaced, the part containing the hexachloride is heated directly by the flame so that the hexachloride slowly boils. The current of carbon dioxide carries the vapour over the dioxydichloride, and reddish needles of the oxytetrachloride sublime into the cooler part of the tube. The product is resublimed in a current of carbon dioxide to remove traces of hexachloride and dioxydichloride.

A. Bonnet, and A. Riche obtained the salt by heating a mixture of tungsten trioxide and carbon in a current of dry carbon dioxide until all the air and moisture is expelled, and then in a current of dry chlorine. It is purified by distillation in a current of carbon dioxide. R. D. Hall, and E. F. Smith and F. Fleck prepared the oxytetrachloride by passing sulphur monochloride vapour over tungsten trioxide, or wolframite, or scheelite at 145°, and purifying the product by distillation between 215° and 225°. F. Bourion, and C. Matignon and F. Bourion passed the vapour of sulphur monochloride alone or mixed with hydrogen chloride over tungsten trioxide at 230° to 250° and cooled the product in a current of hydrogen chloride. When the vapour of sulphur monochloride is passed over wolframite or scheelite heated to about 150°, prismatic scarlet crystals are obtained when the red soln. cools. Similar crystals are obtained by the action of the same substance on tungsten trioxide. The third oxygen atom of tungsten trioxide is not removed by heating with sulphur monochloride. The product is immediately decomposed on exposure to air, it gives off hydrogen chloride and leaves tungsten trioxide. This salt is readily soluble in carbon disulphide or sulphur monochloride, but sparingly soluble in benzene. Sulphur monochloride does not attack tungsten itself. C. W. Watts and C. A. Bell, and H. E. Quantin heated tungsten trioxide in the vapour of carbon tetrachloride and obtained a mixture of the dioxydichloride and oxytetrachloride ; P. Camboulives recommended for the oxytetrachloride a temp. of 560°, and A. Michael and A. Murphy added that one of the best methods of preparing the oxytetrachloride is to heat tungsten trioxide with a soln. of chlorine in carbon tetrachloride in a sealed tube at 240°. C. W. Watts and C. A. Bell said that a mixture of chlorine and carbon monoxide, or dioxide, can be substituted for carbon tetrachloride ; and E. F. Smith and V. Oberholtzer, and K. Lindner recommended passing the vapour of carbonyl chloride over red-hot tungsten. H. Schiff observed that the oxytetrachloride is formed by heating a mol of tungsten trioxide with one or two mols of phosphorus pentachloride, and sublimation of the product in a current of carbon dioxide to separate the more volatile oxytetrachloride from the less volatile dioxydichloride. E. H. Ehrenfeld obtained a mixture of chlorides and oxychlorides by the action of phosphorus pentachloride on tungsten trioxide. G. Rauter heated the trioxide in the presence of silicon tetrachloride, although E. H. Ehrenfeld said that silicon tetrachloride does not act on tungsten trioxide. H. Rose, C. W. Blomstrand, and V. Forcher prepared the oxytetrachloride by heating the dioxydichloride in hydrogen ; C. W. Blomstrand heated tungsten pentachloride in oxygen, and C. G. de Laval, the hexachloride in oxygen ; and H. Debray distilled tungsten hexachloride with oxalic acid—some dioxydichloride is simultaneously formed.

Analyses in agreement with $WOCl_4$ were reported by A. Riche, H. Schiff, C. W. Blomstrand, C. G. de Laval, A. Bonnet, V. Forcher, H. E. Roscoe, etc. F. J. Malaguti represented it by the formula W_2Cl_5, and J. B. von Borck, by WCl_4. Various observers described the oxytetrachloride as forming red, or scarlet-red, prismatic needles, which, according to H. Debray, have a vapour density of 10·58, and, according to H. E. Roscoe, 11·92, which is approximately normal. The vapour is pale red; F. Wöhler said that it has the colour of nitrogen trioxide. The oxytetrachloride was found by A. Riche to melt at 199°, and solidify at 197·5°; C. W. Blomstrand gave 208° to 210° for the m.p., C. W. Blomstrand, 204°; and H. E. Roscoe, 210·4°—and 206·7° for the f.p. A. Riche, and C. W. Blomstrand found that it can be volatilized without melting, and H. E. Roscoe gave 227·5° for the b.p. W. Hampe observed that neither the molten salt nor the vapour is a conductor of electricity. L. von Uslar, and A. Riche observed that when heated in hydrogen it can be reduced to metal. F. Wöhler, J. B. von Borck, C. G. de Laval, V. Forcher, and H. E. Roscoe observed that, when exposed to air, the salt is very quickly hydrolyzed by moisture to hydrogen chloride and tungstic acid. C. W. Blomstrand found that it can be sublimed in oxygen without change, but it finally loses chlorine, passing into the dioxydichloride observed by A. Vosmaer. F. Wöhler, and A. Riche observed that it hisses when in contact with water, heat is evolved, and it is rapidly hydrolyzed into tungstic acid and hydrochloric acid. J. B. von Borck added that some hydrogen may be evolved, but this statement has not been confirmed; alkali-lye was found by V. Forcher to form tungstate, and presumably chloride. When the oxytetrachloride is mixed with carbon, and heated in chlorine, H. E. Roscoe observed that it is converted into tungsten hexachloride. S. Rideal found that ammonia converts it into a mass of black hemitrinitride; and when heated with phosphorus pentachloride in a sealed tube at about 170°, tungsten hexachloride and phosphoryl chloride are formed. E. W. Smith and F. Fleck said that the oxytetrachloride is soluble in carbon disulphide and sulphur monochloride, and sparingly soluble in benzene; and B. Kalischer added that it is not dissolved by the usual solvents.

F. Wöhler prepared **tungsten dioxydichloride,** WO_2Cl_2, by heating tungsten dioxide in dry chlorine. The reaction occurs with incandescence, and a dense, yellow vapour is formed, which forms a crystalline sublimate. V. Forcher used blue tungsten oxide, and C. G. de Laval warmed the dioxide. V. I. Spitzin and L. Kaschtanoff found that the dioxydichloride is formed when hydrogen chloride acts on tungsten dioxide, hemipentoxide, and trioxide, or on the tungstates. H. Rose, and E. F. Smith and O. L. Shinn employed a similar process. F. Wöhler, and F. J. Malaguti thought that the dioxydichloride is the hexachloride, but H. Rose showed that this is wrong. It was analyzed by H. Rose, A. Riche, J. B. von Borck, C. G. de Laval, H. E. Roscoe, and O. Ruff and co-workers. A. Riche obtained the dioxydichloride by heating tungsten trioxide in dry chlorine; V. Forcher similarly heated a mixture of carbon and tungsten trioxide or wolframite; and J. B. von Borck heated tungsten in a mixture of chlorine and air. F. Bourion heated tungsten trioxide in the vapour of sulphur monochloride and obtained both the dioxydichloride and the oxytetrachloride. C. W. Watts and C. A. Bell passed the vapour of carbon tetrachloride over red-hot tungsten trioxide; H. Debray heated tungsten hexachloride with oxalic acid—*vide supra*, tungsten oxytetrachloride; and C. G. de Laval sublimed tungsten hexachloride or pentachloride over the heated trioxide. H. O. Schulze heated in the absence of air a mixture of calcium chloride and tungsten trioxide, and obtained tungsten dioxydichloride and calcium tungstate—the chlorides of magnesium, iron, cobalt, and nickel can be used, but not the alkali, lead, or silver chlorides.

Tungsten dioxydichloride obtained by sublimation was described by F. Wöhler, A. Riche, C. G. de Laval, V. Forcher, and H. E. Roscoe as a pale yellow or dark golden-yellow solid with four-sided plates resembling natural boric acid; and the vapour is variously described as pale yellow, or dark red. H. Debray, and H. E. Roscoe said that complete volatilization does not occur at 450°, and no vapour density determination was made at this temp. H. Rose said that when suddenly heated it is partially dissociated into tungsten trioxide and oxytetrachloride; and H. Schiff also noted that at a high temp. this decomposition occurs. F. Wöhler, J. B. von Borck, C. W. Blomstrand, and H. E. Roscoe said that it usually vaporizes before melting, but A. Riche gave 259° for the m.p. and 256° for the f.p.; and V. Forcher, 265° to 267° for the m.p. L. von Uslar observed that it is reduced to metal when it is heated in a current of hydrogen. H. E. Roscoe said that it is not decomposed by moist air, but F. Wöhler, and V. Forcher observed that moist air slowly decomposes it into hydrochloric acid and hydrated tungsten trioxide. C. G. de Laval also observed that it fumes strongly in air. F. Wöhler, J. J. Berzelius, and A. Riche also observed that the salt is slowly decomposed by water as in the case of moist air; while H. E. Roscoe said that it is not decomposed by cold water; and after many evaporations with water, the residue is not free from chlorine. V. Forcher observed that alkali-lye dissolves the dioxydichloride slowly in the cold, and rapidly when heated. J. J. Berzelius found that conc. hydrochloric acid extracts some tungsten trioxide from the salt. At ordinary temp., ammonia gas reacts giving off fumes of ammonium chloride; and the residue was found by S. Rideal to contain only a little nitrogen, and to be mainly tungsten dioxide, while E. F. Smith and O. L. Shinn observed that $W_4N_4O_4H_2$ is formed; with liquid ammonia, A. Rosenheim and F. Jacobsohn observed the formation of brown tungsten triamminoxide, $WO_3.3NH_3$; and F. Wöhler observed that with aq. ammonia, there is a hissing noise and the development of heat. H. Schiff observed that phosphorus pentachloride converts it into the oxytrichloride. B. Kalischer found that owing to the insolubility of the dioxydichloride in all solvents tried, he was unable to prepare complex salts. Soln. of tungsten trioxide in alcoholic hydrochloric acid, when treated with pyridinium or quinolinium chlorides, yield acicular crystals of $WO_2Cl_2.3C_5H_5N.HCl$, and $WO_2Cl_2.3C_9H_7N.HCl$. R. F. Bernhardi-Grisson obtained similar products.

S. M. Tanatar and E. Kurowsky[3] treated a soln. of sodium tungstate with beryllium chloride, and obtained precipitates of **beryllium chlorotungstates** of variable composition, $BeO.mBeCl_2.nBeWO_4$, insoluble in water and organic solvents, and sparingly soluble in acids. P. Didier found that yellow, channelled crystals of **cerium chlorotungstates,** are formed when equal parts of normal sodium tungstate and anhydrous cerium chloride are heated, with or without fusion in an inert atmosphere. If the cerium chloride be in excess, yellow or red hexagonal plates are formed. The salt may also be prepared by passing hydrogen chloride over a mixture of heated cerium and tungsten oxides.

§ 21. Tungsten Bromides and Oxybromides

H. E. Roscoe[1] reported **tungsten dibromide,** WBr_2, to be formed by passing hydrogen over tungsten pentabromide heated in a bath of molten zinc. If the temp. is too low, say 350°, the product is not homogeneous. The pentabromide and oxybromide and bromine may distil over, and the dibromide remains as a bluish-black powder. It behaves towards water and nitric acid vapour like the corresponding dichloride. F. W. Bergstrom observed that a slightly soluble ammoniobasic bromide is formed when the dibromide is treated with liquid ammonia.

J. B. von Borck first prepared impure **tungsten pentabromide,** WBr_5, and A. Riche also obtained it but regarded it as a hexabromide. C. W. Blomstrand showed that it is really the salt of quinquevalent tungsten. Analyses supporting this view were made by J. B. von Borck, C. W. Blomstrand, H. E. Roscoe, and E. Defacqz. J. B. von Borck, A. Riche, and H. E. Roscoe obtained it by passing the vapour of bromine, preferably diluted with carbon dioxide, over red-hot tungsten. All traces of moisture and air must be rigorously excluded. The product is purified from any traces of oxybromide which might be present by repeated sublimation. The temp. of formation is higher than is needed for the pentachloride, and the union is not attended by incandescence. E. Defacqz obtained it by passing dry hydrogen bromide, freed from air, over tungsten hexabromide at 300°—the reaction begins at about 250°. H. E. Roscoe described the crystals as dark brown needles; J. B. von Borck said that the crystals are black with a blue or violet tint; and E. Defacqz, that the sublimate consists of fan-like aggregates of dark needles. J. B. von Borck said that the vapour is dark purple red, almost black, H. E. Roscoe, dark brown. J. B. von Borck found that the pentabromide sublimes almost at its m.p. A. Riche said that it melts to a black, oily liquid which on cooling solidifies to a crystalline mass. H. E. Roscoe gave 276° for the m.p., and 273° for the f.p.; and added that it boils at 333° and decomposes when distilled forming bromine and a lower bromide. E. Defacqz said that it can be volatilized without decomposition in carbon dioxide. E. Defacqz, and H. E. Roscoe found that the pentabromide is reduced to the dibromide by hydrogen at 350°, and at higher temp. to the metal. A. Riche said that when heated in oxygen, it forms a sublimate of the dioxydibromide, and E. Defacqz, that it is decomposed by oxygen into a mixture of oxybromide and tungsten trioxide. J. B. von Borck, A. Riche, C. W. Blomstrand, H. E. Roscoe, and E. Defacqz found that it is very hygroscopic, and fumes in air; it is decomposed by moist air forming hydrogen bromide and blue tungsten oxide; it is also hydrolyzed by water with which it reacts with a hissing noise and the development of much heat. E. Defacqz added that the pentabromide is readily attacked by alkali-lye or fused alkalies, as well as by fused alkali nitrates, carbonates, or hydrosulphates. J. B. von Borck said that some hydrogen is developed when the pentabromide dissolves in alkali-lye. E. Defacqz added that when the pentabromide is heated with chlorine, it forms the hexachloride. Conc. hydrofluoric acid dissolves it, and it forms with conc. hydrochloric acid a blue soln.—the dil. acid acts like water. Dry hydrogen bromide does not decompose it at 300°; and dry fuming hydrobromic acid partially dissolves it. Hydrogen iodide decomposes the pentabromide at 400°, forming an iodide. Sulphur decomposes it forming the sulphide; hydrogen sulphide also converts it into sulphide; conc. sulphuric acid does not act in the cold, but the dil. acid precipitates the blue oxide. The pentabromide is oxidized by nitric acid into tungsten trioxide; phosphorus, and phosphine convert it into the phosphide. A. Riche found that the pentabromide decomposes organic substances, rapidly forming hydrogen bromide and blue tungsten oxide. E. Defacqz added that the pentabromide is soluble in alcohol, ether, carbon tetrachloride, chloroform, bromoform, benzene, and turpentine; if these solvents are not thoroughly dried, blue tungsten oxide may be formed. F. W. Bergstrom observed that a liquid ammonia soln. of tungsten pentabromide in contact with potassamide for several days furnishes *tungsten potassimidamide*, $W(NK)_2NH_2$.

According to H. A. Schaffer and E. F. Smith, **tungsten hexabromide,** WBr_6, is obtained by gently warming tungsten in dry bromine vapour carried along by nitrogen purified by passage through chromous acetate, sulphuric acid, and phosphorus pentoxide. Tungsten hexabromide forms bluish-black, crystalline masses, melts readily, and when carefully resublimed forms blue-black needles. It is decomposed when heated at a high temp., fumes when brought into contact with the air, is decomposed by water with the formation of a blue oxide, and dissolves in aq. ammonia to a colourless soln.

E. Defacqz found that when liquid hydrogen bromide is allowed to act on tungsten hexachloride at ordinary temp., it yields **tungsten trichlorotribromide,** WCl_3Br_3, and at 60° to 70°, **tungsten trichloroenneabromide,** $WBr_3.W_3Cl_3Br_6$, or $W_2Cl_3Br_9$. The latter compound forms small, olive-green crystals which melt at 232° and dissolve in many organic solvents. It is very unstable, alters rapidly when exposed to air, is immediately decomposed by water, and by steam at 200°, and is readily attacked by hydrogen, oxygen, chlorine, sulphur, phosphorus, halogen hydracids, hydrogen sulphide, nitric and sulphuric acids, alkalies, oxidizing mixtures, and potassium hydrosulphate.

H. P. von Beck prepared some oxybromides—$R'_2(WOBr_5)$; $R'\{WOBr_4(H_2O)\}$; and $R'(WOBr_4)$—analogous to the oxychlorides obtained by O. O. Collenberg. By treating 5 grms. of potassium oxalatotungstite with 35 c.c. of hydrobromic acid at 50°, and afterwards adding rubidium sulphate he obtained **rubidium pentabromotungstite,** $Rb_2(WOBr_5)$, in olive-green octahedra; if cæsium sulphate be employed, **cæsium pentabromotungstite,** $Cs_2(WOBr_5)$, is formed in greenish-yellow octahedra. By adding 17 grms. of ammonium oxalatotungstite to a soln. of 180 c.c. of hydrobromic acid and 3·5 grms. of ammonium bromide at 55°, **ammonium pentabromotungstite,** $(NH_4)_2(WOBr_5)$, was formed in olive-green octahedra.

By treating 10 grms. of potassium oxalatotungstite with 80 c.c. of hydrobromic acid at 55°, **pyridinium tetrabromotungstite,** $(C_5H_5NH)(WOBr_4)$, was formed in brownish-green quadratic plates. If soln. of 10 grms. of sodium oxalatotungstite in 75 c.c. of hydrobromic acid and of 8 grms. of tetraethylammonium bromide in 40 c.c. of hydrobromic acid be mixed, **tetraethylammonium tetrabromoaquotungstite,** $(C_2H_5)_4N\{WOBr_4(H_2O)\}$, is formed in pale green, microscopic scales.

According to A. Bonnet, when bromine vapour is passed over a mixture of tungsten trioxide and carbon, **tungsten oxytetrabromide,** $WOBr_4$, is formed. C. W. Blomstrand obtained it by heating tungsten in bromine vapour mixed with a little air, and by rapidly heating the dioxydibromide which then forms tungsten trioxide and oxytetrabromide. H. E. Roscoe obtained it by the action of bromine vapour on a heated mixture of tungsten and tungsten dioxide. The oxytetrabromide is usually accompanied by less volatile dioxydibromide from which it can be separated by sublimation. Analyses were made by A. Bonnet, J. B. von Borck, C. W. Blomstrand, and H. E. Roscoe. J. B. von Borck thought that the product was tungsten tetrabromide, but C. W. Blomstrand showed that it is the oxytetrabromide. The brownish-black needles form a heavy, yellowish-red vapour; the salt can be resublimed in a current of carbon dioxide. It melts at 277°, and boils at 327°. It is very hygroscopic; and is decomposed by moist air, and water into hydrobromic acid and pseudomorphous tungsten trioxide.

J. B. von Borck, C. W. Blomstrand, and H. E. Roscoe prepared **tungsten dioxydibromide,** WO_2Br_2, by the action of bromine vapour—not free from air—on heated tungsten dioxide, blue tungsten oxide, tungsten trisulphide, or a mixture of tungsten trioxide and carbon; H. E. Roscoe, by passing the vapour of tungsten pentabromide over the trioxide; and H. O. Schulze, by heating tungsten trioxide with bromides—*vide supra,* the dioxydichloride. A. Bonnet by working as in the case of the preceding compound at a lower temp., thought that $W_2O_5.2WBr_2$ is formed, but C. W. Blomstrand could not verify this. The analyses of J. B. von Borck, and H. E. Roscoe agree with the formula WO_2Br_2. The pale yellow vapour, said H. E. Roscoe, condenses to black prismatic crystals, which on cooling, appear pale red, and furnish a yellow bromide. J. B. von Borck, and C. W. Blomstrand said that the quadratic plates are a brassy yellow resembling muscovite gold. H. E. Roscoe, and J. B. von Borck said that the salt volatilizes at a red-heat without melting, and with a partial decomposition into tungsten oxytetrachloride and trioxide. H. E. Roscoe found that the salt is not decomposed by cold water; and J. B. von Borck, that it is hydrolyzed in moist air and by water to form hydrobromic acid, and hydrated tungsten trioxide.

§ 22. Tungsten Iodides and Oxyiodides

No *tungsten hexaiodide,* WI_6, has been prepared, nor have *tungsten oxyiodides* been obtained. According to A. Riche,[1] the vapour of iodine attacks tungsten superficially, and the sublimed product is difficult to purify; it appears to contain a brown iodide, and green scales of another iodide. J. B. von Borck observed that tungsten trioxide dissolves in hydriodic acid, and when the soln. is evaporated, in vacuo, it is decomposed. No tungsten iodide is formed when the vapour of tungsten chloride is passed over molten potassium iodide or silver iodide, or when it is brought in contact with the vapour of mercuric iodide, ammonium iodide, or hydrogen iodide. H. E. Roscoe reported that **tungsten diiodide,** WI_2, is formed when iodine vapour is passed over red-hot tungsten or tungsten dioxide. The diiodide collects quite near to the heated portion of the tube in small scales which cannot be volatilized without decomposition. E. Defacqz obtained it by passing chlorine over tungsten at a dark-red heat; driving out the chlorine by dried carbon dioxide; and allowing dried hydrogen iodide to act on the sublimed tungsten hexachloride at 400°. At first some iodine is set free, and the product is accordingly washed with carbon disulphide, dried in air, washed with alcohol, and dried in air, first at 95° and then at 100°. According to E. Defacqz, tungsten diiodide is an amorphous, brown powder of sp. gr. 6·9 at 18°, and insoluble in water, alcohol, or carbon disulphide. It is infusible and non-volatile; when heated in air, it is oxidized, and when heated above 500° in hydrogen it is reduced. Chlorine decomposes it at about 250°, and bromine at about 350°. Hydrogen iodide reduces it at 500° to 600°, and it is also attacked by carbon dioxide at this temp. Sulphur and phosphorus at 500° convert the iodide into sulphide and phosphide respectively, and boiling water gradually converts it into the blue oxide. Hydrochloric and hydrofluoric acids attack the iodide very slowly, but boiling nitric or sulphuric acid, or aqua regia, converts it into tungstic anhydride. Potash-lye or fused potassium hydroxide, alkali carbonates, or mixtures of alkali carbonates and nitrates readily oxidize the iodide.

According to E. Defacqz, **tungsten tetraiodide,** WI_4, is obtained by the action of an excess of liquid hydrogen iodide on tungsten hexachloride at 110°. It is a black, crystalline substance of sp. gr. 5·2 at 18°; insoluble in water, ether, chloroform, and turpentine, but soluble in absolute alcohol; it does not melt, and does not sublime without decomposing. Hydrogen reduces it below a red-heat; chlorine displaces the iodine at the ordinary temp.; and bromine displaces it at 100°. Water decomposes it slowly in the cold, and rapidly on boiling, and it is readily attacked by dil. hydrochloric and sulphuric acids, and by nitric acid and aqua regia, which convert it into tungstic acid. Alkali hydroxides and carbonates, whether in soln. or fused, and fused potassium hydrosulphate also readily decompose the tetraiodide.

§ 23. The Tungsten Sulphides

J. B. von Borck[1] obtained **tungsten disulphide,** WS_2, by melting a mixture of the constituent elements; J. J. Berzelius passed sulphur vapour or hydrogen sulphide over red-hot tungsten trioxide. The action is incomplete, and A. Riche recommended mixing the tungsten trioxide with carbon, or passing the vapour of carbon disulphide over the red-hot trioxide. J. J. Berzelius, and J. B. von Borck heated a mixture of tungsten trioxide and an excess of mercuric sulphide in a fireclay crucible contained in a larger crucible packed with carbon. When ammonium sulphotungstate is heated in a current of carbon dioxide, E. Corleis found that porous pseudomorphs of tungsten disulphide are formed. F. J. Faktor obtained the disulphide by the action of tungsten trioxide on sodium thiosulphate. L. von Uslar heated a mixture of tungsten trisulphide and potassium cyanide and extracted the soluble matter with water; A. Riche melted a mixture of potassium tungstate and tungsten trioxide, and added sulphur—after half an hour's fusion, the cold mass was extracted with water. E. Defacqz melted at a dull red-heat an intimate mixture of dry potassium carbonate, sulphur, and tungsten trioxide (138 : 558 : 464), and when completely fused, the cold mass was powdered and extracted with water. When hydrogen sulphide free from air acts on tungsten hexachloride heated to 375° and the temp. is raised to 550°, and the product cooled in hydrogen sulphide, E. Defacqz found that tungsten disulphide is formed.

Analyses were made by E. Defacqz, J. J. Berzelius, L. von Uslar, E. Corleis, and A. Riche, and the results were in agreement with the formula WS_2. R. C. Wells and B. S. Butler found the disulphide occurring as a mineral which they called **tungstenite** in the Emma mine, of the Cottonwood district, Salt Lake Co., Utah. It occurs in feathery flakes resembling graphite. It is lead-grey in colour; opaque with a metallic lustre; and is soft enough to mark paper. J. J. Berzelius described the disulphide as a greyish-black, soft powder; and E. Defacqz, as a black, scaly mass, or as friable crystals with a blue reflex. A. E. van Arkel found that the

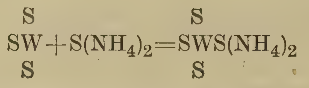
X-radiogram of tungsten disulphide corresponded with a space-lattice resembling that of molybdenite (*q.v.*), with two mols per unit cell. The unit cell has a base 3·18 A., and a height 12·5 A. The S-atoms form layers of trigonal pyramids which are 3·63 A. in length along the pyramid edges and 3·18 A. along the basal edges. The structure was discussed by J. W. Gruner. According to E. Defacqz, the sp. gr. is 7·5 at 10°. M. Picon found that the sulphide is dissociated at 1200° to 1300°, and not volatilized at 2000°. R. C. Wells and B. S. Butler gave 7·4 for the sp. gr. of tungstenite. A. Karl studied the triboluminescence of tungsten sulphide. W. W. Coblentz found that tungsten sulphide is not photoelectrically sensitive. J. J. Berzelius said that when roasted in air it forms tungsten trioxide, and in the absence of air, E. Defacqz said that it can be heated to redness without change, while in the electric furnace it gradually loses its sulphur without melting. A. Riche observed that when heated in hydrogen it is reduced to metal, and E. Corleis said that the reduction is complete in about 7 hrs. at the temp. of a blowpipe flame; and E. Defacqz added that the reaction begins at about 800°. N. Parravano and G. Malquori found the equilibrium constant $K=p_{H_2S}/p_{H_2}$ for the reaction $2H_2+WS_2 \rightleftharpoons W+2H_2S$ over the range of temp. 795° to 1065°; and the calculated heat of formation of WS_2 is 73·4 Cals. They also gave for the dissociation press., $\log p_{S_2}=-10{\cdot}453$ at 600°; $-6{\cdot}938$ at 795°; $-5{\cdot}611$ at 895°; $-4{\cdot}603$ at 985°; and $-4{\cdot}642$ at 1065°. Fluorine attacks it at ordinary temp.; chlorine, at 400° with the formation of the hexachloride; whilst the reaction with bromine is incomplete at 700°. Hydrogen chloride has no action on the disulphide. Mineral acids employed singly are without action, but it is attacked by mixtures of nitric acid with hydrofluoric or hydrochloric acid. J. J. Berzelius found that the disulphide is oxidized by aqua regia to sulphuric acid and tungsten trioxide; R. C. Wells and B. S. Butler found that tungstenite is not attacked by hydrochloric or nitric acid but is decomposed by aqua regia. E. Defacqz found that molten alkali hydroxides or carbonates readily dissolve the disulphide, and so does a fused mixture of potassium nitrate and carbonate. L. Weiss reduced it to the metal by heating it with lime in an electric furnace.

L. von Uslar obtained **tungsten trisulphide,** WS_3, by melting wolframite with powdered carbon, sulphur, and sodium carbonate (1 : 0·2 : 3) at a dull red-heat, extracting the product with water, and precipitating the compound by the addition of sulphuric acid. J. J. Berzelius dissolved tungsten trioxide in a soln. of potassium hydrosulphide, and precipitated the compound by means of an acid; he also saturated a soln. of ammonium tungstate with hydrogen sulphide, added an acid to the soln., and washed the precipitate with cold water. J. B. von Borck said that all these products contain tungsten trioxide and much water. The trisulphide can be obtained of a high degree of purity by protecting it from atm. air while being prepared. E. Corleis also obtained the trisulphide as a chocolate brown powder by adding hydrochloric acid to a soln. of ammonium sulphotungstate in an apparatus from which atm. air is excluded. The product was washed with aq. hydrogen sulphide in an atmosphere of carbon dioxide and dried at 100° in a similar atmosphere.

Tungsten trisulphide is a black or dark brown powder, which when heated in a closed vessel was found by J. J. Berzelius to form the disulphide; and when boiled with water in a retort it gives off some hydrogen sulphide. Water dissolves a little trisulphide, particularly warm water, and it is precipitated from the yellow soln. by acids, or ammonium chloride. E. Corleis emphasized its acid character by showing that it dissolves in a cold conc. soln. of an alkali carbonate with the evolution of carbon dioxide; it also forms dark brown soln. with alkali hydroxides or hydrosulphides from which no crystals can be obtained. J. J. Berzelius added that the soln. in alkali hydroxide or carbonate contains alkali tungstate, and sulphotungstate—and probably colloidal tungsten trisulphide; when dissolved in soln. of the alkali sulphides, hydrogen sulphide is evolved; and with the basic metal sulphides it forms **sulphotungstates,** R_2WS_4, from which soln. an excess of acid precipitates tungsten trisulphide with the evolution of hydrogen sulphide. Aq. ammonia dissolves the dried sulphide very slowly, and the freshly precipitated, moist sulphide, quickly.

As just indicated, J. J. Berzelius observed that when the freshly-precipitated trisulphide is washed with water, it appears to dissolve, forming a yellow soln. of what is now called **colloidal tungsten trisulphide.** According to C. Winssinger, a dark brown colloidal soln. of the trisulphide is obtained by adding to a dil. soln. of sodium sulphotungstate rather more hydrochloric acid than is needed to liberate tungsten trisulphide. Its colour is orange, and the soln. can be obtained quite clear. The absorption spectrum of the reddish-brown soln. shows a dark band from the extreme violet to the green. The extreme red is feeble, and the visible part of the spectrum is also feeble. The soln. becomes turbid, or a precipitate is formed by boiling, by adding conc. hydrochloric acid, ammonium chloride, or other salts; or by dialysis. If precipitated, the sulphide can be washed by decantation, and as the impurities are removed the sulphide is again peptized so as to re-form a colloidal soln. Freshly precipitated trisulphide is easily oxidized so that air must be excluded during these operations.

The normal sulphotungstates, R_2WS_4, are prepared by dissolving tungsten trisulphide in the metal hydrosulphide; by the prolonged action of hydrogen sulphide on normal tungstates; and by double decomposition. The alkali sulphotungstates are soluble and crystalline; some of the alkaline earth and metal sulphotungstates form gummy or gelatinous masses. According to C. Scheibler, if an aq. soln. of metatungstic acid be saturated with hydrogen sulphide, and neutralized with ammonia, or ammonium sulphide, blue sulphur separates out, and after a time bluish-black, cubic crystals are formed. They oxidize in air, and decolorize. They are very unstable. A. Werner discussed the formula, $(NH_4)_2[WS_4]$:



$$\underset{\mathrm{S}}{\overset{\mathrm{S}}{\mathrm{SW}}}+\mathrm{S(NH_4)_2}=\underset{\mathrm{S}}{\overset{\mathrm{S}}{\mathrm{SW}}}\mathrm{S(NH_4)_2}$$

J. J. Berzelius obtained **ammonium sulphotungstate,** $(NH_4)_2WS_4$, in yellowish-red crystals by saturating a conc. soln. of ammonium tungstate with hydrogen sulphide; on evaporating the mother-liquor, yellow plates of a double salt of tungstate and sulphotungstate are formed. E. Corleis obtained this salt by the action of hydrogen sulphide for 5 or 6 hrs. on a soln. of 10 grms. of hydrated tungsten trioxide in 100 c.c. of aq. ammonia of sp. gr. 0·94, and 20 c.c. of water, and allowing the liquid to stand in a closed vessel for crystallization. In about 8 days, the orange-yellow crystals can be washed successively with a soln. of hydrogen sulphide, alcohol, and ether, and finally dried in vacuo over phosphorus pentoxide. The mother-liquid containing dioxydisulphotungstate can be again saturated with hydrogen sulphide, and treated as before. The precipitation is accelerated if one-third to half a vol. of alcohol is added. H. Vater said that the pale orange-yellow, rhombic bipyramidal crystals have the axial ratios $a:b:c=0·7783:1:0·5675$; the (010)-cleavage is complete, the (001)-cleavage clear. The crystals are isomorphous with those of the corresponding molybdenum salt. J. J. Berzelius, and E. Corleis found that the crystals decrepitate when heated, and then give off water and ammonium sulphide, leaving tungsten disulphide as a residue, pseudomorphous after ammonium sulphide. The salt is fairly stable when dry, but when moist it is unstable. It is slowly reduced to metal when heated in hydrogen. It is freely soluble in water, and in aq. ammonia; and it is precipitated from these soln. by the addition of alcohol. The aq. soln. slowly decomposes in air. L. Storch discussed the solubility of the metal sulphides in a soln. of ammonium sulphotungstate.

J. J. Berzelius said that **sodium sulphotungstate,** Na_2WS_4, crystallizes with difficulty from an aq. soln. of its components, but if the aq. alcoholic soln. be spontaneously evaporated the salt is obtained in crystals. E. Corleis prepared it by adding sodium hydrosulphide to a conc. soln. of the ammonium salt. The crystals contain some isomorphous ammonium salt; they deliquesce rapidly in air, and resemble the crystals of the potassium salt. J. J. Berzelius prepared **potassium sulphotungstate,** K_2WS_4, by saturating an aq. soln. of potassium tungstate with hydrogen sulphide and evaporating the soln. in vacuo over potassium carbonate, or in air; and by evaporating a soln. of tungsten trioxide or trisulphide in potassium hydrosulphide, or of tungsten trisulphide in potassium hydroxide. E. Corleis found that the salt is precipitated on adding potassium hydrosulphide and alcohol to a soln. of ammonium sulphotungstate. By recrystallization of the salt from a soln. of potassium hydrosulphide, it can be completely freed from the isomorphous ammonium sulphotungstate. E. Kalkowsky said that the yellow, rhombic bipyramids have the axial ratios $a:b:c=0{\cdot}7495:1:0{\cdot}5665$; and that the (010)-cleavage is incomplete. J. J. Berzelius found that the crystals, in the absence of air, melt to a dark brown liquid which solidifies on cooling to a brownish-yellow mass. The salt is freely soluble in water, and on adding alcohol to the brownish-yellow aq. soln., cinnabar-red prisms are deposited, but the precipitation is not complete, for the salt is slightly soluble in alcohol. If an acid be added to the aq. soln., *potassium sulphoditungstate*, $K_2S.2WS_3$, is formed, and deposited as a black mass when the dark brown soln. is evaporated. J. J. Berzelius described a complex salt, formed by fusing a mixture of sulphur and potassium tungstate, which was considered to be $K_2WO_4.K_2WS_4$, presumably an isomorphous admixture.

J. J. Berzelius described **copper sulphotungstate** as a dark brown precipitate; **silver sulphotungstate** as a dark brown, almost black, precipitate; and **gold sulphotungstate,** $Au_4(WS_4)_3$, as a dark brown mixture of aurous and auric salts on adding a soln. of the metal salt to a soln. of potassium sulphotungstate. He also obtained calcium sulphotungstate by treating freshly prepared calcium tungstate, suspended in water, with hydrogen sulphide, and evaporating the yellow soln., or by dissolving tungsten trisulphide in a hot soln. of calcium disulphide, or hydrosulphide. The pale yellow, amorphous mass is easily soluble in water, and in alcohol. With an excess of tungsten trisulphide it forms a reddish-brown, non-crystallizable soln. which with ammonia gives a pale yellow precipitate. The corresponding **strontium sulphotungstate** and **barium sulphotungstate** were similarly obtained. No precipitate of **beryllium sulphotungstate** is obtained when a soln. of a beryllium salt is treated with potassium sulphotungstate; **magnesium sulphotungstate** is prepared like the barium salt, and the aq. soln., in vacuo, dries to a gummy mass soluble in water and alcohol. F. Rodolico obtained a complex salt, $MgWS_4.2X.10H_2O$, with hexamethylenetetramine. J. J. Berzelius prepared **zinc sulphotungstate** which forms a pale yellow, pulverulent precipitate; and with **cadmium sulphotungstate** which forms a lemon-yellow powder; mercurous salts give a black precipitate of more or less decomposed **mercurous sulphotungstate;** and mercuric salts, yellow **mercuric sulphotungstate** which, after drying, is dark red.

When an aluminium salt soln. is treated with potassium sulphotungstate, no **aluminium sulphotungstate** is precipitated; similarly with **yttrium sulphotungstate;** but a soln. of a cerous salt in 24 hrs. gives a yellow precipitate of **cerous sulphotungstate.** Stannous salt soln. gives a brown, flocculent precipitate of **stannous sulphotungstate,** $SnWS_4$; a soln. of a stannic salt, greyish-yellow **stannic sulphotungstate,** a lead salt, dark brown **lead sulphotungstate,** $PbWS_4$; whilst a dark brown **bismuth sulphotungstate,** $Bi_2(WS_4)_3$; brown **vanadyl sulphotungstate;** yellow **manganese sulphotungstate,** $MnWS_4$; deep yellow **ferrous sulphotungstate,** $FeWS_4$; dark brown **ferric sulphotungstate,** $Fe_2(WS_4)_3$; dark brown **cobalt sulphotungstate,** $CoWS_4$; similarly with **nickel sulphotungstate,** $NiWS_4$; dark brown **platinum sulphotungstate,** $Pt(WS_4)_2$, are obtained from soln. of the metal salts concerned.

According to E. Defacqz, if liquid hydrogen sulphide be left in contact with tungsten hexachloride in a sealed tube for 36 hrs., at 60° to 65°, a brown powder of **tungsten hexachloroenneasulphide,** $WCl_6.3WS_3$, is formed. It is insoluble in carbon disulphide, alcohol, and benzene, and is decomposed by water. It burns in air at a red-heat; and is easily attacked by nitric acid, and by fused alkali hydroxide. E. F. Smith and V. Oberholtzer found that if tungsten is heated to redness in the vapour of sulphur monochloride, a red crystalline sublimate of **tungsten octochloroheptasulphide,** $W_2S_7Cl_8$, is formed. The unstable product is considered to be a complex of $W_2S_3Cl_4$ with $2S_2Cl_2$. For the complex $WCl_4.N_4S_4$, *vide supra*, tungsten tetrachloride.

§ 24. The Tungsten Oxysulphides and Sulphates

A series of oxysulphotungstates has been reported by J. J. Berzelius,[1] and E. Corleis, but they have not been closely investigated. They include the oxytrisulphotungstates, R_2WOS_3, the dioxysulphotungstates, $R_2WO_2S_2$, and the trioxysulphotungstates, R_2WO_3S. They are obtained by the action of hydrogen sulphide on the normal tungstates, and by fusion of the normal tungstate with definite proportions of sulphur while protected from air. When a soln. of normal sulphotungstate is mixed with alcohol and ether, and treated with hydrochloric acid, two layers of liquid are formed. The ethereal layer is brown, the aq. layer is colourless and clear; an oxysulphide under similar conditions gives a coloured ethereal layer, and a turbid or milky aq. layer. The normal sulphotungstates do not give a precipitate with zinc sulphate, while the oxysulphotungstates give a precipitate. The *oxytrisulphotungstates* give a lemon-yellow precipitate which forms a reddish-brown soln. with hydrochloric acid; the precipitate with the *dioxydisulphotungstates* is pale yellow, and with hydrochloric acid, the liquid becomes clear and then deposits a dirty blue precipitate; and the *trioxysulphotungstates* give a white precipitate, soluble in hydrochloric acid. This soln. after a time deposits a white precipitate with a bluish tinge. J. W. Retgers said that the intermediate stages between potassium tungstate and sulphotungstate cannot be regarded as isomorphous with the end-members of the series, but they are *selbständige chemische Verbindungen.*

According to E. Corleis, **potassium oxytrisulphotungstate,** $K_2WOS_3.H_2O$, is obtained in quadratic plates by the prolonged action of hydrogen sulphide on potassium tungstate. It dissolves freely in water, deliquesces in a damp atmosphere, and effloresces in a dry atm. The soln. gives a lemon-coloured precipitate with zinc sulphate. The precipitate with zinc sulphate may be *zinc oxytrisulphotungstate.* F. Rodolico prepared **magnesium oxytrisulphotungstate** as a complex salt with hexamethylenetetramine, $MgWOS_3.X.10H_2O$.

If an acid be added to a soln. of alkali tungstate and sulphotungstate,

J. J. Berzelius said that a pale reddish-brown precipitate of tungsten dioxysulphide, WO_2S, is formed; and C. Winssinger added that after tungsten trisulphide has been precipitated from its colloidal soln., the remaining lemon-yellow liquid contains the dioxydisulphide. The individuality of the compound is not well-established.

According to E. Corleis, **ammonium dioxydisulphotungstate,** $(NH_4)_2WO_2S_2$, is produced when hydrogen sulphide is passed into a filtered soln. of 10 grms. of hydrated tungstic trioxide in 40 c.c. of aq. ammonia of sp. gr. 0·90, and 10 c.c. of water, until yellow crystals begin to appear, and after crystallization has ceased, washing the crystals successively with a little water, alcohol, and ether, and drying them over calcium chloride or potassium hydroxide. E. Kalkowsky said that the yellow, triclinic pinacoids have the axial ratios $a:b:c=0{\cdot}760:1:0{\cdot}339$, and $\alpha=90°$, $\beta=92° 10'$, and $\gamma=90°$. The (011)- and $(0\bar{2}1)$-cleavages are clear; there is lamellar twinning. E. Corleis found that the crystals are not hygroscopic; they are stable when dry, but decompose when moist. J. J. Berzelius obtained **potassium dioxydisulphotungstate,** $K_2WO_2S_2.H_2O$, by melting a mixture of the normal potassium tungstate and sulphur in a covered crucible, extracting with water, and evaporating the aq. soln. Lemon-yellow, rectangular plates are formed. The salt can be melted, out of contact with air, without decomposition. It is freely soluble in water. The lemon-yellow aq. soln. is coloured red or reddish-yellow by acids, and it gives no precipitate with alcohol, or with manganous salts. F. Rodolico obtained a complex salt of **magnesium dioxydisulphotungstate** with hexamethylenetetramine, $MgWS_2O_2.2X.10H_2O$. J. J. Berzelius found that the potassium salt forms with a soln. of a lead salt, a yellowish-brown precipitate of **lead dioxydisulphotungstate,** $PbWO_2S_2$.

E. Corleis prepared **potassium trioxysulphotungstate,** $K_2WO_3S.H_2O$, by passing hydrogen sulphide into a conc. soln. of potassium tungstate, until a slight yellow precipitate is formed. The colourless, deliquescent crystals are deposited when the filtered soln. is mixed with five times its vol. of alcohol. With an aq. soln. of the salt, zinc sulphate gives a white precipitate soluble in hydrochloric acid. F. Rodolico obtained a complex salt of **magnesium trioxysulphotungstate** with hexamethylenetetramine, $MgWSO_3.2X.10H_2O$.

J. J. Berzelius[2] obtained a white precipitate presumably a mixture of tungsten trioxide, sulphuric acid, and water when conc. nitric acid acts on tungsten trisulphide. It is very doubtful if the precipitate can be regarded as a *tungsten sulphate.* According to E. D. Desi, if tungsten be heated with conc. sulphuric acid until the evolution of sulphur dioxide has ceased, a blue precipitate and a colourless soln. are formed. If the clear soln. be evaporated a black substance of the composition **tungsten sulphatotrioxide,** $WO_3.SO_3$, is formed. The solid soln. of lead sulphate and tungstate has been previously discussed.

§ 25. Tungsten Carbonates and Nitrates

No *tungsten carbonate* has been prepared; and similarly with *tungsten nitrate.* J. C. G. de Marignac[1] prepared **ammonium nitratometatungstate,** $NH_4NO_3.2\{(NH_4)_2O.4WO_3.2H_2O\}$, by evaporating a mixed, filtered soln. of ammonium paratungstate and nitric acid, or a mixed soln. of ammonium metatungstate and nitrate. The hexagonal crystals lose half their water at 100°; and when heated decrepitate and decompose without melting. J. J. Berzelius saturated a mixed soln. of potassium tungstate and nitrate with hydrogen sulphide, and obtained ruby-red crystals of **potassium nitratosulphotungstate,** $KNO_3.2K_2WS_4$. They explode when heated just as they begin to melt, forming potassium tungstate, and sulphotungstate, and tungsten bisulphide. With sulphuric or hydrochloric acid, hydrogen sulphide is evolved, and if heated, nitric oxide also is given off. The salt is soluble in water, forming a deep red soln., from which alcohol precipitates the salt in crystalline grains. When the soln. is treated with hydrated copper oxide, copper sulphide is precipitated and a soln. of **copper nitratotungstate** is formed. According to E. Péchard, a hot, mixed soln. of barium metatungstate and nitrate furnishes on cooling acicular crystals of **barium nitratometatungstate,** $2Ba(NO_3)_2.BaO.4WO_3.6H_2O$. The crystals effloresce in air; and they are soluble in warm water with partial decomposition. S. M. Tanatar and E. Kurowsky treated a soln. of sodium tungstate with beryllium nitrate and obtained complexes of **beryllium nitratometatungstate,** of variable composition, $BeO.mBe(NO_3)_2.nBeWO_4$, soluble in acids. H. Copaux described **mercurous nitratometatungstate**—*vide supra*, mercury metatungstates; and A. Rosenheim and F. Kohn, V. Forcher, and E. F. Smith, **lead nitratometatungstate**—*vide supra*, lead metatungstates.

§ 26. Phosphotungstic Acids.—Phosphatotungstic Acids and their Salts

Tungsten trioxide was found by F. de Carli[1] to behave like molybdenum trioxide when admixed with sodium metaphosphate. The fusion curve has two minima and a maximum at 850° corresponding with **sodium tungstatometaphosphate,** $NaPO_3.WO_3$, or $Na.O.WO_2.O.PO_2$. The first minimum is at 350° corresponding with 30 per cent. of sodium metaphosphate.

The history of the **tungsten phosphates** commences in 1872 when C. Scheibler[2] observed that a soln. of sodium tungstate containing phosphoric acid is able to precipitate certain organic compounds; and isolated two acids which contained, as he supposed, $P_2O_5 : WO_2$ in the ratios 1 : 22 and 1 : 20 respectively. The barium salt in the first case was derived from the normal sodium tungstate and in the second case from the paratungstate. E. Zettnow reported a number of salts of these acids. O. W. Gibbs suggested that the second acid has the formula $H_{16}P_2W_{21}O_{73}.nH_2O$, and he postulated the existence of six series of these acids in which 24, 22, 20, 18, 16, and 14 mols. of WO_3 are present per mol. of P_2O_5. Acids corresponding with all the members of the series have not been prepared, and other acids containing less tungstic acid have been reported. The general result of the work on these **phosphatotungstic acids** is to show that they are heteropoly-acids closely analogous with the phosphatomolybdic acids. The following phosphatotungstic acids have been reported, although their claims for recognition as chemical individuals have not, in all cases, been established:

Phosphatododecatungstic acid	$P_2O_5.24WO_3.nH_2O$
Phosphatohenatungstic acid	$P_2O_5.22WO_3.nH_2O$
Phosphatohemihenicositungstic acid	$P_2O_5.21WO_3.nH_2O$
Phosphatodecatungstic acid	$P_2O_5.20WO_3.nH_2O$
Phosphatoenneatungstic acid	$P_2O_5.18WO_3.nH_2O$
Phosphatohemiheptadecatungstic acid . . .	$P_2O_5.17WO_3.nH_2O$
Phosphatoctotungstic acid	$P_2O_5.16WO_3.nH_2O$
Phosphatohexatungstic acid	$P_2O_5.12WO_3.nH_2O$
Phosphatohemiheptatungstic acid	$P_2O_5.7WO_3.nH_2O$
Phosphatotritungstic acid	$P_2O_5.6WO_3.nH_2O$

The first number of the series, **phosphatododecatungstic acid,** $P_2O_5.24WO_3.nH_2O$, $H_7[P(W_2O_7)_6].nH_2O$, belongs to a group of heteropoly acids represented by $H_7[P(Mo_2O_7)_6]$, $H_7[As(Mo_2O_7)_6]$, and $H_7[As(W_2O_7)_6]$. This acid is that commonly understood as *phosphotungstic acid.* The following mode of preparation is due to F. Kehrmann :

Phosphatododecatungstic acid is prepared by dissolving 100 grms. of normal sodium tungstate and 15 grms. of crystalline sodium hydrophosphate in a large proportion of boiling water ; and adding hydrochloric acid while the liquid is vigorously stirred so that the crystalline powder which may separate is all dissolved by the boiling water. A conc. soln. of 20 grms. of barium chloride is then added to the liquid. The cold liquid is then heated to boiling, and 10 grms. of barium chloride are added. The precipitated barium salt is washed with cold water, and purified by recrystallization from boiling water. The barium salt in soln. is then treated with the calculated amount of sulphuric acid, and the filtrate evaporated for crystallization.

E. Drechsel recommended the following process :

Phosphatododecatungstic acid is obtained by dissolving 500 grms. of sodium tungstate and 250 grms. of sodium hydrophosphate in 500 c.c. of water, and evaporating the liquid until a skin forms on the surface. 700 to 800 c.c. of hydrochloric acid, of sp. gr. 1·14, are then added to the boiling soln., which is again evaporated, and allowed to cool. The whole is gradually treated with pure ether, being well shaken all the time, until a layer is formed above the acid soln. It is left until the lower layer is clear, then separated and treated with an equal vol. of water ; the ether is then evaporated ; if the soln. becomes bluish, chlorine-water is added. It is evaporated to dryness, dissolved in hot water ; and on cooling, the acid separates in splendid crystals.

The literature has a strangely indefinite answer to the question : What hydrates are formed by phosphatododecatungstic acid ? P. F. M. Sprenger reported the 19½-*hydrate,* from the soln. obtained from silver tungstate mixed with the calculated amount of phosphoric acid, and treated with hydrochloric acid ; O. W. Gibbs, the 20-*hydrate,* by treating a soln. of potassium phosphatoenneatungstate with mercurous nitrate, and afterwards adding hydrochloric acid ; M. Soboleff, the 22½-*hydrate,* by rapidly cooling a supersaturated soln.—*vide infra ;* C. H. Brandhorst and K. Kraut, the 23¼-*hydrate,* by treating a soln. of 100 grms. of crystalline sodium phosphatododecatungstate in 40 c.c. of water with nitric acid of sp. gr. 1·5 ; O. W. Gibbs, the 26½-*hydrate,* by evaporating, in vacuo, the liquid obtained by treating the mercurous salt with hydrochloric acid ; and C. H. Brandhorst and K. Kraut, by adding hydrochloric acid to a soln. of the sodium salt, extracting the acid with alcohol-free ether, and evaporating off the ether ; E. Péchard, the 29½-*hydrate,* from a mixture of eq. proportions of phosphoric and metatungstic acids and evaporating in vacuo ; and P. F. M. Sprenger, the 30½-*hydrate,* by evaporating the soln. obtained by treating the barium salt with sulphuric acid—and a little nitric acid—first on a water-bath and afterwards in vacuo ; and O. W. Gibbs, by evaporating an aq. soln. of the acid in vacuo over sulphuric acid. With the co-ordination formula $H_7[P(W_2O_7)_6].nH_2O$, these hydrates correspond with $n=16$, 16½, 19, 20, 23, 26, and 27.

H. Copaux concluded that there are only the three hydrates of the $H_7[P(W_2O_7)_6]$-acid, *viz.,* (i) the 27½-*hydrate* which separates in octahedra from conc. aq. soln. at about 35° ; (ii) the 22-*hydrate* which separates from a hot, sat. soln. acidified with a little nitric acid, and rapidly cooled ; and (iii) the 19-*hydrate* which crystallizes from a cold soln. strongly acidified with nitric acid. A. Rosenheim and J. Jänicke found that when a conc. aq. soln. is crystallized at ordinary temp., the *octocosihydrate,* $H_7[P(W_2O_7)_6].28H_2O$, *i.e.* $P_2O_5.24WO_3.63H_2O$, is formed, in octahedral crystals. This hydrate is probably the same as the 27½-hydrate of H. Copaux, and it is unstable at ordinary temp. and readily passes into trigonal crystals of the *docosihydrate,* $H_7[P(W_2O_7)_6].22H_2O$, *i.e.* $P_2O_5.24WO_3.51H_2O$. This hydrate, also obtained by H. Copaux, is deposited at ordinary temp. from soln. feebly acidified with nitric acid. The octocosihydrate loses $24H_2O$ in vacuo over sulphuric acid at room temp., and the docosihydrate loses its $22H_2O$ under similar conditions. The transition temp. between these two hydrates is assumed to be somewhere below 0°. If the aq. soln. be strongly acidified with nitric acid, the *enneadecahydrate*, $H_7[P(W_2O_7)_6].19H_2O$, *i.e.* $P_2O_5.24WO_3.45H_2O$, is formed. This is probably the hydrate prepared by H. Copaux, and M. Soboleff.

In agreement with the fact that many of the metal salts have the general formula $R_3'PW_{12}O_{40}nH_2O$, M. Soboleff represented the acid by the formula $H_3PO_4.12WO_3.21H_2O$, to indicate that the acid is tribasic; and P. F. M. Sprenger employed the formula $PO(O.WO_2.O.WO_2.O.WO_2.O.WO_2.OH)_3$. A. Rosenheim, and R. Häberle showed that the eq. conductivity of the guanidinium salt agrees better with the assumption that the acid is heptabasic rather than tribasic. A. Rosenheim and J. Jänicke found that the acid dried in vacuo over sulphuric acid has the composition $P_2O_5.24WO_3.7H_2O$. All this supports the hypothesis that the formula for the acid is $H_7[P(W_2O_7)_6].nH_2O$. A. Miolati and R. Pizzigheli measured the electrical conductivity of soln. of phosphatodecatungstic acid (0·0473 grm. $H_3PO_4.12WO_3.7H_2O$ per c.c.) and of sodium hydroxide (0·0008212 grm. NaOH per c.c.) at 25° when 1 c.c. of the NaOH soln. has 0·1304 mol of NaOH per mol of the acid. The curve has two breaks corresponding with $H_3PO_4.12WO_3.7H_2O : NaOH=1 : 6$ and $1 : 26$. This shows that phosphatododecatungstic acid is at least hexabasic. A. Rosenheim and J. Jänicke's neutralization curve also has a minimum with 6·1 mols. of NaOH per mol. of $H_7[P(W_2O_7)_6].nH_2O$. If the formula $H_7[P(W_2O_7)_6].nH_2O$ be correct, the acid is probably heptabasic. This agrees with the guanidinium salt, $(CN_3H_6)_7[P(W_2O_7)_6].12H_2O$, prepared by A. Rosenheim and J. Jänicke by adding guanidinium carbonate to the free acid; and this is in agreement with the conductivity data. Only acid or hydro-salts of the metals have been prepared. The acid character of the salts is confirmed by conductivity data. The break in the curve with 26 mols. of NaOH corresponds with the formation of the normal tungstate. L. Malaprade found that in the electrometric neutralization of phosphotungstic acid, the general behaviour is the same as in the case of phosphomolybdic acid, but the decomposition of the normal salt begins before an inflexion of the curve occurs.

It is not easy to identify the hydrates reported above with those obtained by H. Copaux, and A. Rosenheim and J. Jänicke. The crystals are in all cases colourless or tinged pale yellow. O. W. Gibbs' and P. F. M. Sprenger's $30\frac{1}{2}$-hydrate was described as forming colourless octahedra which rapidly effloresced in air. These crystals probably represent H. Copaux's, and A. Rosenheim and J. Jänicke's octocosihydrate. E. Péchard's crystals—possibly A. Rosenheim and J. Jänicke's and H. Copaux's docosihydrate—measured by E. Dufet, were said to be cubic octahedral combinations of trigonal crystals with the axial ratio $a : c=1 : 1·2648$, and $\alpha=88° 46'$. M. Soboleff's crystals of presumably the $19\frac{1}{2}$-hydrate were definitely stated to belong to the cubic system. He said:

> The supersaturated soln., when quickly cooled, gives skeleton crystals belonging to the regular system, and then well-formed cubes and octahedra; the last form is the most stable, and is always obtained on cooling saturated soln., or by prolonged crystallization in a desiccator. When these octahedra are separated from the soln., they quickly become covered with six-sided stars, arranged parallel to the edges of the octahedron, and the crystals break up into new crystals which contain less water. The crystals of the second hydrate are obtained by crystallizing a supersaturated soln. in a thermostat at 50°.

The second hydrate furnishes rhombic crystals with the axial ratios $a : b : c = 0·94207 : 1 : 1·96187$, and with the optical character negative. When the soln. is quickly evaporated, long, thin needles are obtained which act on polarized light. If these crystals had effloresced a little before analysis, they probably represented the enneadecahydrate of H. Copaux, and A. Rosenheim and J. Jänicke. The subject is somewhat confused because it is lacking in precise data. M. Soboleff gave 4·68 for the sp. gr. of, presumably, the enneadecahydrate; and for the sp. gr. of sat. aq. soln. at 0°, 1·189; at 22°, 1·6913; at 43°, 1·8264; and at 92°, 2·5813. He also found that soln. of 0·2983, 5·930, and 25·192 grms. of the acid in 100 c.c. of water lower the f.p. of water respectively 0·0146°, 0·1360°, and 0·4710°. The depression with the complex acid was found to be much less than the sum of the effects of the components. At high concentrations, the difference is a constant, 0·023, but at low concentrations the difference is less 0·013. The acid lost 0·11 per cent., or 4·09 mols. of water by efflorescence in air ; and at :

	50°	100°	150°	200°	300°	350°	Red-heat
Percentage loss .	4·40	5·75	6·91	9·29	10·17	10·23	12·42
Mols lost . .	15·3	20·1	24·3	34·1	37·3	37·4	45·00

The acid is freely soluble in water, and, as indicated above, the soln. have a large sp. gr. ; the solubility, *S* grms. of $P_2O_5.24WO_3.45H_2O$, per 100 c.c. of water, is :

	0°	22°	43°	92°
S . .	16·206	49·718	53·64	86·75

while the solubility in ether, *S* grms. of $P_2O_5.24WO_3.45H_2O$ per 100 c.c. of ether, is :

	0°	7·8°	18·2°	24·2°
S . .	81·196	85·327	96·017	101·348

O. W. Gibbs found that the aq. soln. is a colourless oily liquid with a high index of refraction and it has an acidic and bitter taste ; it easily drives carbon dioxide from carbonates. When the aq. soln. has stood for a day, decomposition occurs, and a white, crystalline powder is precipitated. The same powder is always formed in the preparation of the acid. E. Drechsel found that the ethereal soln. can be mixed with alcohol in all proportions, and a soln. with equal vols. of ether and alcohol is not rendered turbid by one vol. of hydrochloric acid, but another vol. of the acid does render the soln. turbid. The ethereal soln. can be mixed with much water without becoming turbid. According to A. Miolati and R. Pizzigheli, with methyl orange as indicator, in the titration of the acid, 6 mols. of NaOH are consumed per mol. of acid $H_7[P(W_2O_7)_6].nH_2O$; and with phenolphthalein as indicator, 26 mols. of NaOH are consumed—*vide supra.* E. Brauer gave $[H^{\cdot}]=0\cdot0041$ for the hydrogen ion concentration of a $0\cdot005N$-soln. of the acid. M. Soboleff found the electrical conductivity of the aq. soln. to be smaller than that of its components ; A. Rosenheim and J. Jänicke found the electrical conductivity, λ mhos, of soln. of $\frac{1}{7}H_7[P(W_2O_7)_6].22H_2O$ in v litres of water at 25° to be :

v .	16	32	64	128	256	512	1024
λ .	160·8	168·9	181·0	198·4	220·3	249·3	274·5

T. G. y Arnal discussed the reactions of phosphotungstic acid with various salts. Phosphatododecatungstic, phosphododecatungstic, or simply phosphotungstic acid forms ammonium, alkali, alkaline earth, silver and mercurous salts of the type $R_2O.P_2O_5.24WO_3.nH_2O$. According to F. Kehrmann and co-workers, if the acid or a salt is mixed with a large excess of a strong base, the first decomposition product is a salt of the formula $7R_2O.P_2O_5.22WO_3.nH_2O$, and a large excess produces tribasic phosphate, and dibasic tungstate, Fig. 51. According to O. W. Gibbs, the phosphatotungstates are only decomposed a little by hydrogen sulphide, and the reduction by zinc is incomplete. Mercurous nitrate gives an almost complete precipitation of the mercurous salt which is yellow, and almost insoluble in water, and sparingly soluble in dil. nitric acid. Owing to the low solubility of the potassium and ammonium salts, phosphotungstic acid could be used for their detection. Many alkaloids give almost insoluble more or less crystalline

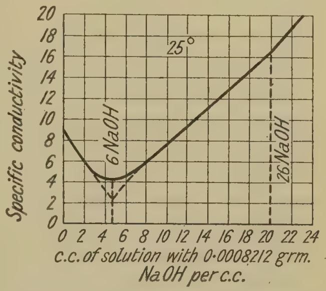

FIG. 51.—Neutralization Curve of Phosphatododecatungstic Acid with Sodium Hydroxide.

precipitates. C. Scheibler said that bulky precipitates are obtained with liquids containing $\frac{1}{200,000}$th of strychnine, or $\frac{1}{100,000}$th of quinine; and he said that the acid can be used as an antidote to poisoning with the organic bases. Egg-albumen also gives a white precipitate, and it is accordingly used as a reagent for precipitating these substances. The behaviour of phosphotungstic acid or the phosphotungstates towards various organic substances was examined by C. Scheibler, E. Winterstein, E. Schulze and E. Winterstein, E. Wechsler, L. Bleibtreu, J. Sebelien, A. von Bäyer and V. Villiger, F. Mylius, H. Moreigne, Z. H. Skraup and co-workers, M. Barber, H. and L. Pellet, P. A. Levene and W. A. Beatty, W. A. Jacobs, L. Guglialmelli, O. Folin and W. Denis, C. Funk and co-workers, J. C. Drummond, A. Heiduschka and L. Wolf, L. Lematte and co-workers, etc. The acid gives white precipitates with substances containing urea, and is used as a clarifying agent in urine analysis—B. Oppler, C. E. May, O. Folin and A. B. Macallum, and C. Funk and A. B. Macallum. The acid is also used for precipitating peptones, and for separating them from acid amido-compounds—A. Stutzer, S. Bondzynsky, A. Vivian, and L. L. van Slyke and E. B. Hart.

O. W. Gibbs prepared **ammonium phosphatododecatungstate,** $3(NH_4)_2O.P_2O_5.24WO_3.29H_2O$, or $(NH_4)_3H_4[P(W_2O_7)_6].12\frac{1}{2}H_2O$, in white or pale yellow crystals, by mixing a soluble ammonium salt with a soln. of mixed sodium tungstate and hydrophosphate, and adding an excess of nitric or hydrochloric acid. F. Kehrmann added a soluble ammonium salt to a dil. soln. of the acid or a salt. F. Kehrmann and E. Böhm found that this salt is also formed when ammonium phosphatohemiheptadecatungstate is treated with dil. hydrochloric acid.

O. W. Gibbs made **sodium hydrophosphatododecatungstate,** $2Na_2O.P_2O_5.24WO_3.27H_2O$, or $Na_2H_5[P(W_2O_7)_6].11H_2O$, by adding an excess of hydrochloric or nitric acid to a soln. of 12 mols. of sodium tungstate and one mol. of sodium hydrophosphate; and C. H. Brandhorst and K. Kraut, used the following process:

750 grms. of hydrochloric acid, of sp. gr. 1·175, diluted with 4 vols. of water, were slowly added, with stirring, to a soln. of a kilogram of sodium tungstate and 100 grms. of sodium hydrophosphate in 4 litres of water, and the soln. evaporated to dryness. $2\frac{1}{2}$ litres of a mixture of equal vols. of alcohol and ether is poured over the mixture, and after 24 hrs., the sodium chloride is filtered off, and the filtrate distilled. The residue is treated with a litre of water and warmed with bromine-water or nitric acid and allowed to stand. The clear soln. is evaporated for crystallization, and recrystallized from water.

The large, colourless or pale yellow crystals are either monoclinic or triclinic, and, according to C. H. Brandhorst and K. Kraut, have a sp. gr. 4·722. The salt is freely soluble in water, and at 20°, the sp. gr. of the soln. with the following proportions of the anhydrous salt, are:

	5	15	25	35	45	55
Sp. gr. .	1·044	1·143	1·262	1·414	1·613	1·872

The salt is more soluble in alcohol than it is in water. The aq. soln., said O. W. Gibbs, gives a white, crystalline precipitate with silver nitrate; and precipitates with barium chloride, and ammonium nitrate after standing some time. With sufficient sodium carbonate the salt is resolved into normal sodium tungstate and phosphate.

F. Kehrmann and co-workers prepared **sodium phosphatododecatungstate,** $3Na_2O.P_2O_5.24WO_3.nH_2O$, as described above in connection with the addition of barium chloride, is recrystallized from boiling water a number of times. This is one of the salts prepared by C. Scheibler—*vide supra.* F. Kehrmann and co-workers showed that if a hot, sat. soln. be cooled, it furnishes colourless, octahedral crystals with cube faces of the *enneadecahydrate*, $Na_3H_4[P(W_2O_7)_6].19H_2O$. The crystals readily effloresce in air, and the salt is very soluble in water. Soln. sat. at 0°, 22°, and 93° were found by M. Soboleff to dissolve respectively 22·04, 59·65, and 98·184 grms. of the crystallized acid per 100 c.c. of water. F. Kehrmann found that the salt is less soluble in hydrochloric acid, and in soln.

of sodium chloride. F. Kehrmann and co-workers found that if the preceding hydrate be allowed to stand in the cold mother-liquor, it slowly dissolves, and the soln. deposits colourless plates which M. Soboleff found to be the tridecahydrate, $Na_3H_4[P(W_2O_7)_6].13H_2O$, and to be triclinic pinacoids with the axial ratios $a:b:c=1\cdot0875:1:2\cdot0814$, and $\alpha=85° 21'$, $\beta=95° 28'$, and $\gamma=87° 41\cdot5'$. The same hydrate is obtained by keeping a conc. soln. at a temp. below 50°. According to C. H. Brandhorst and K. Kraut, if an aq. soln. of the hydrophosphatododecatungstate be shaken with ether, the *enneahydrate*, $Na_3H_4[P(W_2O_7)_6].9H_2O$, is formed as a white powder. E. Hartmann prepared *sodium phosphatododecatungstatomolybdate*, $3Na_2O.P_2O_5.24(MoO_3,WO_3).nH_2O$. According to F. Kehrmann, **potassium phosphatododecatungstate,** $K_3H_4[P(W_2O_7)_6].nH_2O$, is formed when a soluble potassium salt is added to a dil. soln. of the acid or a soluble salt. O. W. Gibbs obtained the *hemiheptahydrate* or the *hemitridecahydrate* by double decomposition with a soluble potassium salt, and the sodium salt, or, as in the analogous case of the sodium salt, by adding hydrochloric or nitric acid to a mixed soln. of potassium phosphate and tungstate. O. W. Gibbs prepared a salt, $4K_2O.P_2O_5.24WO_3.20H_2O$, from a soln. of metaphosphoric acid and potassium pentatungstate. P. F. M. Sprenger, and F. Kehrmann prepared **copper phosphatododecatungstate,** $Cu_3\{H_4[P(W_2O_7)_6]\}_2.54H_2O$, by treating copper carbonate with the calculated quantity of the acid, and evaporating the clear soln. in vacuo. The green, cubic crystals are freely soluble in water. P. F. M. Sprenger, and F. Kehrmann also prepared **silver phosphatododecatungstate,** $Ag_3H_4[P(W_2O_7)_6].26H_2O$, by adding silver nitrate to a dil. soln. of the acid. The white powder is sparingly soluble in water. P. F. M. Sprenger reported **barium hydrophosphatododecatungstate,** $Ba\{H_6[P(W_2O_7)_6]\}_2.54H_2O$, by evaporating a soln. of the calculated quantity of barium carbonate in the acid; and $BaH_5[P(W_2O_7)_6].27H_2O$ in a similar manner; while O. W. Gibbs prepared barium phosphatododecatungstate, $Ba_3\{H_4[P(W_2O_7)_6]\}_2.42H_2O$, which is produced by the action of barium chloride on a soln. of the sodium salt. The *dotessaracontahydrate* forms colourless, octahedral crystals which rapidly effloresce, and are very soluble in hot water; F. Kehrmann and co-workers also prepared this salt. M. Soboleff obtained the *tetratessaracontahydrate*, $Ba_3\{H_4[P(W_2O_7)_6)\}_2.44H_2O$, in octahedral crystals, and P. F. M. Sprenger also prepared the *tetrapentecontahydrate*, $Ba_3\{H_4[P(W_2O_7)_6]\}_2.54H_2O$, in cubic crystals. C. H. Brandhorst and K. Kraut obtained **sodium barium phosphatododecatungstate,** $NaBaH_4[P(W_2O_7)_6].22H_2O$, by treating a cold soln. of sodium hydrophosphatododecatungstate with freshly precipitated barium carbonate, and adding alcohol to the clear soln. The turbid soln. formed by water becomes clear on the addition of hydrochloric acid. F. Kehrmann and M. Freinkel obtained yellow prisms of **silver barium phosphatododecatungstate,** by adding silver nitrate to a soln. of ammonium barium phosphatododecatungstate. O. W. Gibbs added mercurous nitrate to a soln. of 24 mols. of sodium tungstate, and 2 mols. of sodium hydrophosphate, acidified with nitric acid, and obtained a yellow precipitate of **mercurous phosphatododecatungstate,** which is insoluble in water, and slightly soluble in dil. nitric acid. H. Copaux said that the composition is not constant, but varies with the mode of preparation. F. Kehrmann prepared **mercuric phosphatododecatungstate,** $3HgO.P_2O_5.24WO_3.nH_2O$, freely soluble in water, and **lead phosphatododecatungstate,** $3PbO.P_2O_5.24WO_3.nH_2O$.

O. W. Gibbs found that a boiling soln. of sodium phosphatododecatungstate readily dissolves platinic hydroxide forming an orange liquid, which, when filtered and evaporated, furnishes orange crystals of, presumably, **platinic phosphatododecatungstate.** Ammonium chloride precipitates orange yellow crystals from the soln.—presumably ammonium **platinic phosphatododecatungstate.**

P. F. M. Sprenger reported that he had obtained a soln. of **phosphatohenatungstic acid,** $P_2O_5.22WO_3.nH_2O$, by the action of dil. sulphuric acid on the barium salt. The acid itself, however, has not been isolated. Strong mineral acids decompose the salts into the phosphatododecatungstates and the phosphatohemihenacositungstate, and A. Rosenheim and J. Jänicke suggested that the molecule has two nuclei $H_7[P(OH)(W_2O_7)_5]$ linked by a bivalent W_2O_7-bridge, thus:

$$H_7[P(OH)(W_2O_7)_5]\text{–}W_2O_7\text{–}[(W_2O_7)_5(OH)P]H_7\text{–}nH_2O.$$

By treating barium phosphatohemiheptatungstate with sulphuric acid, C. Scheibler obtained an acid which he represented by the formula $H_{11}PW_{11}O_{43}.18H_2O$. O. W. Gibbs reported **ammonium phosphatohenatungstate,** $3(NH_4)_3O.P_2O_5.22WO_3.21H_2O$, to be formed from a mixture of sodium tungstate and hydrophosphate, ammonium nitrate, and an excess of hydrochloric acid. The colourless crystals are freely soluble in cold water, and partially soluble in hot water to form a turbid liquid. The properties of the salt are, in general, like those of the phosphatododecamolybdate. This may be a phosphatododecatungstate. F. Kehrmann prepared the ammonium salt, $7(NH_4)_2O.P_2O_5.22WO_3.nH_2O$, by adding an excess of ammonium carbonate to a boiling conc. soln. of ammonium phosphatododecatungstate so long as effervescence occurs. On cooling, octahedral crystals are obtained, very soluble in water. The salt can be purified by recrystallization from water, acidified with acetic acid. O. W. Gibbs prepared **sodium phosphatohenatungstate,** $2Na_2O.P_2O_5.22WO_3.9H_2O$, by adding an excess of hydrochloric or nitric acid to a soln. of 24 mols. of sodium tungstate, and a mol. of sodium hydrophosphate. The white, crystalline powder is sparingly soluble in water. This may be a phosphatododecatungstate. When the barium salt is treated with sodium sulphate, F. Kehrmann and co-workers found that the filtered soln., on evaporation, furnishes acicular crystals of $7Na_2O.P_2O_5.22WO_3.33H_2O$. O. W. Gibbs added hydrochloric or nitric acid to a soln. of potassium phosphatoenneatungstate, when **potassium phosphatohenatungstate,** $2K_2O.P_2O_5.22WO_3.6H_2O$, was formed as a white precipitate very soluble in water. This may be a phosphatododecatungstate. F. Kehrmann and co-workers prepared $7K_2O.P_2O_5.22WO_3.31H_2O$, by the process used for the ammonium salt. L. Duparc and F. Pearce found the axial ratio of the colourless, tetragonal crystals to be $a:c=1:0{\cdot}6053$. According to F. Kehrmann and co-workers, the salt is readily soluble in hot or cold water, but insoluble in alcohol. Crystalline double salts are obtained when salts of the heavy metals are added to its conc. aq. soln. The general formula is $(7-m)K_2O.mRO.P_2O_5.22WO_3.nH_2O$. The salts are readily broken down into simpler phosphatotungstates—*vide infra.* O. W. Gibbs obtained **barium phosphatohenatungstate,** $4BaO.P_2O_5.22WO_3.41H_2O$, by neutralizing with acetic acid a mixed soln. of 24 mols. of sodium tungstate and 2 mols. of sodium hydrophosphate, and adding barium chloride. The prismatic crystals are soluble in hot water; and the hot aq. soln. deposits needle-like crystals on cooling. P. F. M. Sprenger obtained doubly-refracting needles of the salt $7BaO.P_2O_522WO_3.59{\cdot}5H_2O$, by adding to a soln. of phosphatododecatungstic acid to excess of barium hydroxide, and evaporating the clear filtrate. F. Kehrmann and co-workers prepared the salt $7BaO.P_2O_5.22WO_3.53H_2O$ by adding powdered barium carbonate to a boiling, conc. soln. of barium phosphatododecatungstate so long as effervescence occurs. On cooling, the salt separates in octahedra; and it can be purified by crystallization from water acidified with acetic acid. If barium chloride is added to the potassium salt, octahedral crystals of **potassium barium phosphatohenatungstate,** $2K_2O.5BaO.P_2O_5.22WO_3.48H_2O$, are formed; the action of silver nitrate on a soln. of ammonium barium phosphatohenatungstate furnishes **silver barium phosphatohenatungstate,** $3Ag_2O.4BaO.P_2O_5.22WO_3.34H_2O$. They also prepared **potassium mercuric phosphatohenatungstate** in colourless, soluble needles; and **barium mercuric phosphatohenatungstate,** in sparingly soluble crystals. O. W. Gibbs reported white, crystalline **ammonium stannic phosphatohenatungstate,** $2(NH_4)_2O.2SnO_2.P_2O_5.22WO_3.15H_2O$.

According to F. Kehrmann and M. Freinkel, **phosphatohemihenicositungstic acid,** $P_2O_5.21WO_3.33H_2O$, is produced as follows: Potassium phosphatohenatungstate is dissolved in a little water, and, after adding an excess of dil. hydrochloric acid, the soln. is boiled and filtered from the potassium phosphatododecatungstate. The filtrate slowly deposits the potassium salt of the required acid; this is converted into the ammonium salt by the action of ammonium chloride, and the latter mixed into a mush with aqua regia, and the mixture boiled. The salt decomposes with the evolution of nitrogen, and the required acid separates from the soln. on cooling. The acid is also obtained by treating the barium salt with sulphuric acid; on evaporation, phosphatododecatungstic acid first separates, and the mother-liquor yields a crop of hexagonal crystals of the required acid. It is also obtained by treating the potassium salt with acid, and extraction with ether. The acid forms colourless, four-sided prisms. It is extremely soluble in water, and the aq. soln. can be boiled without decomposition; but not so with a soln. of salts of the acid; they are decomposed. Soln. of the acid can be repeatedly evaporated with conc. hydrochloric or nitric acid without decomposition. Unlike phosphatododecatungstic acid, potassium and ammonium phosphatohemihenicositungstates are not sparingly soluble in water; and the colour, crystal form, and solubilities of the salts of phosphatoenneatungstic acid, are very different from those of the salt of phosphatohemihenicositungstic acid. E. Brauer found that the $H^{\cdot}$-ion conc. of $0{\cdot}005N$-soln. of the acid is $[H^{\cdot}]=0{\cdot}0070$. The structure of the acid has not been determined; but the acid is very probably more than sexibasic, for the salts of the type $3K_2O.P_2O_5.21WO_3.nH_2O$ behave as if they were acid salts. This is supported by the electrical conductivity of the potassium salt which gives normal values on the assumption that it is hexabasic or heptabasic. Soln. with an eq. of salt—*i.e.* $\frac{1}{6}(3K_2O.P_2O_5.21WO_3.31H_2O)$ in v litres at 25° have the conductivities:

v .	32	64	128	256	512	1024
λ .	166·8	184·2	202·2	226·3	254·1	285·2 mhos.

If attempts are made to prepare normal salts, the complex anion is broken down. F. Kehrmann and co-workers prepared **ammonium phosphatohemihenicositungstate,** $3(NH_4)_2O.P_2O_5.21WO_3.nH_2O$, by adding ammonium chloride to a soln. of the potassium salt, and repeating the precipitation from lukewarm soln. in dil. hydrochloric acid a number of times so as to get the salt free from potassium salts. The six-sided prisms are decomposed by boiling water. The salt is sparingly soluble in cold water, but more soluble in hot water; it is insoluble in a sat. soln. of ammonium chloride; and soluble in alcohol. If a boiling, conc. soln. of potassium phosphatohenatungstate be treated with dil. hydrochloric acid added drop by drop, with agitation, until no more precipitate is formed, and the soln. is acid, and potassium chloride added to the filtrate, a crystalline precipitate of **potassium phosphatohemihenacositungstate,** $3K_2O.P_2O_5.21WO_3.nH_2O$, is formed. The colourless, six-sided prisms are decomposed by boiling water; the salt is soluble in cold water.

According to E. Péchard, the evaporation of a soln. of one eq. of phosphoric acid with 5 eq. of metatungstic acid furnishes efflorescent regular octahedra of **phosphatodecatungstic acid,** $P_2O_5.20WO_3.62H_2O$, and if these are dissolved in very little water, and the soln. concentrated, less efflorescent, trigonal crystals of $P_2O_5.20WO_3.50H_2O$ with the axial ratio $a:c=1:1{\cdot}2929$ are formed. O. W. Gibbs also obtained the acid by adding nitric acid in excess to a mixed soln. of sodium phosphate and tungstate; but later, he added that the free acid could not be prepared. There is a doubt about the acid and its salts, because the methods of preparation, and the properties described are similar to those required for the phosphatododecatungstates. C. Scheibler also prepared cubic crystals of an acid which he represented by the formula $H_{11}PW_{10}O_{38}.8H_2O$. O. W. Gibbs obtained **sodium phosphatodecatungstate,** $Na_2O.P_2O_5.20WO_3.19H_2O$, in efflorescent colourless needles, by adding a small excess of hydrochloric acid to a soln. of 12 mols. of sodium tungstate and one mol. of sodium phosphate. E. Péchard also described $Na_2O.P_2O_5.20WO_3.25H_2O$, in prismatic crystals obtained by evaporating on a water-bath a soln. of eq. proportions of the free acid and sodium hydroxide. It is easily soluble in water, and insoluble in alcohol. E. Péchard obtained $2Na_2O.P_2O_5.20WO_3.30H_2O$, from a soln. of an eq. of the free acid and 2 eq. of sodium hydroxide; and by the action of metatungstic acid on sodium hydrophosphate. The rhombohedral crystals do not effloresce in air. The salt is soluble in water, and insoluble in alcohol. If heated to 100°, 20 mols. of water are given off. A sat. soln. of an eq. of the free acid and 2 eq. of sodium hydroxide yields regular octahedral crystals of $3Na_2O.P_2O_5.10WO_3.32H_2O$. The salt is soluble in water, and insoluble in alcohol. E. Péchard prepared **potassium phosphatodecatungstate**, $K_2O.P_2O_5.20WO_3.5H_2O$, as in the case of the corresponding sodium salt. The addition of silver nitrate to a soln. of the potassium salt furnishes **silver phosphatodecatungstate.** E. Péchard obtained **calcium phosphatodecatungstate**, $2CaO.P_2O_5.20WO_3.22H_2O$, in efflorescent octahedra by the action of metatungstic acid on calcium hydrophosphate; **barium phosphatodecatungstate**, $2BaO.P_2O_5.20WO_3.27H_2O$, in colourless octahedra, by the action of metatungstic acid on barium hydrophosphate; and by adding 2 eq. of baryta-water to a soln. of one eq. of the free acid; $2BaO.P_2O_5.20WO_3.36H_2O$, in colourless octahedra, by adding barium chloride to a soln. of sodium paratungstate mixed with phosphoric and hydrochloric acids. O. W. Gibbs reported $6BaO.P_2O_5.20WO_3.48H_2O$, to be formed by adding hydrochloric acid to mixtures of sodium tungstate and sodium hydrophosphate in the proportions between 24 to 2 to 12 : 2. The colourless crystals are readily soluble in hot water. E. Péchard prepared colourless, efflorescent octahedra of **magnesium phosphatodecatungstate**, $2MgO.P_2O_5.20WO_3.19H_2O$, by evaporating in vacuo a soln. of 2 eq. of magnesium carbonate and one eq. of the acid; also **lead phosphatodecatungstate**, $2PbO.P_2O_5.20WO_3.6H_2O$, in white needles.

The so-called **luteophosphotungstic acid**—*luteus*, yellow—or **phosphatoenneatungstic acid**, $P_2O_5.18WO_3.42H_2O$, was prepared by F. Kehrmann as follows:

A soln. of 100 grms. of sodium tungstate in sufficient boiling water was mixed with 50 grms. of syrupy phosphoric acid and 50 c.c. of water, and the water renewed as the soln. is boiled until it acquires a yellow colour. 20 c.c. of conc. nitric acid were added drop by drop to the boiling liquid. The cold liquid was treated with powdered ammonium chloride so long as a yellow precipitate was produced. The powder was isolated by suction, dissolved in a little cold water, and again precipitated by ammonium chloride; the operation was repeated twice more. The pale yellow needles were removed from the large lemon-yellow prisms of the ammonium salt of this acid by levigation, and the salt recrystallized. The product is mixed with 3 parts of conc. hydrochloric acid and one part of conc. nitric acid boiled until the ammonia is all expelled. The yellow soln. is evaporated to remove nitric acid; and the product recrystallized from lukewarm water. The acid is also obtained by decomposing the silver salt with hydrochloric acid. The acid can be extracted from its aq. soln. by ether.

The acid forms lemon-yellow, six-sided, triclinic plates which are stable in air, and melt at 28°. A. Rosenheim and J. Jänicke's analysis corresponds with the empirical formula just indicated. F. Kehrmann's analysis gave $41H_2O$, and he thought that the acid is tribasic. When 25 c.c. of a $\frac{1}{32}N$-soln., on the assumption that an eq. of the acid is one-fifth of the mol $P_2O_5.18H_2O.42H_2O$, is treated with n c.c. of $0{\cdot}1N$-NaOH, and the conductivity measured, the values

C.c. 0·1*N*-NaOH	1	2	4	5	6	8	9
	2·754	2·416	1·739	1·402	1·067	1·066	1·148

show a minimum for 4·4 mols. of base to a mol. of acid, meaning that the acid is at least pentabasic. A. Rosenheim and J. Jänicke found that the lowering of the f.p. of aq. soln. corresponds with a decabasic acid. The electrical conductivity of a soln. of one-third of a mol of $P_2O_5.18WO_3.42H_2O$ in v litres of water at 25° is:

v .	16	32	64	128	256	512	1024
λ .	66·23	68·76	71·14	73·57	76·16	78·01	80·14

The guanidinium salt, $5(CN_3H_6)_2O.P_2O_5.18WO_3.18H_2O$, as also is the silver salt, prepared by R. Häberle, agrees with the assumption that the acid is decabasic, although the corresponding molybdate is dodecabasic, but the complex ion of that acid is not so stable. The constitutional formula of the acid is $H_5[P(OH)(W_2O_7)_4]\text{–}W_2O_7\text{–}[P(OH)(W_2O_7)_4]H_5.36H_2O$, or $H_{10}[(HO)(W_2O_7)_4P\text{–}W_2O_7\text{–}P(W_2O_7)_4(OH)].36H_2O$. H. Wu supposed that the acid exists in two isomeric forms. E. Brauer gave for the $H^{\cdot}$-ion conc. in a $0{\cdot}005N$-soln., 0·0041. The acid is freely soluble in water; it is not changed by strong mineral acids; but the least excess of a strong base breaks down the molecule. When the acid is treated with chlorides or nitrates of the bases, it readily forms salts which are usually fairly soluble. Alkaloids and other nitrogenous organic bases give coloured precipitates with this acid. Alkali carbonates break down the salts into phosphatohemiheptadecatungstates; and with strong acids, phosphatododecatungstates may be formed.

O. W. Gibbs reported **ammonium phosphatoenneatungstate,** $2(NH_4)_2O.P_2O_5.18WO_3.11H_2O$, to remain as a white, crystalline mass, when ammonium paratungstate is boiled with a soln. of metaphosphoric acid. F. Kehrmann and co-workers prepared $3(NH_4)_2O.P_2O_5.18WO_3.14H_2O$, in lemon-yellow, triclinic prisms isomorphous with the potassium salt, as indicated above in connection with the preparation of the acid. A. Rosenheim and J. Jänicke gave $(NH_4)_3H_2[P(OH)(W_2O_7)_4–W_2O_7–(W_2O_7)_4(HO)P]H_2(NH_4)_3.11H_2O$ for the formula. The crystals effloresce in dry air, and in consequence of partial reduction become greenish. The ammonium salt is more soluble than the potassium salt. F. Kehrmann reported **sodium phosphatoenneatungstate,** $3Na_2O.P_2O_5.18WO_3.nH_2O$, to be formed in soluble, lemon-yellow, six-sided plates, by evaporating a mixed soln. of sodium tungstate with an excess of phosphoric acid; or by adding sodium sulphate to a soln. of the barium salt. F. Kehrmann prepared **potassium phosphatoenneatungstate,** $3K_2O.P_2O_5.18WO_3.14H_2O$, by adding potassium chloride to a soln. of the acid. A. Rosenheim and J. Jänicke represented the formula $K_3H_2[P(OH)(W_2O_7)_4–W_2O_7–(W_2O_7)_4(OH)P]K_3H_2.11H_2O$. He first represented the formula by $3K_2O.P_2O_5.16WO_3.16H_2O$. The lemon-yellow, triclinic crystals were found by C. Stuhlmann to have the axial ratios $a : b : c = 0·6278 : 1 : 0·9508$, and $\alpha = 80° 26'$, $\beta = 118° 34'$, and $\gamma = 81° 15'$. The salt is freely soluble in water. Like the ammonium salt it is decomposed when treated with potassium carbonate, forming the phosphatohemiheptadecatungstate. O. W. Gibbs reported $K_2O.P_2O_5.18WO_3.19H_2O$ to be formed as a sparingly-soluble, white, crystalline mass on adding an excess of hydrochloric acid to a soln. of the normal salt; and he obtained prismatic crystals of $6K_2O.P_2O_5.18WO_3.23H_2O$, by adding alcohol to a boiling soln. of 20 mols. of sodium tungstate and 2 mols. of sodium hydrophosphate acidified with acetic acid, and then adding potassium chloride to an eq. soln. of the product. If the salt separates from conc. soln. it has $30H_2O$. F. Kehrmann obtained emerald green plates of **copper phosphatoenneatungstate,** $3CuO.P_2O_5.18WO_3.nH_2O$, easily soluble in water. If a soln. of the potassium salt is treated with silver nitrate, **silver phosphatoenneatungstate,** $3Ag_2O.P_2O_5.18WO_3.14H_2O$, is precipitated. A. Rosenheim and J. Jänicke represented it by $Ag_3H_2[P(OH)(W_2O_7)_4–W_2O_7–(W_2O_7)_4(OH)P]H_2Ag_3.13H_2O$; F. Kehrmann at first regarded it as $3Ag_2O.P_2O_5.16WO_3.40H_2O$. If a 30 per cent. soln. of the acid be treated with 5 to 6 molar proportions of sodium hydroxide, a soluble silver salt, a yellow flaky precipitate of $5Ag_2O.P_2O_5.18WO_3.34H_2O$, or $Ag_5[P(OH)(W_2O_7)_4–W_2O_7–(W_2O_7)_4(OH)P]Ag_5.34H_2O$, is formed. It is almost insoluble in water. F. Kehrmann at first regarded it as $5Ag_2O.P_2O_5.16WO_3.nH_2O$. The corresponding guanidinium salts were obtained in an analogous manner. F. Kehrmann found that **barium phosphatoenneatungstate,** $3BaO.P_2O_5.18WO_3.nH_2O$, separates out when barium chloride is added to a conc. soln. of the acid. The pale yellow plates are sparingly soluble in water. F. Kehrmann also prepared **mercuric phosphatoenneatungstate,** $3HgO.P_2O_5.18WO_3.nH_2O$, freely soluble in water; **lead phosphatoenneatungstate,** $3PbO.P_2O_5.18WO_3.nH_2O$, in six-sided plates, soluble in water.

F. Kehrmann and E. Böhm prepared salts of **phosphatohemiheptadecatungstic acid,** $P_2O_5.17WO_3.nH_2O$, by neutralizing a 30 per cent. soln. of phosphatoenneatungstic acid with aq. ammonia or potash-lye, or ammonium or potassium hydrocarbonates, using litmus as an indicator. The yellow colour of the soln. slowly disappears, and, in the case of ammonia, white, cubic, or tabular crystals of **ammonium phosphatohemiheptadecatungstate,** $5(NH_4)_2O.P_2O_5.17WO_3.16H_2O$, separate out. The salt is sparingly soluble in cold water, and when the aq. soln. is boiled the salt is decomposed with the escape of ammonia. The salt is converted by dil. hydrochloric acid into phosphatoenneatungstate and free phosphoric acid. F. Kehrmann seems to have at first regarded these salts as phosphato-octotungstates.

By using a similar process, or by the action of potassium hydrocarbonate on potassium phosphatoenneatungstate, F. Kehrmann, and F. Kehrmann and E. Böhn prepared **potassium phosphatohemiheptadecatungstate,** $5K_2O.P_2O_5.17WO_3.21$ or $22H_2O$, in white plates, sparingly soluble in cold water; and by treating the potassium salt with a soln. of silver nitrate in excess, **silver phosphatohemiheptatungstate,** $5Ag_2O.P_2O_5.17WO_3.20H_2O$, is formed in yellow plates. The salts were also studied by A. Rosenheim and J. Jänicke, but neither the free acid nor salts of a lower basicity are known.

E. Péchard reported **phosphatoctotungstic acid,** $P_2O_5.16WO_3.69H_2O$, to be formed in colourless, cubic octahedra by concentrating in vacuo a soln. of metatungstic and phosphoric acids in theoretical proportions. O. W. Gibbs reported ammonium phosphatoctotungstate, $6(NH_4)_2O.P_2O_5.16WO_3.10H_2O$, to be formed by adding ammonium chloride to a boiling soln. of sodium paratungstate in phosphoric acid. The prismatic crystals are easily soluble in hot water, and the hot soln. deposits crystals of the salt on cooling. O. W. Gibbs also prepared colourless needles of **potassium phosphatoctotungstate,** $4K_2O.P_2O_5.16WO_3.21H_2O$, in colourless needles, soluble in hot water; he reported the complex salt **sodium potassium phosphatoctotungstate,** $2Na_2O.3K_2O.P_2O_5.16WO_3.20H_2O$; and he also prepared **calcium phosphatoctotungstate,** $CaO.P_2O_5.16WO_3.8H_2O$, in colourless, soluble plates. E. Péchard obtained **barium phosphatoctotungstate,** $2BaO.P_2O_5.16WO_3.10H_2O$, by evaporating a soln. of 2 eq. of barium carbonate in the free acid. The regular octahedra are freely soluble in water, and insoluble in alcohol. F. Kehrmann reported insoluble **mercurous phosphatoctotungstate,** $3Hg_2O.P_2O_5.16WO_3.nH_2O$; and **lead phosphatoctotungstate,** $5PbO.P_2O_5.16WO_3.nH_2O$, as a yellow insoluble powder, and $3PbO.P_2O_5.16WO_3.nH_2O$ in yellow prisms or needles; soluble in water; and with an excess of water forming a basic salt. F. Kehrmann also reported $P_2O_5.16WO_3.41H_2O$, as well as the **phosphatoctotungstates** of ammonium, potassium, and silver salts, but improved analytical methods showed that the products were phosphatohemiheptadecatungstates, or phosphatoenneatungstates.

E. Péchard found that **phosphatohexatungstic acid,** $P_2O_5.12WO_3.42H_2O$, is the most easily prepared of all the phosphotungstic acids. It is obtained by concentrating in vacuo a soln. of metatungstic and phosphoric acids in theoretical proportions. The triclinic, pinacoidal crystals were found by E. Dufet to have the axial ratios $a:b:c=0{\cdot}9916:1:1{\cdot}5931$, and $\alpha=90°\ 6'$, $\beta=97°\ 53\frac{1}{2}'$, and $\gamma=84°\ 25\frac{1}{2}'$. The (110)-cleavage is marked. The crystals do not effloresce in air; and are soluble in water and alcohol. Warm acids decompose the acid liberating tungstic acid; and with bases, it forms salts. An excess of alkali decomposes the salts forming a tungstate and a phosphate. The salts are prepared by treating the acid with a carbonate of the base, or by the action of metatungstic acid on a phosphate. E. Péchard said that **ammonium phosphatohexatungstate,** $2(NH_4)_2O.P_2O_5.12WO_3.5H_2O$, is insoluble in cold water, an excess of aq. ammonia converts it into ammonium paratungstate. A soln. of the acid treated with 2 eq. of lithium carbonate furnishes trigonal crystals of **lithium phosphatohexatungstate,** $2Li_2O.P_2O_5.12WO_3.21H_2O$. The triclinic pinacoids of **sodium phosphatohexatungstate,** $2Na_2O.P_2O_5.12WO_3.18H_2O$, were obtained in a similar manner. E. Dufet found that the crystals have imperfect (110)-, and (001)-cleavages. The crystals effloresce slowly in air. The salt is soluble in water, and is precipitated from its aq. soln. by alcohol. Conc. hydrochloric acid gives a white crystalline precipitate. If hydrochloric acid be left in contact with the salt, or if the salt be treated with warm acid, it is decomposed. White, insoluble potassium phosphatohexatungstate, $K_2O.P_2O_5.12WO_3.9H_2O$, was prepared in a similar manner. E. Péchard also prepared green, trigonal crystals of **copper phosphatohexatungstate,** $2CuO.P_2O_5.12WO_3.11H_2O$, which E. Dufet found had the axial ratio $a:c=1:2{\cdot}6534$, and $\alpha=56°\ 30'$. E. Péchard obtained **silver phosphatohexatungstate,** $Ag_2O.P_2O_5.12WO_3.8H_2O$, as a white insoluble precipitate stable in light; trigonal crystals of **calcium phosphatohexatungstate,** $2CaO.P_2O_5.12WO_3.19H_2O$, which rapidly effloresce in air, and are insoluble in alcohol. E. Dufet gave for the axial ratio $a:c=1:2{\cdot}6759$, and $\alpha=56^\circ\ 8'$. E. Péchard prepared trigonal crystals of **barium phosphatohexatungstate,** $2BaO.P_2O_5.12WO_3.15H_2O$, which, according to E. Dufet, have the axial ratio $a:c=1:2{\cdot}6839$, and $\alpha=56^\circ\ 1'$. The salt effloresces rapidly in air; it is stable in water; and is precipitated by alcohol from its aq. soln. The trigonal crystals of **magnesium phosphatohexatungstate,** $2MgO.P_2O_5.12WO_3.10H_2O$, prepared by E. Péchard were found by E. Dufet to have the axial ratio $a:c=1:2{\cdot}6523$, and $\alpha=56^\circ\ 23'$. E. Péchard also prepared trigonal crystals of **zinc phosphatohexatungstate,** $2ZnO.P_2O_5.12WO_3.7H_2O$; sparingly soluble **cadmium phosphatohexatungstate,** $2CdO.P_2O_5.12WO_3.13H_2O$; and yellow, **mercurous phosphatohexatungstate,** $Hg_2O.P_2O_5.12WO_3.nH_2O$, insoluble in nitric acid. E. Péchard obtained a white precipitate of **thallous phosphatohexatungstate** by the action of metaphosphoric and tungstic acids on thallous carbonate. White, insoluble needles of **lead phosphatohexatungstate,** $2PbO.P_2O_5.12WO_3.6H_2O$, were prepared.

According to F. Kehrmann and R. Mellet, when a very conc. soln. of a mixture of sodium tungstate and phosphate is faintly acidified with acetic acid, and allowed to stand a few days, a mass of crystals is formed. When washed with cold water, there remains a sparingly-soluble *sodium phosphatotungstate,* $14Na_2O.5P_2O_5.19WO_3.nH_2O$, or $29Na_2O.10P_2O_5.39WO_3.nH_2O$. The soluble portion contains a phosphatotritungstate—*vide infra.* O. W. Gibbs reported a complex *sodium potassium phosphatotungstate,* $7Na_2O.11K_2O.6P_2O_5.22WO_3.42H_2O$.

O. W. Gibbs reported **sodium phosphatohemiheptatungstate,** $5Na_2O.2P_2O_5.14WO_3.42H_2O$, to be formed by boiling sodium paratungstate with less than half its weight of syrupy phosphoric acid. Colourless, prismatic crystals are deposited in a few days. The salt may be a mixture. F. Kehrmann reported $3Na_2O.P_2O_5.7WO_3.nH_2O$ to be formed by the action of a cold sat. soln. of sodium tungstate on aq. phosphoric acid, and allowing the acid liquid to stand for a month at ordinary temp. C. Scheibler reported crystals of sodium phosphotungstate, $Na_5H_{11}P_2W_6O_{31}.13H_2O$, to be formed by dissolving sodium paratungstate in water, adding half its weight of phosphoric acid, and allowing the mixture to stand for some time. F. Kehrmann and R. Mellet showed that the salt is really a sodium phosphatohemiheptatungstate, $3Na_2O.P_2O_5.7WO_3.nH_2O$. F. Kehrmann treated a soln. of this salt with ammonium chloride for a number of times in the cold, and obtained **ammonium phosphatohemiheptatungstate,** $3(NH_4)_2O.P_2O_5.7WO_3.nH_2O$, in cubic crystals which are deposited when the aq. soln. is treated with alcohol. The salt is sparingly soluble in cold water without decomposition, but with boiling water, ammonia is evolved. The aq. soln. with a calcium salt gives after standing some time a sparingly-soluble, crystalline **ammonium calcium phosphatohemiheptatungstate;** with barium chloride, sparingly soluble **barium phosphatohemiheptatungstate** is precipitated. C. Scheibler prepared barium phosphatohemiheptatungstate by the action of barium chloride on the sodium salt which he prepared. F. Kehrmann found that a soln. of ammonium or sodium phosphatohemiheptatungstate with silver nitrate, furnishes white insoluble **silver phosphatohemiheptatungstate.** It dissolves in a soln. of the ammonium salt forming **ammonium silver phosphatohemiheptatungstate.**

F. Kehrmann and R. Mellet did not succeed in preparing **phosphatotritungstic acid,** but, as indicated above, they found that the aq. filtrate obtained from sodium phosphatotetratungstate contains a salt which when crystallized out consists of **sodium phosphatotritungstate,** $3Na_2O.P_2O_5.6WO_3.16H_2O$. It is best obtained by the slow crystallization of an aq. soln. of 3 mols. of sodium tungstate, and a mol. of sodium hydrophosphate neutralized with acetic acid. The salt was purified by recrystallization from water. It forms aggregates of white, striated prisms, and contains 3 mols. of water of constitution. The potassium salt could not be prepared directly from its constituents; but when a soln. of the sodium salt is treated with potassium chloride, prismatic needles of **potassium phosphatotritungstate,** $3K_2O.P_2O_5.6WO_3.14H_2O$, are formed; and if ammonium chloride is used, stout prisms of **ammonium phosphatotritungstate,** $3(NH_4)_2O.P_2O_5.6WO_3.9H_2O$, are formed.

O. W. Gibbs prepared a series of **pyrophosphatotungstates** by boiling tungstic acid with an alkali pyrophosphate. The phosphoric acid can be separated from the salts only by boiling them repeatedly with hydrochloric acid. White, granular **potassium pyrophosphatotungstate,** $18K_2O.9P_2O_5.22WO_3.49H_2O$, was so obtained; and **ammonium sodium pyrophosphatotungstate,** $14(NH_4)_2O.6Na_2O.9P_2O_5.22WO_3.31H_2O$, as a white, crystalline precipitate easily soluble in hot water. The potassium salt when treated with copper sulphate furnishes **copper pyrophosphatotungstate,** or a double salt; while mercurous nitrate with the potassium or sodium ammonium salt gives a yellow or white crystalline precipitate of **mercurous pyrophosphatotungstate.** A mixed soln. of sodium paratungstate and manganese pyrophosphate on evaporation yields orange-brown crystals of **sodium manganese pyrophosphatotungstate,** $6Na_2O.3MnO.P_2O_5.14WO_3.36H_2O$; and when this salt is treated with ammonium chloride it furnishes orange prisms of **ammonium sodium manganese pyrophosphatotungstate,** $5(NH_4)_2O.2Na_2O.6MnO.2P_2O_5.14WO_3$, which are soluble in cold and hot water.

INDEX

A

Acetylated salts, 437
Achrematite, 568
Acide tungstique, 753
Alexandrite, 177
Alkali-alkaline earth tungsten bronzes, 751
Alkali tellurosulphostannates, 114
Alkaline earths, 522
Allotelluric acid, 87
Altaite, 2, 56
Aluminium ammonium barium oxydodecamolybdate, 600
—— —— chromium sulphate, 463
—— —— dodecamolybdate, 599
—— barium oxydodecamolybdate, 600
—— chromide, 172
—— chromite, 200
—— chromium alloys, 172
—— decachlorotellurite, 103
—— dioxychromate, 284
—— ditungstide, 762
—— lead oxydodecamolybdate, 600
—— molybdate, 563
—— molybdenum alloys, 523
—— oxydichromate, 285, 342
—— paratungstate, 819
—— pentatungstate, 829
—— pentitatelluride, 54
—— potassium decamolybdate, 598
—— —— dodecamolybdate, 599
—— —— tellurate, 96
—— silver dioxymolybdate, 600
—— —— oxydodecamolybdate, 600
—— sodium dodecamolybdate, 599
—— sulphomolybdate, 652
—— sulphotungstate, 859
—— tellurate, 96
—— telluride, 53
—— tellurite, 81
—— tetritatungstide, 742
—— trichromide, 172
—— tritatungstide, 742
—— tungstate, 789
—— —— octohydrate, 789
Aluminotungstates, 789
Amarillo de barita, 273
—— di estronciana, 271
—— ultrames, 273
Ammonia, 368
Ammonium aluminium chromium sulphate, 463
—— —— dodecamolybdate, 599
—— aluminotungstate, 789
—— aquopentafluoride, 363
—— barium aluminium oxydodecamolybdate, 600
Ammonium barium chromate, 274
—— —— chromidodecamolybdate, 602
—— —— cobaltic decamolybdate, 575
—— —— paramolybdate, 586
—— —— phosphatomolybdate, 663
—— bismuth molybdate, 570
—— —— tungstate, 795
—— blue perchromate, 357
—— cadmium amminoquadrichromate, 280
—— —— diamminochromate, 280
—— —— diamminomolybdate, 563
—— —— dihydroxyquadrichromate, 280
—— —— paramolybdate, 587
—— —— paratungstate, 819
—— —— phosphatotetritaenneamolybdate 670
—— —— phosphatotrimolybdate, 668
—— —— tungsten tetramminoenneachloride, 842
—— calcium chromate, 270
—— —— paramolybdate, 586
—— —— phosphatohemiheptatungstate, 873
—— ceric dihydrododecamolybdate, 600
—— —— dodecamolybdate, 600
—— cerous molybdate, 587
—— —— tungstate, 790
—— chlorochromate, 397
—— chromate, 241
—— chromatopentamminobischromate, 311
—— chromatosulphate, 450
—— chromic chloropentaquodichlorosulphate, 468
—— —— chloropentaquodisulphate, 468
—— —— chloropentaquosulphatohydrosulphate, 468
—— —— dichloro-hydrosulphatotrisulphate, 469
—— —— dichlorotetraquochlorotrisulphate, 469
—— —— dichlorotetraquodisulphate, 468
—— —— heptamminoctonitrate, 407
—— —— hexachloride, 417, 418
—— —— hexahydrate, 418
—— —— hexamminotrioxalate, 409
—— —— monohydrate, 418
—— —— pentachloride, 418
—— —— trichlorodisulphate, 468
—— chromidodecamolybdate, 601
—— chromipyrophosphate, 481
—— chromite, 397
—— chromium heptamminoctonitrate, 478
—— —— hexafluoride, 363
—— —— hydroxyphosphate, 482
—— —— pentafluoride, 363
—— —— phosphate, 482

Ammonium chromium sulphate, 452
—— —— tetrachloride, 417
—— —— triammino-oxalatochloride, 417
—— chromochromate, 210
—— chromotellurate, 97
—— chromous carbonate, 471
—— —— fluoride, 362
—— —— sulphate, 434
—— chromyl difluochromate, 365
—— cobalt decamolybdate, 574
—— cobaltic aquopentamminomolybdate, 575
—— —— decamolybdate, 598
—— —— dodecamolybdate, 574
—— cobaltous chromate, 312
—— —— diamminomolybdate, 574
—— —— diamminoquaterochromate, 312
—— —— dichromate, 344
—— —— dihydrophosphatohemipentamolybdate, 670
—— —— phosphatohemipentamolybdate, 670
—— —— paramolybdate, 587
—— —— pentamolybdate, 594
—— copper chromate, 262
—— —— diamminochromate, 262
—— —— diamminomolybdate, 559
—— —— molybdate, 559
—— —— pentafluodioxytungstate, 839
—— —— phosphatohemipentamolybdate, 669
—— —— tellurite, 79
—— —— tungstate, 782
—— —— tungsten tetramminoenneachloride, 842
—— cupric dichromate, 339
—— decamolybdate, 597
—— —— enneadecahydrate, 597
—— diarsenatotellurate, 96
—— dichromate, 323
—— dichromyl tetrafluochromate, 365
—— difluotellurate, 109
—— dihydrophosphatohemipentamolybdate, 668
—— —— heptadecahydrate, 668
—— —— heptahydrate, 668
—— dihydrophosphatomolybdate, 671
—— dihydrothoridodecamolybdates, 601
—— dimercuriammonium chromate, 284
—— dimolybdate, 580
—— dimolybditetramolybdate, 531
—— dimolybditotetramolybdate, 593
—— dioxydisulphomolybdate, 654
—— dioxydisulphotungstate, 861
—— dioxypentafluomolybdate, 614
—— dioxytetrafluomolybdate, 613
—— dioxytrifluoride, 613
—— diperchromates, 357
—— diphosphatotellurate, 120
—— diplatinic triacontatungstate, 803
—— disulphatochromate, 452
—— ditelluratohexamolybdate, 97
—— ferric chromate, 309
—— —— chromium sulphate, 463
—— —— dodecamolybdate, 602
—— —— dodecatungstate, 832
—— —— paratungstate, 820
—— —— pentadecaoxysexieschromate, 310
—— —— sulphate, 831
—— fluochromate, 365
Ammonium gold amminophosphatomolybdate, 671
—— heptahydrodecamolybdate, 595
—— —— heptahydrate, 595
—— hexabromotellurite, 109
—— hexachlorotellurite, 102
—— hexachromate, 352
—— hexadecatungstate, 832
—— hexaiodotellurite, 106
—— hexamolybdate, 594
—— hexatungstate, 829
—— hexoxyhenafluomolybdate, 614
—— hydroheptamolybdate, 594
—— hydrophosphatodimolybdate, 670
—— —— hemipentahydrate, 670
—— hydropyrotellurate, 89
—— hydrostannidodecamolybdate, 601
—— hydrotellurate, 89
—— hydrotelluride, 40
—— hydrotetroxytrisulphodimolybdate, 655
—— hydroxylamine paramolybdate, 552
—— hydroxylamine tungstate, 773
—— hypomolybdatomolybdate, 604
—— isotungstate, 773
—— lanthanous molybdate, 587
—— lanthanum hexachromate, 287
—— —— tungstate, 790
—— lead chromate, 304
—— —— phosphatopentadecamolybdate, 671
—— lithium chromate, 244
—— magnesium chromate, 275
—— —— molybdate, 562
—— —— paratungstate, 818
—— —— telluride, 50
—— manganic dodecamolybdate, 602
—— —— molybdate, 572
—— —— paratungstate, 820
—— —— tridecamolybdate, 602
—— —— tungstate, 797
—— manganous chromate, 309
—— —— decamolybdate, 598
—— —— dihydrophosphatohemipentamolybdate, 669
—— —— dodecamolybdate, 602
—— —— molybdate, 571
—— —— permanganitomolybdate, 573
—— —— phosphatohemipentamolybdate, 669
—— —— pyrophosphatomolybdate, 671
—— —— trischromate, 309
—— mercuric tungstate, 788
—— mercurous aluminotungstate, 789
—— metatungstate, 821
—— —— hexahydrate, 821
—— —— tetrahydrate, 821
—— molybdate, 551
—— molybdatosulphate, 658
—— molybdatotrisulphate, 658
—— molybdenum amminopentachloride, 622
—— —— chloride, 629
—— —— dioxytetrachloride, 632
—— —— enneafluoride, 610
—— —— hemipentoxide, 532
—— —— heptachloride, 621
—— —— hexachloride, 621
—— —— oxypentabromide, 637
—— —— pentabromide, 635

Ammonium molybdenum pentachloride, 621
—— —— tetrachlorotetrabromide, 640
—— —— tetrachlorotetraiodide, 640
—— —— tetradecachloride, 623
—— —— tetrafluoride, 609
—— —— trioxytetradecafluoride, 611
—— —— tungstate, 796
—— molybdenyl pentabromide, 637
—— —— pentachloride, 629
—— molybditetramolybdate, 533
—— molybdosic sulphates, 657
—— molybdous heptachloride, 619
—— —— octochloride, 618
—— monoperditungstate, 834
—— neodymium molybdate, 587
—— nickel chromate, 313
—— —— diamminochromate, 313
—— —— dihydrophosphatohemipentamolybdate, 670
—— —— dihydroxyquaterchromate, 313
—— —— phosphatohemipentamolybdate, 670
—— nickelic tridecamolybdate, 602
—— —— tungstate, 802
—— nickelous decamolybdate, 598
—— —— diamminomolybdate, 576
—— —— enneamolybdate, 597
—— —— henitricontamolybdate, 604
—— —— hexadecamolybdate, 603, 604
—— —— tetratricontamolybdate, 604
—— nitratometatungstate, 814, 861
—— octomolybdate, 595
—— octotungstate, 830
—— oxalatotriamminochromate, 409
—— oxychromate, 241
—— oxydimercuriammonium dichromate, 342
—— oxypentachlorotungstate, 849
—— oxypentafluomolybdate, 611
—— paramolybdate, 583
—— —— dodecahydrate, 583
—— —— tetrahydrate, 583
—— parasulphomolybdate, 651
—— paratungstate, 812
—— —— henahydrate, 812
—— —— heptahydrate, 813
—— —— hexahydrate, 813
—— —— pentahydrate, 812
—— pentabromotungstite, 854
—— pentafluotellurite, 98
—— pentahydrotrimolybdate, 594
—— —— pentahydrate, 594
—— pentamolybdate, 593
—— pentatungstate, 828
—— perchromate, 356
—— perdichromates, 359
—— perdisulphomolybdate, 654
—— permanganitomolybdates, 572, 573
—— permanganous octomolybdate, 597
—— permolybdate, 607
—— permonosulphomolybdate, 653
—— pernickelic enneamolybdate, 597
—— perparamolybdate, 608
—— phosphatoctomolybdate, 667
—— phosphatodecamolybdate, 664
—— phosphatododecamolybdate, 662
—— phosphatododecatungstate, 866
—— phosphatoenneamolybdate, 666
—— phosphatoenneatungstate, 871
Ammonium phosphatohemihenicositungstate, 869
—— phosphatohemiheptadecamolybdate, 667
—— phosphatohemiheptadecatungstate, 871
—— phosphatohemiheptatungstate, 873
—— phosphatohenamolybdate, 664
—— phosphatohenatungstate, 868
—— phosphatoheptamolybdate, 667
—— phosphatohexamolybdate, 667
—— phosphatohexatungstate, 872
—— phosphatotetrachromate, 482
—— phosphatotetramolybdate, 667
—— phosphatotritungstate, 874
—— potassium chromate, 257
—— —— chromium sulphate, 463
—— —— manganous permanganitomolybdate, 573
—— —— permanganitomolybdate, 573
—— præseodymium molybdate, 587
—— —— tungstate, 791
—— pyrotellurite, 77
—— rhodic dodecamolybdate, 603, 604
—— samarium molybdate, 587
—— silver aluminotungstate, 789
—— —— chromate, 267
—— —— phosphatohemiheptatungstate, 873
—— sodium chromate, 249
—— —— decatungstate, 831
—— —— 3 : 1-decatungstate, 831
—— —— gold pyrophosphatohemihenamolybdate, 671
—— —— hexadecatungstate, 832
—— —— manganese pyrophosphatotungstate, 874
—— —— manganic tridecamolybdate, 602
—— —— 1 : 3-metatungstate, 824
—— —— octotungstate, 830
—— —— 1 : 3-paratungstate, 816
—— —— 3 : 2-paratungstate, 816
—— —— 4 : 1-paratungstate, 816
—— —— —— heptahydrate, 816
—— —— —— pentahydrate, 816
—— —— —— tridecahydrate, 816
—— —— 3 : 2-pentadecatungstate, 832
—— —— 4 : 2-pentadecatungstate, 832
—— —— phosphatohemiheptadecamolybdate, 667
—— —— phosphatomolybdate, 663
—— —— pyrophosphatotungstate, 874
—— stannic phosphatohenatungstate, 868
—— —— phosphatohexitetradecamolybdate, 670
—— stannidodecamolybdate, 601
—— strontium chromate, 271
—— sulphatotellurite, 118
—— sulphomolybdate, 650
—— sulphotellurite, 113
—— sulphotungstate, 858
—— sulphovanadatomolybdate, 652
—— tellurate, 89
—— tellurite, 77
—— telluratohexamolybdate, 97
—— tetrachlorotellurite, 100
—— tetrachromate, 351, 352
—— tetrafluodioxytungstate, 838
—— tetrahydrate, 834

Ammonium tetrahydroxylaminotetramolybdate, 592
—— tetramolybdate, 591
—— thoridodecamolybdates, 601
—— titanidodecamolybdate, 600
—— titanium chromate, 288
—— triarsenatotellurate, 96
—— trichromate, 349
—— trifluodioxytungstate, 838
—— trifluotrioxytungstate, 839
—— trihydroheptamolybdate, 594
—— trihydrophosphatohemipentamolybdate, 668
—— —— hemitridecahydrate, 669
—— —— hexahydrate, 668
—— —— tetrahydrate, 668
—— trimolybdate, 588
—— trioxydifluomolybdate, 612
—— trioxypentafluomolybdate, 615
—— trioxytrifluomolybdate, 613
—— triperchromates, 356
—— triphosphatotellurate, 120
—— trisulphatochromiate, 464
—— trisulphomolybdate, 651
—— tritungstate, 810
—— tungstate, 773
—— tungsten tetrafluoride, 837
—— uranium tungstate, 797
—— uranyl chromate, 308
—— —— hexahydrate, 308
—— —— trihydrate, 308
—— zinc chromate, 279
—— —— diamminobischromate, 280
—— —— paramolybdate, 586
—— —— paratungstate, 819
—— —— triamminosexichromate, 280
—— zirconidodecamolybdate, 601
—— zirconium tungstate, 791
Aniline ceric dodecamolybdate, 600
—— hydrochloride, 831
Antamokite, 2, 49
Antimonatotungstates, 795
Antimony molybdates, 570
—— oxychromite, 201
—— tellurate, 97
—— telluride, 59
—— tetroxybischromate, 305
—— tungstates, 795
Aquopentammines, 401
Argent molybdique, 60
Arsenic molybdates, 570
—— octodecatungstic acid, 832
—— sulphomolybdates, 652
—— sulphotellurite, 114
—— tellurate, 96
—— telluride, 58
Arsenotellurite, 2, 114
Auric telluride, 49
Aurotellurite, 1
Aurum bismuticum, 1
—— graphicum, 1, 47
—— gulena, 114
—— paradoxum, 1

B

Barium aluminium oxydodecamolybdate, 600
—— aluminotungstate, 789
Barium ammonium aluminium oxydodecamolybdate, 600
—— —— chromate, 274
—— —— chromidodecamolybdate, 602
—— —— cobaltic decamolybdate, 575
—— —— paramolybdate, 586
—— —— phosphatomolybdate, 663
—— calcium chromate, 274
—— chlorochromate, 398
—— chlorochromatochloride, 398
—— —— hydrate, 398
—— chromate, 199, 271
—— chromatosulphate, 450
—— chromidioxydodecamolybdate, 602
—— chromioxydodecamolybdate, 601
—— cobaltic enneamolybdate, 575
—— dichromate, 341
—— —— dihydrate, 341
—— diplatinic triacontatungstate, 803
—— ditungstate, 810
—— enneamolybdate, 597
—— ferric tungstate, 801
—— hydrophosphatododecatungstate, 867
—— —— dotessaracontahydrate, 867
—— —— tetrapentecontahydrate, 867
—— —— tetratessaracontahydrate, 867
—— hydropyrotellurate, 93
—— hydropyrotellurite, 80
—— hydrotellurate, 93

Y

Yellow ultramarine, 278
Ytterbium chromate, 288
—— metatungstate, 826
—— oxymolybdate, 565
—— oxytungstate, 791
—— paramolybdate, 587
—— paratungstate, 819
—— sodium tungstate, 791
Ytterbium tungstate, 791
Yttrium chromate, 288
—— molybdate, 565
—— paratungstate, 819
—— potassium chromate, 288
—— sodium tungstate, 791
—— sulphomolybdate, 652
—— sulphotungstate, 859
—— tellurate, 96
—— tellurite, 81

Z

Zinc aluminotungstate, 789
—— amminochromate, 277
—— —— monohydrate, 277
—— ammonium chromate, 279
—— —— diamminobischromate, 280
—— —— paramolybdate, 586
—— —— paratungstate, 819
—— —— triamminosexichromate, 280
—— chlorochromate, 399
—— chromate, 277
—— —— monohydrate, 277
—— chrome, 278
—— chromite, 200
—— chromium alloys, 171
—— —— pentafluoride, 364
—— chromous sulphate, 435
—— decamminochromate, 278
—— diamminomolybdate, 562
—— dichromate, 341
—— dioxychromate, 279
—— dioxytetrafluomolybdate, 614
—— ditungstate, 810
—— docositungstate, 833
—— dodecatungstate, 832
—— hypomolybdate, 529
—— lead chromate, 304
—— metatungstate, 826
—— —— octohydrate, 826
—— molybdate, 562
—— —— monohydrate, 562
—— molybdenum alloys, 523
—— —— oxypentafluomolybdate, 611
—— octomolybdate, 597
—— oxybischromate, 279
—— oxychromate, 279
—— —— hemitrihydrate, 279
—— —— monohydrate, 279
—— oxydecachromite, 200
—— oxydichromite, 200
—— oxytetrachromite, 200
—— oxytrisulphotungstate, 860
—— paramolybdate, 586
—— paratungstate, 819
—— pentatungstate, 829
—— pentoxyhexachromite, 200
—— perdichromate, 359
—— permonosulphomolybdate, 653
—— phosphatohexatungstate, 873
—— potassium chromate, 277
—— —— chromatodichromate, 341
—— —— paratungstate, 819
—— —— trioxybischromate, 279
—— sodium paratungstate, 819
—— sulphate, 831
—— sulphomolybdate, 652
—— sulphotellurite, 113

Zinc sulphotungstate, 857
—— tellurate, 94
—— telluride, 50
—— tellurite, 80
—— tetrafluodioxytungstate, 839
—— tetramminochromate, 278
—— —— pentahydrate, 278
—— —— trihydrate, 278
—— tetramminotungstate, 788
—— —— dihydrate, 788
—— tetramolybdate, 593
—— thoridodecamolybdate, 601
—— trichromate, 351
—— trimolybdate, 590
—— trioxychromate, 279
—— —— pentahydrate, 279
—— —— trihydrate, 279
—— tritungstate, 811
—— tungstate, 788
Zinc tungstate hydrate, 788
—— yellow, 278
Zinkgelb, 278
Zirconidodecamolybdates, 601
Zirconium ammonium tungstate, 791
—— chromate, 288
—— decahydroxychromate, 289
—— hexacosioxypentachromate, 289
—— hexahydroxychromate, 289
—— molybdate, 565
—— octohydroxychromate, 289
—— oxychloride, 831
—— oxychloromolybdate, 565
—— potassium tungstate, 792
—— tellurate, 96
—— tellurite 81
—— tungstate, 791
Zirconyl tetrahydroxychromate, 288
